Tungsten Oxide by Non-Hydrolytic Sol-Gel: Effect of Molecular Precursor on Morphology, Phase and Photocatalytic Performance

Emma Oakton,[a] Georges Siddiqi,[a] Alexey Fedorov,[a] and Christophe Copéret[a*]

A practical gram-scale synthesis of high surface area blue tungsten oxide via a non-hydrolytic sol-gel method is reported. The use of diisopropyl ether in 1,2-dichloroethane at 180 ºC transforms W(VI) and W(IV) chloride precursors into WO_x materials of cube or rod-like morphology respectively. These oxides are characterised by a range of methods including TEM, N_2 adsorption-desorption, XRD, XAS, EPR, UV-Vis DRS, elemental analysis and conductivity measurements. Treatment of WO_x under N_2 causes a decrease in surface area and increase in electrical conductivity. Prepared materials are investigated as catalysts for oxygen evolution by photocatalytic water splitting.

Introduction

High surface area tungsten oxide has potential applications in fabrication of electrochromic devices,[1, 2] gas sensors,[3-5] photocatalysts[6, 7], and low temperature proton exchange fuel cells (PEFCs).[8, 9] In particular, tungsten oxide is a widely studied oxidation catalyst for the degradation of organic compounds and photocatalytic oxygen evolution[6, 10-12] with potential for energy generation, waste remediation, and other applications.[13, 14]

Due to this wide variety of potential applications of tungsten oxide materials, investigation of a range of synthetic routes is vital.[15] Previously mesoporous tungsten oxide was prepared by a sol-gel route, reacting a variety of alcohols with WCl_6 in the presence of steam.[16] Non-hydrolytic sol-gel (NHSG) is an alternative route to metal oxides that uses anhydrous organic alcohols or aprotic oxygen donors.[17] This approach offers many advantages, including the ability to control oxide particle size and shape by the nature of oxygen donor. In addition, slower reaction rates for NHSG often lead to crystalline materials.[18] A variety of publications have discussed how the alteration of NHSG reaction conditions can affect the resulting oxide morphology.[19, 20] The texture of metal oxides, including crystallinity, surface area and particle shape, is an important parameter influencing, for example, photocatalytic performance.[11, 21, 22] Mesoporous blue tungsten oxide was prepared by reaction of WCl_6 in a 1-butanol/tert-butanol mixture, where the alcohol ratio influences porosity.[19] The investigation of precursor influences on morphology has also

shown some interesting results, where the use of $W(OiPr)_6$[5] or WCl_6[20] in combination with benzyl alcohol provided nanowires or nanoplatelets, respectively. In the latter reported case, the addition of 4-tert-butylcatechol triggered the formation of rod-like structures.[20] In place of alcohols, diisopropyl ether has been found to be a very efficient aprotic oxygen donor, which reacts with metal chlorides to yield a broad range of metal oxides,[23, 24,25-28] including homogeneous mixed oxides.[29-31] The preparation of pure tungsten oxide from WCl_6 and diisopropyl ether has been reported, although this route involves highly toxic CS_2 solvent.[32]

Here we utilise NHSG chemistry with diisopropyl ether taken in excess to investigate the effect of tungsten chloride precursor oxidation state (4+ vs. 6+) on the morphology and phase of blue tungsten oxide. TEM imaging shows a distinct change in particle shape and X-ray powder diffraction indicates materials prepared from a W(IV) precursor form significantly oxygen deficient phase, supported by W L_3-edge XANES. This information is used to rationalise the differences in photocatalytic oxygen evolution activity of these materials before and after post-synthetic treatment.

Results and Discussion

Tungsten oxide materials were prepared by the reaction of WCl_6 or WCl_4(DME) (DME = 1,2-dimethoxyethane) with diisopropyl ether in 1,2-dichloroethane at 180 °C to give $WO_{x(VI)}$ or $WO_{x(IV)}$, respectively. The TEM images of these two WO_x materials show a notable difference in morphology, with $WO_{x(VI)}$ forming cubes around 20-50 nm in size and $WO_{x(IV)}$ forming rods approximately 20-100 nm in width as well as some amorphous-like material (Figure 1). The N_2 adsorption-desorption data of both samples are similar, showing a type II isotherm, indicating minimal microporosity, some mesoporosity and mainly macroporosity. The BET surface areas of both materials are comparable with values of 85 and

ARTICLE
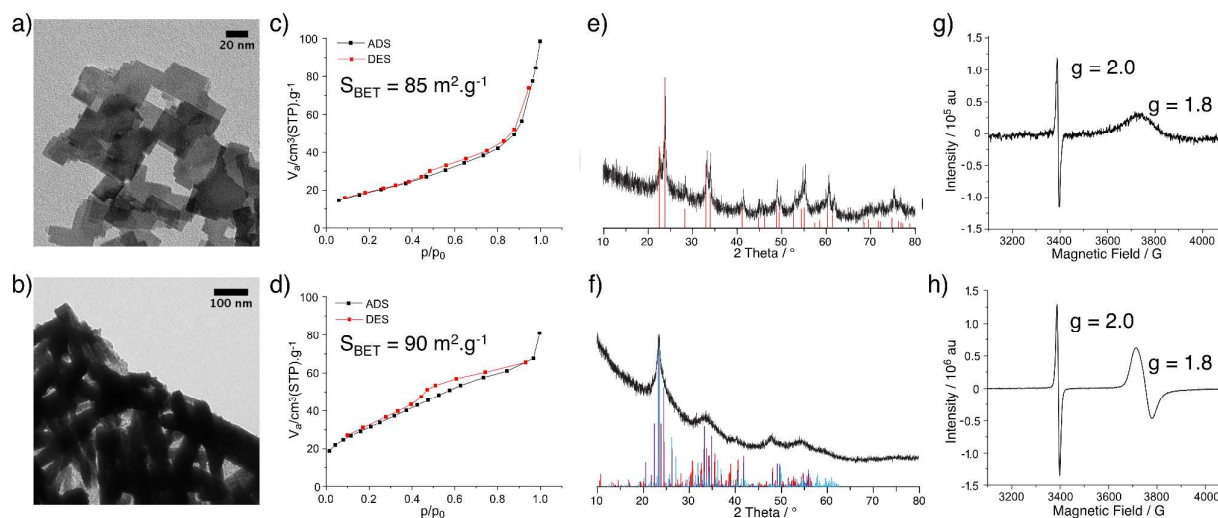

Figure 1. TEM micrographs of WO$_{x(VI)}$ (a) and WO$_{x(IV)}$ (b); N$_2$ adsorption-desorption isotherms of WO$_{x(VI)}$ (c) and WO$_{x(IV)}$ (d); XRD diffraction pattern of WO$_{x(VI)}$ with reference pattern of tetragonal WO$_3$ (red lines) (e) and XRD diffraction pattern of WO$_{x(IV)}$ (f) with reference patterns of WO$_{2.65}$ (purple), W$_{18}$O$_{49}$ (red) and WO$_{2.90}$ (blue) (f); EPR spectra of WO$_{x(VI)}$ (g) and WO$_{x(IV)}$ (h)

90 m^2·g^{-1} for WO$_{x(VI)}$ and WO$_{x(IV)}$ respectively (Figure 1). Both WO$_{x(VI)}$ and WO$_{x(IV)}$ are blue in colour, which is consistent with the presence of oxygen defects and thus electron rich tungsten centres.[33, 34] This is supported by the increased electrical conductivity of WO$_{x(VI)}$ and WO$_{x(IV)}$ in comparison (1.5·10^{-4} and 1.0·10^{-4} S·cm^{-1}, respectively) to commercial WO$_3$, (4.5·10^{-7} S·cm^{-1}). XRD shows a significant difference between these WO$_x$ materials, with the XRD powder diffraction pattern of WO$_{x(VI)}$ matching that of tetragonal WO$_3$, whilst WO$_{x(IV)}$ is consistent with an oxygen deficient phase distinguishable from WO$_3$, such as WO$_{2.65}$, W$_{18}$O$_{49}$ or WO$_{2.90}$ (Figure 1). These sub stoichiometric phases have highly similar powder patterns, making a more accurate assignment difficult. WO$_3$ is composed of WO$_6$ octahedral units connected by corner atoms. Removal of oxygen from this structure results in vacancy sites, the presence of which can trigger the formation of edge sharing octahedra.[35] WO$_3$ can be substoichiometric until WO$_{2.98}$ and therefore the defects in WO$_{x(VI)}$ are likely low in concentration and randomly distributed.[36] In contrast, distinct oxygen deficient phases have highly ordered arrays of edge sharing octahedra.[37] This characterisation shows that a different phase of tungsten oxide, with a significantly lower oxygen stoichiometry, is formed from the W(IV) precursor. The presence of paramagnetic species consistent with the formation of oxygen defects was confirmed by EPR spectroscopy with a signal at g = 1.8 for both samples.[38] Another signal at g = 2.0 present in both materials likely arise from remaining organic functionalities on the oxide surface after the NHSG synthesis.[39] Given that these WO$_x$ materials were prepared from precursors with different oxidation states,

Figure 2. XANES characterisation of WO$_3$ (orange), WO$_{x(VI)}$ (black), WO$_{x(IV)}$ (red) and WO$_2$ (pink)

the bulk oxidation state of W in the as-prepared oxides was determined by X-ray Absorption Near Edge Spectroscopy and compared to commercial WO$_3$ and WO$_2$ (Figure 2, Table S3). XANES characterisation of WO$_{x(VI)}$ shows that its white line is shifted by −0.35 eV compared to WO$_3$, while WO$_{x(IV)}$ is shifted further by −0.75 eV. Though small, this shift to lower energies

ARTICLE
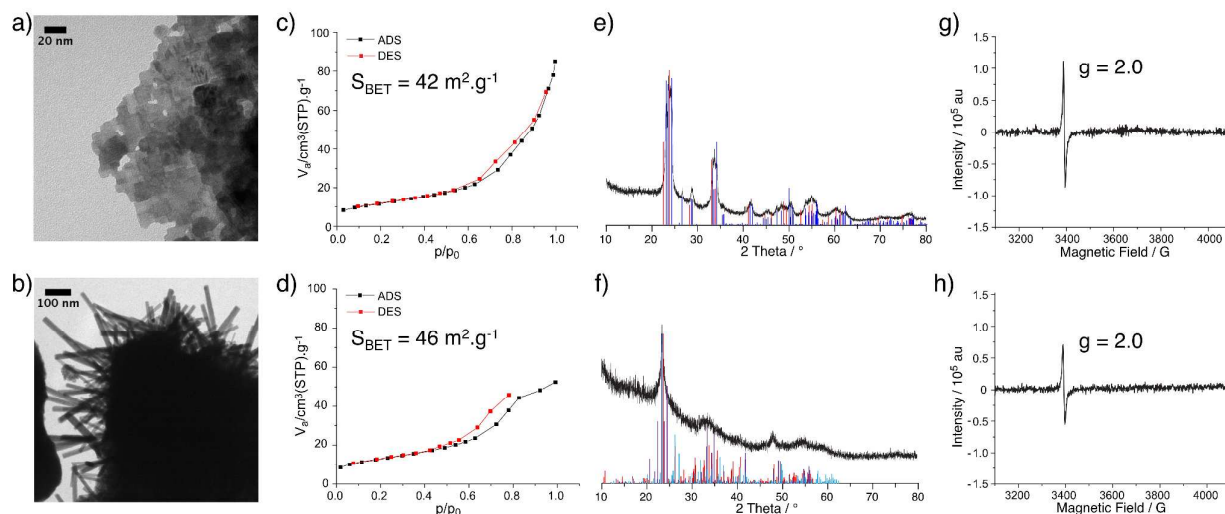

Figure 3. TEM micrographs of WO$_{x(VI)}$-N$_2$ (a) and WO$_{x(IV)}$-N$_2$ (b); N$_2$ adsorption-desorption isotherms of WO$_{x(VI)}$-N$_2$ (c) and WO$_{x(IV)}$-N$_2$ (d); XRD diffraction pattern of WO$_{x(VI)}$-N$_2$ with reference pattern of tetragonal (red) and monoclinic (blue) WO$_3$ (e) and XRD diffraction pattern of WO$_{x(IV)}$-N$_2$ with reference patterns of WO$_{2.65}$ (purple), W$_{18}$O$_{49}$ (red) and WO$_{2.90}$ (blue) (f); EPR spectra of WO$_{x(VI)}$-N$_2$ (g) and WO$_{x(IV)}$-N$_2$ (h)

indicates that the W species present in these as-synthesised WO$_x$ samples are more reduced than bulk WO$_3$, and that WO$_{x(IV)}$ is more reduced than WO$_{x(VI)}$.[40] These XANES results are in agreement with the aforementioned XRD and EPR results.

The treatment of both WO$_{x(VI)}$ and WO$_{x(IV)}$ under N$_2$ flow at 500 °C for 3 h produced dark blue and dark blue/black materials respectively and the characterisation of these samples is summarised in Figure 3. TEM images of WO$_{x(VI)}$-N$_2$ show that the previously cubic particles have lost edge sharpness and sintered. The WO$_{x(IV)}$-N$_2$ particles retain the rod-like shape of and WO$_{x(IV)}$ and although they appear to have decreased in width. N$_2$ adsorption-desorption measurements indicate particle sintering leading to a decrease in surface area (90 vs. 46 m^2·g^{-1}). An analogous decrease in surface area is observed for WO$_{x(VI)}$-N$_2$ (85 vs. 42 m^2·g^{-1}). In the case of WO$_{x(VI)}$-N$_2$, there is a shift in the XRD powder diffraction pattern, matching that of monoclinic WO$_3$ (Figure 3). Interestingly the EPR spectra show an absence of any W(V) signal around g = 1.8, although the g = 2.0 signal remains. The lack of the EPR W(V) signal is likely due to the increased spin concentration leading to spin pairing and/or faster spin relaxation. This increased presence of oxygen defects is supported by electronic conductivity measurements, which show a higher electronic conductivity for both samples after N$_2$ treatment (4.1·10^{-3} and 4.0·10^{-2} S·cm^{-1} for WO$_{x(VI)}$-N$_2$ and WO$_{x(IV)}$-N$_2$ respectively), in accord with the literature.[19] The EPR signal at g = 2.0 ascribed to organic radicals is in accord

Figure 4. UV-vis DRS spectra of WO$_x$ materials

with minor amounts of carbon by elemental analysis of nitrogen-treated samples (see ESI for details).

Characterisation of the synthesised materials before and after N$_2$ treatment by UV-vis DRS spectroscopy is shown in Figure 4. Variations in phase and morphology between the WO$_x$ samples hamper direct comparisons between their UV-vis spectra.[41] However, adsorptions between 400 and 800 nm support the presence tungsten centres with different oxidation states formed due to oxygen defects.[38] The prepared WO$_x$ materials absorb less in the UV region as commercial WO$_3$. Comparing the adsorption edges indicates an increase in the optical band gap energy when moving from WO$_3$ to the NHSG synthesised oxides.

The performance of these materials as catalysts in photocatalytic oxygen evolution was then studied and
Figure 5. Photocatalytic oxygen evolution of selected catalysts normalised to mass of catalyst

compared to commercial WO_3 (Figure 5). The characterisation of this reference oxide can be found in the supporting information. The results show that the commercial WO_3 sample has the highest activity, reaching $5.3 \cdot 10^{-3}$ mol·min^{-1}·g^{-1} after 1.2 h. Interestingly, despite their relatively low surface area, both N_2 treated samples reach higher activities than their as-prepared counterparts, with $WO_{x(VI)}$-N_2 achieving a maximum rate of $3.3 \cdot 10^{-3}$ mol·min^{-1}·g^{-1} after 0.5 h. It is important to note that whilst all NHSG prepared materials exhibited lower activities than WO_3 during the first 2.5 h, they show less deactivation with both nitrogen treated samples outperforming WO_3 between 2.5 and 4.5 h. $WO_{x(VI)}$ and $WO_{(IV)}$ show minimal activity.

The previous analysis has shown that the NHSG prepared materials contain oxygen defects. The reaction rates of these defected catalysts are lower than that of WO_3, probably because the defects act as electron-hole pair recombination sites and hence quench photocatalytic activity.[42] Indeed the activity of the $W_{18}O_{49}$ phase is expected to be lower than WO_3 due to increased amount of reduced W(IV) and W(V) centres.[43] Additionally, UV-vis DRS measurements suggest that WO_3 has the smallest optical band gap, which is advantageous in photocatalysis, hence its increased activity. Comparing the NHSG prepared materials, the enhanced activity of the N_2 treated samples can be explained by an increase in particle size, as electron-hole pair recombination is also known to occur at faster rates on smaller tungsten oxide particles.[44] The large increase in activity for $WO_{x(VI)}$-N_2 is attributed to the tetragonal-monoclinic transformation, as monoclinic WO_3 is known to have a higher activity towards oxygen evolution than other WO_3 phases.[45]

Conclusions

In conclusion we report a simple method for the preparation of high surface area blue tungsten oxide by the reaction of WCl_6 and WCl_4(DME) with diisopropyl ether in 1,2-

dichloroethane. Substoichiometric tungsten oxides are obtained, with different morphologies depending on the starting precursor. EPR spectroscopy, UV-vis DRS spectroscopy and electrical conductivity measurements suggest the presence of oxygen defects in both materials. Treatment under N_2 increases electronic conductivity, indicating an increase in defects. Reduction of the surface area by the N_2 treatment improved activity for the photocatalytic evolution of oxygen from water, despite an increased amount of defects. The lower rate of deactivation for the $WO_{x(VI)}$-N_2 and $WO_{x(IV)}$-N_2 catalysts provided activities higher than the reference WO_3 for an extended catalytic test. Future work will involve the preparation of doped WO_x materials by NHSG methods and their application in photocatalysis.

Experimental

General

All experiments were conducted under argon atmosphere using standard Schlenk and glove box techniques unless otherwise stated. Solvents were dried over alumina column (MB SPS-800, MBraun), stored over 4Å molecular sieves and degassed before use, with the exception of 1,2-dichloromethane and diisopropyl ether, which were dried and distilled over CaH_2 and Na respectively. WCl_6 (99.99 %) was purchased from Strem Chemicals. WCl_4(DME) was prepared according to literature.[46] Digestion vessels from the Parr Instrument Company were used for NHSG synthesis. Commercial WO_3 and WO_2 were purchased from Sigma Aldrich.

XRD diffractograms were recorded using a Stoe STADI P diffractometer (Cu Kα radiation, **λ** = 1.54051 Å). TEM images were collected with a Philips CM12 transmission electron microscope. N_2 adsorption-desorption analysis was conducted using a BEL-Mini device supplied by BEL Japan Inc with ca. 500 mg of each sample. Results were fitted using BEL-Master programme and BET theory. EPR samples were prepared in an Ar filled glove-box by suspending ca. 10 mg of solid in 0.5 mL toluene in a quartz Young EPR tube and freezing in liquid N_2. Continuous Wave (CW) EPR spectra were recorded on a Bruker EMX X-Band spectrometer (9.5 GHz microwave frequency) at 110 K. Electrical conductivity values were determined from powder disks under 0.625 MPa pressure with thicknesses in the range 100 – 1000 μm. For commercial WO_3 conductivity values were determined using Electrical Impedance Spectroscopy. In the case of all other samples, DC measurements were used; where the current was recorded for a range of voltages (0.001 – 0.1 V) and conductivity subsequently calculated using Ohm's law. Electrical conductivity was determined for three pellet thicknesses and averaged to give the values reported above. UV-Visible DRS Spectroscopy was conducted under ambient conditions using a Cary UV-vis-NIR spectrophotometer, for clarity the spectra were smoothed using the Smooth function of OriginPro programm from OriginLab. For characterisations conducted under ambient conditions, samples were used immediately after removal from the glove box. No colour change was noted

for any sample during analysis. XANES measurements at W L_{III}-edge were performed at the SuperXAS beamline at the Swiss Light Source (Paul Scherrer Institute, Villigen, Switzerland). The SLS is a third generation synchrotron, which operates under top up mode, 2.4 GeV electron energy, and a current of 400 mA. The SuperXAS beamline is positioned on one of three super-bent ports. The incident beam was collimated by Si-coated mirror at 2.8 mrad, monochromatized using a double crystal Si(111) monochromator, and focused with Rh coated toroidal mirror (at 2.8 mrad) down to 100x100 µm. The beam intensity was of $4\text{-}5\cdot10^{11}$ ph·s^{-1}. We collected XANES data in transmission mode at 298 K under Ar atmosphere.

Representative procedure for the preparation of WO$_{x(VI)}$.

In an Ar filled glove-box, WCl$_6$ (3.96 g, 0.01 mol) was loaded into a digestion vessel with a capacity of 125 mL. 1,2-Dichloroethane (31 mL) was added, followed by excess diisopropyl ether (14 mL, 0.1 mol). After closing, the vessel was removed from the glove box and heated to 180 °C for 3 days using a conventional oven, then allowed to cool overnight. The blue solid obtained was filtered on a glass frit in air, washed with EtOH (3 x 20 mL) and dried overnight under high vacuum (10^{-5} mbar) at 140 °C. The solid was then stored in an Ar filled glove-box (2.0 g, ca. 85 % yield).

Preparation of WO$_{x(IV)}$.

WCl$_4$(DME) (4.05 g, 0.01 mol) was reacted with excess diisopropyl ether (14 mL, 0.1 mol) in 1,2-dichloroethane (31 mL) as described above to afford 2.0 g of dark blue material, with a yield of ca. 85%.

N$_2$ treatment of WO$_x$

WO$_x$ (ca. 2 g) was loaded into a gas flow reactor and heated to 500 °C (2 °C.min^{-1}) under N$_2$ flow (120 mL.min^{-1}) and kept at this temperature for 3 h. The solid was then evacuated using high vacuum (10^{-5} mbar) and stored in an Ar filled glove box.

Photocatalysis

The photoreactor consisting of a 500 mL jacketed reactor with a 220 mm jacketed quartz immersion well was purchased from Ace Glass, Inc. A quartz mercury low pressure UV arc lamp (450 W, Ace Glass, Inc.) is used to illuminate the photocatalysts. All joints of the reactor are lubricated with Teflon grease (Krytox®), as other greases are observed to decompose and release volatiles when under UV illumination. O$_2$ production is monitored using a micro gas-chromatograph (490 Micro GC, Agilent Technologies, AG) with a 1 m CP-COX column used to separate O$_2$. An oil-filled bubbler is used to prevent backflow of ambient air into either the micro GC or the reactor. Photo-catalytic tests are performed under a flow (26 mL.min^{-1}) of N$_2$, with a T-junction going to the microGC allowing on-line sampling of the gases evolved. Photocatalysis is performed within a sealed (non-reflective) light-tight enclosure, and the reactor and UV lamp are cooled with 20 °C

cooling water. Agitation is provided via a Teflon stir bar spinning at 435 rpm.

Prior to starting photocatalysis, the reactor is filled with a 0.1 M AgNO$_3$ solution, and 100-600 mg of catalyst is loaded. The suspension is then degassed under dynamic vacuum (ca. 20 mbar) for 30 min, followed by de-aeration with bubbling N$_2$ (26 mL.min^{-1}) for 1 h. GC analysis of the gas stream is free of oxygen prior to starting each photocatalytic test.

During photocatalysis, the micro GC is programmed to sample the outlet gas stream on regular intervals, and the UV light is turned on at the same moment of the first GC sample. Once photo-catalysis begins the reactor enclosure is not opened and gas production is regularly monitored.

Quantification of the O$_2$ production is done via TCD, which is calibrated prior to use. O$_2$ production was calculated by the following route:
v = volumetric flowrate (mL·min^{-1})
c = concentration (vol %)
n = molar flowrate (mol·min^{-1})
Known quantities: v_{N2} (N$_2$ flowrate, 26 mL·min^{-1}) and c_{O2} (concentration of O$_2$ measured by TCD, vol %), P = atmospheric pressure 1.01 bar, T = 300 K.
Calculating volumetric O$_2$ flow:
$$v_{O2}(mL\cdot) = v_{N2}\cdot c_{O2}$$
Converting volumetric O$_2$ flow to molar O$_2$ flow using the ideal gas law:
$$n_{O2}\ (mol\cdot min^{-1}) = Pv_{O2}/RT$$
This number is then divided the mass of catalyst used.
