This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
STD NMR and molecular modelling insights into interaction of novel mannose-based ligands with DC-SIGN

Anita Kotar, Tihomir Tomasić, Martina Lenarčič Živković, Gregor Jug, Janez Plavec, and Marko Anderluh

Study of interaction of mannose-based ligands with receptor DC-SIGN using high resolution NMR in combination with molecular modelling showed that four α-D-mannoside ligands interact with the binding site predominantly with mannose moiety. The other two aromatic groups that are bound to α-D-mannose through glycerol linker demonstrate interaction that can be related to their substitution pattern. Ligand with naphthyl and meta-substituted phenyl ring exhibited the most favourable binding characteristics. In addition to predicted hydrophobic interactions of aromatic moieties our results propose new contacts of substituted phenyl moiety in more polar area of flat binding site of DC-SIGN and thus offer new possibilities in further designing of novel, more potent DC-SIGN antagonists.

Introduction

Although significant progress was made in HIV vaccine strategies and drugs development, HIV infections remain one of the leading causes of morbidity and mortality worldwide.1-5 Dendritic cells (DCs), hosts professional antigen-presenting cells that represent first line of innate immune system, play an important role in HIV-1 infection.6 The pattern recognition receptors (PRRs) located at the surface of DCs are important factor in HIV-1 transmission that help subvert DC functions and escape immune surveillance.7,8 One of these PRRs that plays fundamental role in cellular immunity is DC-SIGN (Dendritic Cell-Specific Intercellular adhesion molecule-3-Grabbing Non-integrin), a type II transmembrane C-type lectin located specifically on DCs.9-10 DC-SIGN acts as an adhesion molecule and binds highly glycosylated proteins present on the surface of several pathogens, including mannose glycans of the envelope protein gp120 of HIV-1.11-13 On binding, the complex of DC-SIGN and HIV-1 is promptly internalized, degraded into smaller fragments in early endosomes and conjugated with MHC class-II proteins to initiate a humoral immune response from T cells, but unfortunately, a small amount of virus succeeds to escape the normal lytic pathway in DCs' endosomes and avoid the host immune system.6,8,11,13,14 By inhibiting interaction between DC-SIGN and HIV-1 with DC-SIGN antagonists pathogen entry could be prevented causing impediment of the infection of immune defence cells.8,15-23 Different approaches were applied to design medicinally useful DC-SIGN antagonists. Even though reported antagonists vary in structure and properties, they mostly exploit the fact that DC-SIGN recognises various mannose- and fucose-containing glycans exposed on the surface of several viruses, bacteria, yeast and parasites.4,8,11,23 D-mannose (Kd=13.1 mM) and L-fucose (Kd=6.7 mM) alone bind to DC-SIGN with very weak affinities, but when incorporated into suitable glycoconjugates substantially higher affinities can be obtained that offer a promise to prevent the HIV-1 transmission.8,12,23,24 We recently reported a small focused library of branched mannose-based DC-SIGN antagonists bearing diaryl substituted 1,3-diaminopropanol or glycerol moieties incorporated to target the hydrophobic groove of the receptor.23 D-mannose entity was presumed to serve as an anchor for interaction with Ca2+ binding site of the DC-SIGN carbohydrate recognition domain (CRD). The designed molecules were evaluated by in vitro assay of the isolated DC-SIGN extracellular domain for their ability to compete with HIV-1 gp120 for binding to the DC-SIGN CRD. The two most potent compounds were found to inhibit the interactions between gp120 and DC-SIGN with the IC50 values of 40 μM and 50 μM, and were among the most potent monovalent DC-SIGN antagonists reported. Furthermore, the antagonistic effect of these compounds was evaluated by a one-point in vitro assay that measures dendritic cell adhesion to a mannan-coated surface. Again, the same compounds acted as functional antagonists of DC-SIGN-mediated DC adhesion. The binding mode of the most potent compound (4) was also studied by molecular docking and molecular dynamics simulation, which
pointed that the diarylglycerol part of the molecule likely binds into the targeted hydrophobic binding site, and provides a basis for further optimization. Unfortunately, the binding site of DC-SIGN is rather flat and vaguely defined and offers limited (other than van der Waals) ligand-receptor contacts. In the present study we investigated the interactions between four monovalent mannose-based ligands 1-4 (Fig. 1) and extracellular domain of DC-SIGN (hereinafter referred as DC-SIGN). Studied ligands 1-4 consist of α-D-mannose connected by glycerol linker to different aryl moieties, which are expected to tune interactions of ligands in hydrophobic groove of the receptor. The combination of saturation transfer difference (STD) NMR spectroscopy and molecular modelling has been used to examine binding propensity of monovalent glycoconjugates for DC-SIGN at the atomic level of resolution. As expected, ligands 1-4 do not exhibit clear differences in chair conformation of D-mannose sugar moiety regardless of variation of groups attached to its anomeric carbon. On the other hand, differences in ligands’ binding affinities can be correlated with the position of carboxylic group on the phenyl moiety in 1-3 as well as lipophilicity of each of the ligands. Binding mode of ligands was additionally evaluated by molecular dynamic simulations. A good agreement between NMR and molecular modelling results provides new insights into interactions of our novel ligands with DC-SIGN and suggests new possibilities in design of novel anti-HIV therapeutics.

Results

Chemistry

DC-SIGN antagonists 1 and 4 were synthesized as reported, while synthesis of 2 and 3 is outlined in Scheme 1. Hydroxybenzoic acid (5) was first converted to its methyl ester 6 in methanol under acidic conditions. Potassium salt of compound 6, which was prepared using potassium hydroxide in methanol, was used for epoxide ring opening of 7 to obtain racemic diarylglycerol 8. Mannosylation of 8 with 2,3,4,6-tetra-O-acetyl-α-D-mannopyranosyl trichloroacetimidate and with trimethylsilyl trifluoromethanesulfonate (TMSOTf) as promoter yielded α-D-mannoside 9 stereospecifically. Since compound 8 was used as a racemate, compound 9 was obtained as a mixture of two diastereomers that could not be separated using flash column chromatography. Deprotection of compound 9 using Zemplén method gave final compound 3, which was further hydrolysed under alkaline conditions to yield the final compound 2.

STD NMR experiments and epitope mapping

The STD NMR experiments were performed to explore the binding nature and propensity of ligands 1-4 to interact with DC-SIGN. Reference and STD spectra exhibited narrow and well resolved lines (Fig. 2). The significant STD effects observed for ligands 1-4 unequivocally demonstrated their binding to the DC-SIGN. In order to increase accuracy of epitope mapping we used only well resolved and isolated NMR resonances of the individual ligand, avoiding uncertain contributions in the case of signal overlap. Quantitative analyses of the STD spectra were done at receptor-to-ligand ratio of 1:50. Rather high ratio was used to reduce the effect of cross-rebinding, where a previously saturated ligand re-enters a binding pocket.

Scheme 1 Reagents and conditions: a) SOCl₂, MeOH, r.t., 24 h; b) (i) KOH, MeOH, r.t., 20 min; (ii) tetrabutylammonium bromide, toluene/N,N-dimethylformamide, 90 °C, 20 h; c) 2,3,4,6-tetra-O-acetyl-α-D-mannopyranosyl trichloroacetimidate, TMSOTf, CH₂Cl₂, 0 °C, then r.t., 24 h; d) NaOMe, MeOH, 1 h, then Amberlite® IR120 H, 10 min; e) 1 M NaOH, EtOH, r.t., 24 h.
For 1-4 the most intense STD signals were observed between δ 3.3 and 3.9 ppm, which suggested that mannose moiety was in the closest contact with the surface of DC-SIGN. However, quantitative interpretation of STD effects of sugar protons was hampered due to spectral overlap with the exception of anomeric Hα proton. Hα proton exhibited well-resolved signals for all four ligands 1-4. Moreover, it showed the highest relative STD effect among protons that were analysed in epitope mapping. Consequently, the signal of Hα proton was set as a reference with the 100% STD effect. Intensities of other signals were expressed relative to the Hα signal (Fig. 3).

The aromatic groups exhibited weaker STD effects in comparison to mannose moiety regardless of variations in attached aryl entities. Both phenyl Hα protons of 1 together showed STD effect of 51%. However, in STD spectra one cannot distinguish between individual contributions of two Hα atoms due to their symmetric arrangement at meta-position of phenyl group. Hb, Hc and Hα protons of naphthyl group of 1 exhibited STD effects of 61%, 43% and 53%, respectively. Obvious STD effects were seen for other aromatic protons as well.
Fig. 3 Epitope mapping for 1-4. The relative degrees of saturation of marked H_a-H_g protons expressed in % are mapped onto the structure and normalized with respect to H_a proton. STD effect of H_a was arbitrarily set to the 100% in the case of all four ligands. Arrows are used to report the overall STD effects for symmetric groups.

Unfortunately their quantitative elucidation was prevented due to spectral overlap. In 2 the phenyl H_f proton showed STD effect of 68% and H_b, H_c and H_e protons from naphthyl moiety exhibited the STD effects of 78%, 54% and 50%, respectively. However, direct comparison of ligands has to be done with certain degree of caution because of monitoring of protons on different positions on aromatic groups of ligands, namely H_d in 1 and H_e in 2-4 on naphthyl ring, and H_g in 1 and H_f in 2-4 on phenyl moiety. In 3 H_b and H_e protons from naphthyl and H_g from phenyl group showed similar STD effects ranging from 73% to 77%. H_e proton in 3 exhibited STD effects of 65%. Experimentally observed STD effects for H_b and H_c protons on both naphthyl rings in 4 were 90% and 91%, respectively. STD effects of H_g protons were markedly weaker (62%). However, one should keep in mind that H_b, H_c and H_e protons in 4 could not be resolved due to symmetry of the ligand. Observed STD effects therefore represented the overall contribution to the binding for both protons.

STD build-up studies
To precisely map ligand epitopes in close contact with the receptor we acquired STD build-up curves for 1-4 by collecting STD spectra at twelve different saturation times ranging from 0.1 to 5.0 s at receptor-to-ligand ratio of 1:50. The maximal STD intensities, STD_{max}, and the saturation rate constants, k_sat, were obtained by fitting experimental data to Eq. 2. Experimental data as well as best-fit curves for 1 are shown in Fig. 4, whereas the corresponding figures for 2-4 can be found in the Supplementary information (Figs. S2-S4). The agreement between the experimental data and the fitted model was good with typically χ^2 values below 0.1. A clear build-up of the STD effects with increasing saturation time can be observed, reflecting the amplification of the STD (Figs. 4, S4-S6). At longer saturation times flattening of the build-up curves can be observed, because of the relaxation rate of saturated ligand in the free state. For 1 the most prominent STD_{max} belonged to the H_a proton (4.46), while the corresponding values for aromatic H_b, H_d, H_e and H_f protons were markedly lower (2.50,
Organic & Biomolecular Chemistry

ARTICLE

2.60, 2.49 and 2.66, respectively). Accordingly, H₃ proton should be the one most directly involved in binding and closer to the receptor, followed by aromatic protons that are approximatively equidistant from the protein surface. Different kₑₐ₅ values spanning from 0.96 to 1.54 s⁻¹ were calculated for protons of 1. In the case of 2 the STDₘₐₓ values of H₄a, H₄b, H₅a, H₅b, H₁, H₆, H₇ protons were 3.71, 1.30, 1.87, 1.48 and 1.61, respectively. It is interesting that kₑₐ₅ values among protons of 2 did not vary remarkably and were all around 1.30 s⁻¹. For 3 the highest STDₘₐₓ of 3.44 was obtained for H₁ proton. Significantly lower values were acquired for aromatic protons, H₂ (2.01), H₁ (1.58), H₆ (1.08) and H₁ (1.77). Great differences in kₑₐ₅ from 1.19 to 2.45 s⁻¹ were determined among protons of 3. Similarly, protons of 4 exhibited kₑₐ₅ values ranging between 1.59 and 2.44 s⁻¹. The STDₘₐₓ values of 4 were 3.41 for H₇ proton and 1.53, 1.69 and 1.30 for naphthyl H₀, H₁ and H₂ protons, respectively. Once again, results inferred that the H₁ proton was in close contact with the protein and that the mannose moiety contributed primarily to the binding process. Furthermore, initial build-up rates were analysed as well. Initial slopes of the curves at zero saturation time were derived by multiplication of STDₘₐₓ and kₑₐ₅ and correspond to the STD effects (STDₐₑ) in the absence of influence of T₁ longitudinal relaxation time bias and rebinding effects. We calculated STDₐₑ for H₃, H₄a, H₄b, H₅a, H₅b and H₆ protons and compared these results with the STD intensities at 2.0 s saturation time (STDₐₑ) from epitope mapping. For ease of comparison, the values were normalized with respect to H₄ as a 100 (Table 1).

The STDₐₑ values were lower than STDₘₐₓ effects. The two exceptions were H₂ and H₆ protons of 1, which exhibited markedly higher STDₐₑ values. STDₘₐₓ and STDₐₑ values for H₃ of 1 were comparable. The same observations were noticed also for H₁ and H₂ protons of ligand 2. On the contrary, H₂ and H₇ protons of 2 showed significant differences in STD effects. For ligand 3, identical STDₘₐₓ and STDₐₑ values were observed for H₆ proton. On the other hand, significantly lower STDₐₑ effects were detected for H₄a, H₄b and H₅b protons in comparison to STDₘₐₓ values. Surprisingly, the lowest STDₐₑ values and the greatest variances among STD effects were observed for protons of 4.

Characterisation and comparison of binding conformations of 1-4

The normalized build-up curves of STD effects for individual protons were compared to characterise differences in binding modes among ligands 1-4 (Fig. 5). STD effects of analysed protons within individual ligand at different saturation times were normalized to STD effect of H₆ proton at saturation time of 5.0 s.

Good correspondence in overall trend between STD build-up curves was observed for H₆ proton in 1-4 (Fig. 5a). One can observe slight deviation of data points among the ligands at saturation times between 1.0 and 2.0 s (Fig. 5a). Similar build-up curves suggest comparable binding conformation of mannose moiety in 1-4 in the binding site of DC-SIGN.

*Normalized intensities for H₃,H₄ protons at 2.0 s saturation time with respect to STD of H₆ which was arbitrarily given a value of 100.

*Not determined because of peak overlap.

*Ligand does not contain this proton.
Normalized STD-AF values for $H_a$ proton were the most pronounced in all four cases of interaction analysis of 1-4 with DC-SIGN. These results suggest that the $H_a$ proton and associated mannose sugar serve as a binding initiator and are crucial for interaction. Comparison of normalized build-up curves for $H_b$ proton indicated different rate of saturation of this proton within individual ligand. 1 and 3 exhibited comparable outline of build-up curves and reach almost identical plateau value. Build-up curve of 2 grew in the same way, but reached the plateau at a lower value. 4 experienced different build-up mode of $H_b$ protons with steeper initial slope that flattens at value comparable to $H_b$ proton of 2.
Differences in saturation trend originate from contribution of both H₂ protons of 4, which obviously get saturated in shorter time but do not contribute predominantly to the binding. The normalized STD-AF values for H₁ proton showed excellent correspondence with deviation of individual experiments data points within experimental error (Fig. 5c). These observations confirmed analogous binding mode of H₁ proton of 1-4. H₂ protons of 1-3 participate approximately equally in the interaction with the receptor. Both H₂ protons of 4 together showed similar plateau value as 1-3. However, one should keep in mind that the contribution of individual H₂ proton would be markedly reduced, suggesting lower binding propensity of ligand 4. As in the case of H₂ protons of 4 we observed analogous slope outline for H₁ protons of 4 indicating faster rate of saturation in comparison to 1-3. The major differences in build-up curves were observed for H₁/g and H₁/h protons. The discrepancy for H₁ and H₂ protons of 1 was expected due to their different position on aromatic rings in comparison to H₁ and H₂ protons of 2-4. On the other hand, significant alterations in STD effects of H₁ proton of 2 and 3 imply different binding properties of naphthyl group and highlight sensitivity of binding characteristics of ligands. Although, H₂ protons of 2 and 4 exhibited comparable STD build-up curves, direct comparison can be misleading since curve of 4 represents saturation of two H₂ protons (Fig. 5d). When comparing structural setup and position of H₂ proton of 1 and H₂ of 2-4 it is evident that H₂ proton was closer to the surface of receptor with respect to H₁. Furthermore, the comparison of curves of H₁ and H₂ protons of phenyl ring from 1-3 showed similar STD build-up (Fig. 5e). Because of the inseparability of two H₁ protons of 1 and their joint contribution to STD values we believe that the H₁ of 2 and 3 are still spatially closer to the hydrophobic groove of DC-SIGN in comparison to H₁ of 1. Comparative analysis of 2 and 3 additionally revealed that H₁ proton from 3 lies closer to the receptor with respect to H₁ of 2. Higher lipophilicity of 3 evidently enables stronger interactions with the receptor. STD build-up curves comparison for 1-4 led us to conclusion that variations in chemical structures of ligands influence their bound conformations as well as binding modes in the binding site of DC-SIGN.

Evaluation of binding affinities

Amplification of STD effects with increasing concentration of 1-4 was used to determine the binding affinities. Receptor-ligand dissociation constants (Kₐ) were determined with the use of single-ligand titration experiments that were performed at five different ligand concentrations from 80 to 800 μM at constant saturation time of 2.0 s. By monitoring the growth of the STD-AF upon titration Kₐ values were calculated with the use of the Eq. 3 (Fig. 6). Experimental data showed that the maximum STD-AF was not reached for any of ligands even at 800 μM ligand concentration. This observation is in agreement with fast exchange of ligands from the bound to the free state. The variation in exchange kinetics among the ligands is reflected in different slopes of hyperbolic curves (Fig. 6).

Consistently, these results suggest that exchange kinetics was the fastest for 4 and the slowest for 3. Thus 3 stayed in the binding site of DC-SIGN for longer period of time in comparison to other ligands. The binding affinity of 3 and 2 was in lower milimolar range with Kₐ values of 0.45 mM and 0.96 mM, respectively. For 1 and 4 weaker binding with Kₐ values of 1.6 mM and 4.9 mM was observed, respectively.

The direct comparison of Kₐ values is difficult as many experimental factors, such as saturation time, ligand residence time in the complex, intensity of the signal and accumulation of saturation in the free ligand affect determination of receptor-ligand binding affinities by STD NMR spectroscopy. Therefore, we used binding isotherm of STD-AF initial growth approach that allows Kₐ evaluation without aforementioned spurious factors. To verify the sensitivity of the system of individual ligand and DC-SIGN to saturation transfer, we analysed STD-AF of 2-4 at different ligand concentrations from 80 to 800 μM at saturation times between 1.0 and 4.0 s and obtain STD build-up curves The STDₐ values as a function of the ligand concentration were fitted to Eq. 3 to determine Kₐ values without dependence on the spectral properties of the observed signals (Fig. S8). Binding isotherm protocol gave similar Kₐ values in comparison to the titration experiments at a single saturation time. Kₐ values were 0.90 mM for 2, 0.51 mM for 3 and 3.0 mM for 4. These Kₐ values confirmed that 3 exhibits the lowest kₐ rate and thus spend the longest time as part of a complex with DC-SIGN.

Molecular docking

Plausible binding modes of compounds (S)-1, (R)-1, (S)-2, (R)-2, (S)-3 and (R)-3 were first studied by molecular docking calculations using our previously reported and validated FlexX protocol. The docking binding mode of compound 4 was
already described.\textsuperscript{23} DC-SIGN CRD in complex with Man\textsubscript{4} (PDB entry: 1SL4) was selected as receptor for ligand docking under defined pharmacophore type constraints. In detail, to place the core D-mannose residue correctly, the side chain carboxylate groups of Glu354 and Glu347 were defined as hydrogen bond acceptors, which interact with 3- and 4-hydroxyl groups of the core D-mannose in the crystal structure. Additionally, a pharmacophore with spherical coordination around Ca\textsuperscript{2+} ion was defined to correctly consider the complex interactions between Ca\textsuperscript{2+} ion and 3- and 4-hydroxyl group of D-mannose. The D-mannose residue of the studied antagonists 1-4 is predicted to bind to the DC-SIGN Ca\textsuperscript{2+}-binding site. In the case of (S)-3, (R)-3 (Fig. 7) and 4 the binding of the D-mannose residue is in agreement with the defined pharmacophore type constraints, whereas in the case of benzoic acid derivatives (S)-1, (R)-1, (S)-2 and (R)-2, the D-mannose residue is rotated in a way that only 2-hydroxyl group is in contact with the Ca\textsuperscript{2+} ion. Such a D-mannose binding mode does not allow for octacoordination of the Ca\textsuperscript{2+} ion in the binding site and has, to the best of our knowledge, not been observed in the crystal structures of DC-SIGN CRD-ligand complexes. The FlexX-calculated binding modes of both diastereoisomers of compound 3 show the same binding mode of the D-mannose residue, which interacts with Ca\textsuperscript{2+} ion and forms hydrogen bonds with Glu347, Asn349, Glu354, Asn365 and Lys368 side chains (Fig. 7). The main difference is in the orientation of the diarylglycerol moiety. In the case of (R)-3 phenyl ring makes hydrophobic contacts with Phe313 and forms a hydrogen bond between ester carboxyl group and Ser360 side chain hydroxyl group, whereas the naphthalene ring points towards the solvent (Fig. 7a). The opposite can be observed in the binding mode of (S)-3, where the naphthalene ring contacts the Phe313 side chain, while the ester carboxyl group forms hydrogen bond with the Asn344 side chain (Fig. 7b). In contrast to (R)-3 and (S)-3 both naphthalene rings of compound 4 are predicted to form hydrophobic and/or π-π interactions with the side chain of Phe313.\textsuperscript{23}

In order to evaluate whether other docking tools can correctly predict the D-mannose binding pose of compounds 1 and 2, the docking of compounds 1-4 to DC-SIGN CRD was repeated with our recently reported docking protocol\textsuperscript{27} using FRED 3.0.1,\textsuperscript{28-30} as available in OEDocking software (Release 3.0.1, OpenEye Scientific Software, Inc., Santa Fe, NM, USA; www.eyesopen.com/). In this case, the Glu347 and Glu354 side chains were defined as hydrogen bond acceptors and the Asn365 side chain as a hydrogen bond donor to constrain the placement of the D-mannose moiety. FRED docking poses for compounds (R)-3 and (S)-3 were found to be very similar to those obtained by FlexX, positioning the naphthalene and phenyl rings to the same binding pockets of the binding site (Figure S9). In contrast to FlexX, FRED was able to correctly place the D-mannose residue of (S)-1, (R)-1, (S)-2 and (R)-2, allowing the octacoordination of Ca\textsuperscript{2+} by interactions with D-mannose 3- and 4-hydroxyl groups (Fig. S10). Both aromatic moieties of (S)-1, (R)-1, (S)-2 and (R)-2 form hydrophobic contacts and/or π-π interactions with Phe313 side chain (Fig. S10), similarly as observed in the case of compound 4.\textsuperscript{23}
then subjected to molecular dynamics simulation, which consisted of three consecutive steps: (i) solvent equilibration for 0.5 ns with ligand and protein constrained harmonically around the initial structure; (ii) equilibration of the complete system for 1 ns with ligand and protein released; (iii) an unconstrained 10 ns production run to allow the protein and the ligand to position themselves according to physical forces between them. Physical stability of the simulations was monitored by temperature, volume and total energy vs time plots. All these parameters of the system were stable during the production run of the simulation. Structural stability of the system during the simulation was monitored by measuring the RMSD values of protein backbone atoms during the simulation (Fig. 8a and 9a).

Interestingly, R and S isomers of 3 in complex with DC-SIGN showed significantly different behaviour during the molecular dynamics simulations. After 0.3 ns of the production run D-mannose 4-hydroxyl group of (R)-3 slowly began to lose contact with the Ca\(^{2+}\) ion (Fig. 8c). For the next 0.5 ns only D-mannose 3-hydroxyl group of (R)-3 was in contact with Ca\(^{2+}\) ion (Fig. 8d). Since Ca\(^{2+}\) ion was not octacoordinated anymore, the complex became unstable and the ligand left the binding site (Fig. 8e), which is also reflected by the large RMSD values of the ligand (Fig. 8b). In contrast, molecular dynamics simulation showed greater stability of the DC-SIGN CRD-(S)-3 complex (Fig. 9). Although quite high RMSD values for the ligand were observed (Fig. 9b), D-mannose moiety of (S)-3 remained tightly bound to Ca\(^{2+}\) ion and other interacting residues, as described above. Glycerol linker with the two aromatic moieties showed much greater flexibility than D-mannose. At the beginning of the production run, glycerol linker slightly rotated and oriented the phenyl ring of the (S)-3 toward Arg345, while the naphthyl ring remained in contact with Phe313 side chain (Fig. 9c), as observed in the docking conformation (Fig. 7b). During the next few nanoseconds of the simulation, the naphthyl ring of (S)-3 started moving away from the Phe313 (Fig. 9d) and finally reached Asn344/Arg345 site (Fig. 9e). Such a rotation of the glycerol linker resulted also in reorientation of the phenyl ring, which left the Asn344/Arg345 site and moved toward Phe313 (Fig. 9d, e); however, it was mainly in contact with solvent.

To evaluate whether the observed differences in (R)-3 and (S)-3 behaviour during the first MD simulation are relevant, the MD was repeated twice more for each DC-SIGN-ligand complex. In all cases protein backbone was structurally stable, reflected by the low RMSD values (Fig. 8a and 9a). Ligand RMSD values and visual inspection of the trajectory during different MD runs of DC-SIGN-(S)-3 complex showed that the D-mannose moiety is tightly bound to Ca\(^{2+}\) and neighbouring amino acid residues, while the diaryl substituted glycerol linker finally adopts conformation similar to that presented in Fig. 9e. In contrast to the first MD simulation run of DC-SIGN-(R)-3 complex, the second and third runs showed its better stability. Towards the end of the second production run the D-mannose moiety of (R)-3 began to lose contact with Ca\(^{2+}\), which might eventually lead to dissociation of the complex, as presented in Fig. 8d,e. In the third run, the complex remained fairly stable, reflected by the relatively low RMSD values (Fig. 8b). D-Mannose residue of (R)-3 was constantly in contact with Ca\(^{2+}\), while the diarylglycerol moiety showed conformational flexibility.
The final pose of production run was very similar to that of (S)-3 presented in Fig. 9d, with naphthalene ring pointing toward solvent and the phenyl ring interacting with Arg345 side chain.

Discussion

Present study delivers new structural and mechanistic details at the atomic level of binding interactions of novel monovalent antagonists with DC-SIGN. Acquired STD NMR data on 1-4 unequivocally demonstrated their interactions in the binding site of the receptor. The STD group epitope mapping revealed that mannose group formed the strongest interactions with the DC-SIGN and was in the closest contact to the receptor in the case of ligands 1-4 (Fig. 3). Individual STD contributions and interaction involvements of sugar protons were inseparable due to spectral overlap of signals between δ 3.3 and 3.9 ppm. On the other hand, anomeric Hα proton of 1-4 displayed well-resolved signals with δ between 5.0 and 5.2 ppm. Additionally, most effective STD transfer to Hα proton of 1-4 was observed among all investigated protons (i.e. Hα-Hg). Consequently, Hα proton was considered as adequate representative of strong mannose group interaction. These results correlate well with the known binding specificity of DC-SIGN for D-mannose sugar.23, 24, 31

In accord with group epitope mapping results, STD build-up studies revealed the tightest involvement of Hα (and thus mannose group) in DC-SIGN interaction. Normalized build-up curves for Hα-Hg protons of 1-4 exposed structure modification-related differences in binding modes. These curves were consistent in the case of Hα proton, indicating that binding configuration of mannose sugar was very similar for all studied ligands. The latter was confirmed for Hc proton on naphthyl ring as well. Normalized STD build-up curves with great agreement confirmed analogous binding mode of Hc proton regardless of structure variations of ligands. On the other hand, build-up curves of Hb proton indicated altered involvement of this proton in ligand-receptor interaction. Results suggest that Hb proton is in closer contact with receptor in 1 and 3 in comparison to 2 and 4. Additionally, from comparison of Hα-Hg protons it is obvious that Hg of 1 was closer to the surface of the receptor with respect to Hg of 2-4. One should keep in mind that in the case of all naphthyl protons in 4 individual contributions would be markedly reduced because of overall symmetry-related STD effects of
H2, H3, and H4 protons. Although, build-up curves of H2 and H3 of 4 indicating faster rate of saturation in comparison to 1-3, maximum STD-AF were reached at lower values. Rapid saturation at low STD-AF plateau values is an indicator of fast exchange kinetics, which is in agreement with exchange properties of 4. The latter was also confirmed with the highest κ0 value among 1-4 which supports our observations of lowest binding affinity of 4.

While two naphthyl constituents demonstrated low interaction tendency, substitution one of naphthyl ring with phenyl moiety resulted in moderate improvement of binding propensity. Our results indicate that different position of carboxylic group on phenyl ring influence the binding conformation not only of modified part of ligand but also of intact naphthyl ring. When comparing 1 and 2 it is obvious that the position of carboxylic group on phenyl moiety affect the binding propensity of the ligand. Although, STD-build up curves show that H2 and H3 protons of 1 lay closer to the receptor in comparison to 2, the opposite was observed for H4 of 1 and H4 of 2. Contribution of individual H2 proton of 1 is believed to be lower than of H2 of 2. Para-position of carboxylic group on phenyl ring in 1 displays better binding properties of adjacent naphthyl moiety in comparison to 2. However, shift of carboxylic group from para- to meta- position improved binding propensity of phenyl constituent confirmed by STD group epitope mapping and evaluation of κ0 values. Lower κ0 value determined for 2 (0.96 mM) in comparison to 1 (1.6 mM) indicates better binding tendency of overall ligand. First, these results imply that, between both constituents, phenyl moiety primarily contributes to binding affinity and plays more important role in complex formation. And second, carboxylic group at meta-position on phenyl ring prolongs the half-life of ligand-receptor complex.

Furthermore, esterification of carboxylic group at meta-position on phenyl moiety additionally decreased κ0 value. Notable differences in binding properties among 2 and 3 were observed not only for H2 proton but also for the whole set of protons on naphthyl ring. H2 proton was after carboxylic group esterification closer to the surface of the receptor, since STD effect increased from 68% in 2 to 77% in 3. Greater spatial proximity was additionally confirmed with higher normalized STD-AF values for H2 of 3 in regard to 2. While H3, protons of 2 and 3 demonstrated analogous binding involvements, H4 of 3 was shown to be closer to the receptor surface. On the other hand, in the case of H4 proton of 3 we observed less intense contact to the receptor in comparison to 2. It is evident that esterification of carboxylic group enhanced the binding features of 3 which reflected in lowest κ0 value among 1-4 (0.45 mM). Additionally, we confirmed that esterification affected the position of the naphthyl ring in the binding site of DC-SIGN as well.

Our molecular docking and molecular dynamics simulations showed that structure-based design of novel DC-SIGN antagonists based only on docking calculations remains a great challenge and provides very limited information about the protein-ligand interactions in solution. Docking protocol is usually able to correctly predict the binding of the D-mannose moiety, which is in most cases the most tightly bound part of the DC-SIGN antagonist. Because of the rather flat DC-SIGN binding site, there are only few residues that could be targeted with the ligand to increase its affinity. In our case, aromatic moieties for interaction with the Phe313 side chain were introduced to improve the binding by possible π-π stacking/hydrophobic interactions, while carboxylates were introduced to explore possible formation of additional ionic interaction with Arg345 (see Fig. 10). While the docking calculations predicted the targeted hydrophobic interaction between the ligand and DC-SIGN (Fig. 7), molecular dynamics simulations showed that these interactions are probably quite weak given the observed flexibility of the ligands and low stability of the complexes during the molecular dynamics simulations (Fig. 8 and 9). Therefore, taken together the results of STD NMR and molecular dynamics simulations, we can conclude that our ligands bind rather tightly through D-mannose residue. We proposed a binding model of DC-SIGN-3 complex based on combined results obtained by NMR and MD simulations (Fig. 10). Interaction of 3- and 4-hydroxyl group of D-mannose with DC-SIGN CRD Ca2+-binding site is driven by four key bonds, namely two coordination bonds with Ca2+ ion and two H-bonds with side chains of Glu347 and Glu354. Additionally, H-bonds between other D-mannose hydroxyl groups and Asn349, Asn365 and Lys368 side chains of DC-SIGN were predicted as well. Strongest interaction of D-mannose was confirmed by highest STD effects for H2 proton, marked with red (Fig. 10). Other parts of the ligands show moderate flexibility, especially glycerol linker that enables rather free conformations and binding possibilities of attached aryl moieties. However, naphthyl ring was detected in the spatial proximity to Phe313 where it forms hydrophobic interactions as predicted.
STD NMR results suggest that naphthyl moiety adopts conformation where H6 proton (orange on Fig. 10) is the closest to the receptor followed by H7 proton (yellow on Fig. 10). Weakest interaction and thus greatest receptor-ligand interproton distance was observed for H8 proton, marked with blue. On the other hand, flexibility resulting from glycerol linker allowed unforeseen engagement of phenyl group in more polar area, where it forms hydrogen bond with Asn344 and contacts with Arg345 (possible cation-π interaction) of DC-SIGN. Conformation of phenyl entity thus apparently depends on quite prominent H proton-receptor proximity and formation of hydrogen bond between esterified carboxylic group and Asn344 side chain. Observation of phenyl moiety retention in polar environment of the binding site offers new insights in ligand behaviour within flat binding sites and additionally emphasizing the need for further designing of novel and more potent DC-SIGN antagonists.

Experimental

Chemistry.

Detailed information is given in the Supporting information.

**STD experiments.** STD NMR samples were prepared in 25 mM TRIS-d11 (pD = 8.0), 150 mM NaCl, 4 mM CaCl2 in 2H2O and 25% of DMSO-d6. In all STD experiments the concentration of receptor DC-SIGN was 8 μM. DC-SIGN ECD protein (residues 66-604) were overexpressed and purified according to the already published procedure. For the STD NMR studies, a pseudo-2D version of STD NMR sequence with DPFGSE water suppression was used for the interleave acquisition of on- and off-resonance spectra at 25 °C with 512 scans. For selective saturation cascades of Gaussian pulses with a length of 50 ms and 10 dB spaced by 0.1 ms delays were employed. The on-resonance irradiation was performed at 0.9 ppm; the off-resonance frequency was 30 ppm. For the protein signal suppression was used 30 ms spin lock filter. The STD spectrum was obtained by subtraction of saturated spectra from reference spectra. The fractional STD effect was calculated by $I_{\text{sat}} - I_{\text{off}}$/$I_{\text{off}}$, where $I_{\text{sat}}$ stands for intensity of signal in off-resonance spectrum. $I_{\text{off}}$ is intensity of signal in on-resonance spectrum. $I_{\text{off}} - I_{\text{sat}}$ represents the intensity of the STD NMR spectrum. The appropriate blank experiments, in the absence of the protein, were performed to assure the absence of direct irradiation of the ligand. Saturation times to obtain the STD build-up curves were 0.1, 0.3, 0.5, 0.75, 1.0, 1.25, 1.5, 2.0, 2.5, 3.0, 4.0, 5.0 s. In titration study, five STD experiments were performed with varying concentrations, 80, 240, 400, 560 and 800 μM.

STD-amplification factor is determined according to Eq. 1, in which $STD - AF$ is a STD amplification factor. $I_{\text{off}} - I_{\text{off}}$ represents the intensity of signal in off-resonance spectrum. $I_{\text{sat}}$ is intensity of signal in on-resonance spectrum. $I_{\text{off}} - I_{\text{sat}}$ represents the intensity of the STD NMR spectrum. [L] is the concentration of ligand and [P] stands for the concentration of receptor. The build-up curves are fitted to the monoexponential Eq. 2, where $STD - AF$ stands for the STD amplification factor of a given proton at saturation time $t$, $STD_{\text{max}}$ is the maximal STD intensity obtainable when long saturation times are used, and $k_{\text{sat}}$ is the observed saturation rate constant.

$$STD - AF = STD_{\text{max}} \left(1 - e^{-k_{\text{sat}} t}\right) \quad (\text{Eq. 2})$$

The hyperbolic behaviour of the curves obtained from the plot of $STD - AF$ as a function of ligand concentration is appropriately described by Eq. 3, where $STD - AF$ is a STD amplification factor, $\alpha_{\text{STD}}$ represents the maximum amplification factor, [L] is a ligand concentration and $K_0$ is dissociation constant.

$$STD - AF = \frac{\alpha_{\text{STD}} [L]}{K_0 + [L]} \quad (\text{Eq. 3})$$

For the non-linear least-squares curve-fitting to the Eq. 2 and Eq.3 was used Origin 8.1 software. All experimental data were presented with standard errors bars.

Molecular modelling

**Computer hardware and software.** All the computational work was performed on a workstation with four octal core AMD Opteron CPU processors, 16 GB RAM, two 750 GB hard drives, running 64-bit Scientific Linux 6.0.

**Ligand and protein preparation.** The three-dimensional models of compounds 1-4 were built in ChemBio3D Ultra 13.0. The geometries and charges of the molecules were optimized using the MMFF94 force field and partial atomic charges assigned in ChemBio3D Ultra 13.0. The energy was minimized until the gradient value was smaller than 0.001 kcal/ (mol×Å). The optimized structure was further refined with GAMESS interface in ChemBio3D Ultra 13.0, using the semi-empirical PM3 method, QA optimization algorithm and Gasteiger Hückel charges for all atoms for 100 steps.

The crystal structure of DC-SIGN CRD in complex with tetramannoside Man4 (PDB entry: 1SL4) was taken as a receptor for docking calculations using FlexX as available in LeadIT. The receptor was prepared in LeadIT graphical user interface using the Receptor wizard. Amino acid residues within a radius of 7 Å around Man4 were defined as the binding site. Hydrogen atoms were added to the binding site residues and correct tautomers and protonation states were assigned. Water molecules and the ligand were deleted from the crystal structure, while Ca2+ ion in the Ca2+ binding site was defined as part of the receptor. Pharmacophore type constraints in FlexX-Pharm were defined in order to correctly place the core mannose residue during the docking procedure. First, PharmMetal pharmacophore with spherical coordination around Ca2+ ion was defined to account correctly for complex interactions between Ca2+ ion (406) and D-mannose residue of the designed ligands. Secondly, side chain carboxylate groups of Glu347 and Glu354 were defined as hydrogen bond acceptors, which form hydrogen bonds with 3- and 4-hydroxy groups of D-mannose residue in the crystal structure. All three selected pharmacophore type constraints were specified as essential.
For docking with FRED software (Release 3.0.1, OpenEye Scientific Software, Inc., Santa Fe, NM, USA; www.eyesopen.com), the protein was prepared using MAKE
RECEPTOR (Release 3.0.1, OpenEye Scientific Software, Inc., Santa Fe, NM, USA; www.eyesopen.com). We determined the grid box size; inner and outer contours of the grid box were calculated automatically. The outer contour size was 6195 Å³, while the grid box size was 9216 Å³. The setup of contours was set as “Balanced”. Amino acid residues Asn365, Glu347 and Glu354 and Ca²⁺ ion were defined as pharmacophore type constraints. FRED requires the preparation of input conformers of each ligand prior to docking. These conformers were generated using OMEGA 2.4.6 from OpenEye Scientific Software.

**Ligand docking.** The FlexX molecular docking program, as available in LeadIT, was used for ligand docking. Hybrid algorithm (enthalpy and entropy driven ligand binding) was used to place the ‘base fragment’. The Maximum number of solutions per iteration and the Maximum number of solutions per fragmentation parameter values were increased to 1000, while other parameters were set at their default values. Proposed binding modes and scoring function scores of the top ten highest scored docking poses per ligand were evaluated and the highest ranked binding pose was used for graphical representation in PyMOL.

Ligands 1-4 were also docked using FRED (version 3.0.1, OpenEye Scientific Software, Inc., Santa Fe, NM, USA; www.eyesopen.com). Docking resolution was set to high, other settings were set as default. Twenty-five docking solutions were inspected visually and the best ranked FRED-calculated conformation was used for analysis and representation.

**Molecular dynamics.** The molecular dynamics package NAMD (version 2.9) and CHARMM22 force field were used for molecular dynamics simulations of DC-SIGN–ligand complexes. The FlexX best scored docking pose of compounds (R)-3 or (S)-3 in complex with DC-SIGN CRD was used as the initial structure for MD simulation. Molecular mechanics parameters for compounds (R)-3 and (S)-3 were estimated using ParamChem tool. Steepest descent (10 000 steps) and adopted basin Newton–Raphson (10 000 steps) energy minimizations were first performed to remove atomic clashes and to optimize the atomic coordinates of the protein – ligand complex. The structure of the energy minimized complex for MD simulation was prepared using psfgen in VMD (version 1.9.1.). The complex was then embedded in a box of water, which was modelled explicitly by a TIP3P model. The system was neutralized by addition of KCl at 0.4 M concentration. The MD simulation was carried out in the NPT ensemble employing periodic boundary conditions. Langevin dynamics and Langevin piston methods were used for temperature (300 K) and pressure (1 atm) control, respectively. Short- and long-range forces were calculated every 1 and 2 timesteps, respectively, with a time step of 2.0 ps. The smooth particle mesh Ewald method was used to calculate electrostatic interactions. The short-range interactions were cut off at 12 Å. All chemical bonds between hydrogen and heavy atoms were held fixed using SHAKE algorithm. The simulation consisted of three consecutive steps: (i) solvent equilibration for 0.5 ns with ligand and protein constrained harmonically around the initial structure; (ii) equilibration of the complete system for 1 ns with ligand and protein released; (iii) an unconstrained 10 ns production run to allow the protein and the ligand to position themselves according to physical forces between them. The trajectory of the equilibration and production run was used for analysis in VMD. The MD simulation of each complex was repeated three times.

**Conclusions**

In the present study we investigated the interactions between four monovalent mannose-based ligands and extracellular domain of DC-SIGN. Studied ligands, some of which are novel entities, consist of α-D-mannose connected by glycerol linker to different aryl moieties, which were expected to tune interactions of ligands in hydrophobic groove of the receptor. The combination of saturation transfer difference (STD) NMR spectroscopy and molecular modelling has been used to examine binding affinity of monovalent glycomimetics for DC-SIGN at the atomic level of resolution. Our study showed that four α-D-mannoside ligands interact with the binding site predominantly with mannose moiety. Importantly, the other two aromatic groups that are bound to α-D-mannose through glycerol linker demonstrate interaction that can be related to their substituent pattern. Ligand with naphthyl and meta-substituted phenyl ring exhibited the most favourable binding characteristics, which might imply involvement of new contacts of substituted phenyl moiety in more polar area of flat binding site of DC-SIGN. Although our first impression was that carboxylate in the studied ligands should interact primarily with Arg345, it seems that the Asn344 residue forms H-bond with the polar group and thus dictates the main interactions with the polar substituent at phenyl ring, while Arg345 possibly forms cation-π interaction with the phenyl moiety. Our findings point that besides lipophilic residues, possible involvement of H-bonds and /or cation-π might boost the interaction of small molecule DC-SIGN ligands and thus offer new possibilities in further designing of novel, stronger DC-SIGN antagonists.
