This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. This Accepted Manuscript will be replaced by the edited, formatted and paginated article as soon as this is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Production of Cellulose Nanocrystals via a Scalable Mechanical Method

Khairatun Najwa Mohd Amin\textsuperscript{a,b}, Pratheep Kumar Annamalai\textsuperscript{a,*}, Isabel Catherine Morrow\textsuperscript{c,d} and Darren Martin\textsuperscript{a,*}

The production of rigid rod-like cellulose nanocrystals (CNC) via more scalable methods is necessitated by an increasing demand for CNC in various industrial sectors over the last few years. Contemporary protocols involve a consumption of large amounts of strong acids, enzymatic treatments, ultra-sonication and combinations thereof. In an attempt to address this scalability challenge, we aimed to isolate CNC via a scalable mechanical method i.e. high energy bead milling (HEBM). An aqueous dispersion of commercially available microcrystalline cellulose (MCC) was micronized through a HEBM process. This process was optimised by varying the concentration (0.5 - 2 wt. %) and time (15-60 min) parameters, in order to obtain a high yield of well-separated CNCs as characterised by transmission electron microscopy (TEM). Micronisation of cellulose via the HEBM method under mild conditions resulted in cellulose nanocrystals with an average aspect ratio in the range of 20 to 26. The nanocrystals also retained both their crystallinity index ($I_{Cr}$)(85 to 95 \%) and thermal stability described in terms of onset degradation temperature ($T_{onset}$)(230 – 263 °C). The production yield of CNC from MCC via this process ranged between 57 to 76 \%. In addition, we found that micronisation of the MCC in presence of dilute phosphoric acid also resulted in CNC with an average aspect ratio ranging from 21 to 33, high crystallinity (88-90 \%) and good thermal stability ($T_{onset}$ 250 °C). In this study, we demonstrate the micronisation of commercially available MCC into CNC and describe their dimensions and properties after acid treatment and HEBM. Furthermore, we are able to recommend the use of this scalable milling process to produce rod-like cellulose nanocrystals having a thermal stability suitable to withstand the melt processing temperatures of most common thermoplastics.

Introduction

Recently, nanoscale cellulose particles have gained much interest from both academia and industry as a new class of renewable nanomaterials due to their useful mechanical properties (eg. high specific strength and stiffness and thermomdimensional stability) \cite{1} combined with their nanoscale crystalline and fibrous morphology, chemically tuneable surface functionalities, an ability to be obtained in various dimensions (esp. aspect ratio) and renewability \cite{1,2}.

Depending on the processing methods and the sources, they can be obtained as rod-like low-aspect ratio nanocrystals, filament-like long nanofibrils and sphere-like nanocrystals.\cite{2-5} The properties of individual rod-like or rice like cellulose nanocrystals (CNC) are drawing great interest when compared with other engineering materials like aluminium\cite{6-8}, steel\cite{7} and glass fibre\cite{8}. These properties greatly recommend them as advanced reinforcing or functional fillers for thermoplastics, thermosets and elastomers. They have been explored as fillers and rheology modifiers in various fields like thermoplastics\cite{10-12}, foams\cite{13}, aerogels\cite{14} and polymer electrolytes\cite{15, 16}. Isolation of CNCs via sulphuric acid hydrolysis is not ideal as it requires a considerable consumption of solvent (acid) and time. Furthermore, the resulting product also exhibits poor thermal stability (attributed to the dehydration mechanism facilitated by the sulphate groups) \cite{17} and is therefore sometimes unsuitable.
for further processing at the elevated temperatures (180-250 °C) typically employed in the manufacturing of many thermoplastic polymers. Hence, it becomes critical to produce CNCs with enhanced thermal stability. To date, alternative approaches have included the use of some mild mineral and organic acids or enzymatic methods in combination with ultrasonic or microwave irradiation.

Recently, highly thermally stable CNCs have been produced via mild acid hydrolysis (phosphoric acid) and hydrothermal treatment (hydrochloric acid) at laboratory scale. However, these methods are severely limited by low yields and poor scalability due to the high consumption of mild acids (solvents) and time, respectively.

Mechanical methods have also been explored for the preparation of nanoscale cellulose particles, either as part of the production process using combinations of acid hydrolytic, oxidative, and enzymatic treatments, or directly. These mechanical methods include ultrasonication, microfluidization, high pressure homogenization or ball milling. Among these methods, ball milling has many advantages such as the possibility of both dry and wet milling, temperature control and scalability in both batch and continuous formats. For micronising cellulose, wet conditions are preferred as the fluid can create a buffer between bead and cellulose particles thereby minimising the damage to the crystalline structure.

Recently, ball milling methods have been successfully employed for isolating nanoscale cellulose particles whereby water and organic solvents were employed as the milling media resulting in the retention of the inherent crystallinity of the particles. However, most of the mechanical defibrillation methods reported (including wet ball-milling methods), generated a final product of filament like nanofibrils, called nanofibrillated and microfibrillated cellulose (NFC/MFC) or cellulose nanofibres (CNF), which can be characterized with a diameter in nanometers or tens of nanometers and a length of up to several microns.

These filament-like nanoparticles have been explored in several applications where fibre entanglements are required. However, in polymer reinforcements, cellulose nanofibrils can raise an issue in terms of dispersibility and viscosity increases in a polymer matrix, especially with an aspect ratio above 100.

Thus, in this study, we aimed at producing short ‘rod-like’ or ‘rice-like’ cellulose nanocrystals with an aspect ratio below 100 primarily using high-energy bead milling (HEBM) while also investigating various chemical processing conditions.

As shown in Figure 1(a), HEBM operates via an impact mechanism to micronize the particles. When centrifugal force is generated in the mill, beads are forced to rotate around the mill wall. The reverse rotation of disc also applies centrifugal force in the opposite direction leading to the transition of balls to the opposite walls of mill providing an impact effect to micronize the materials in between the beads. Furthermore, HEBM was compared with ultrasonication as one of the mechanical methods explored. As shown in Figure 1(b), ultra-sonication operates on a well-known high-speed shear mechanism. Upon ultrasonication, high-speed liquid jets are created. These liquid jets pressurize the liquid locally between the particles at high speed (1000 km/hr) to separate or fibrillate them and to promote additional particle collisions, so as to result in very small particles.

By evaluating the resulting dimensions, crystallinity and the properties of CNC produced from both methods, we hereby demonstrate the potential of HEBM to cost-effectively produce CNCs with good thermal stability in a scalable quantity.

**Experimental**

**Materials**

Microcrystalline cellulose (MCC) used is Avicel PH-101 (wood based cellulose)(USA, FMC biopolymer corporation). Ortho-phosphoric acid (H₃PO₄, 85%) from Merck (Australia) was used for HEBM with acid treatment.

**Isolation of CNC via ultrasonication**

MCC (5 g) was dispersed in 500 ml deionized water and stirred by magnetic bar overnight. The ultrasonication was carried out with an aqueous dispersion of MCC was sonicated using QSonica ultrasonicator for 50 minutes at an output of 500 W, frequency of 20 kHz and amplitude of 20 %.
ultrasonication, the dispersion was stirred for 1 hour and was left in a stationary position for 1 day. At this point two layers of the dispersion were observed with a top layer in consisting of well dispersed CNCs. This top layer was decanted and freeze dried, and this material was designated as CNC-U.

Isolation of CNC via high-energy bead milling

MCC was dispersed in deionized water overnight at various concentrations (0.5 – 2 wt %). The dispersion was milled using a Laboratory agitator bead mill (LabStar, Netzsch, Germany) with 0.4 mm zirconium beads in a batch process mode, at 1000 rpm for 15, 30 or 60 min. The dispersions obtained were freeze-dried. The resulting CNCs were designated as follows: CNC-MAn where A is MCC concentration (0.5, 1, 2 wt. %) and n is milling time (15, 30, 60 min).

To evaluate the effect of mild phosphoric acid on the milling process, MCC was dispersed in dilute 1wt. % H$_3$PO$_4$ for one hour before the milling process. After milling, the CNCs were separated from the liquid by centrifugation. The supernatant was decanted and replaced by an equal amount of deionised water and the mixture was centrifuged again until the supernatant reached neutral pH. Finally the CNCs suspension obtained were freeze-dried. The CNC produced via milling with H$_3$PO$_4$ was coded as CNC-MA$n$, where P denotes the acid pre-treatment.

Characterization

MORPHOLOGY AND DIMENSIONS
To investigate the structure and the aspect ratio of the CNC preparations, transmission electron microscopy (TEM) was performed. CNCs were suspended in deionized water at a concentration of 0.08 mg/ml and the suspension was sonicated for 1 hour. Two microlitres of the suspension was spotted onto a copper-palladium TEM grid. After drying the grids were stained with 2% uranyl acetate and analysed in a JEOL 1011 TEM (JEOL,Japan) at 100 kV, and images were captured on an IS Morada 4K CCD camera system.

THERMAL STABILITY ANALYSIS
The thermal stability of the CNC variants was determined using Thermogravimetric analysis (TGA) under a nitrogen atmosphere. The samples were first heated from room temperature to 110 °C, at a heating rate of 10 °C/min, isothermally held for 10 min and further heated to 500 °C at a heating rate 5°C/min.

ICP-OES ANALYSIS
ICP-OES analysis was used to determine the presence of the element Zirconia contained in CNCs samples. The analysis was performed to identify the presence of any metal elements in the sample as Zirconia balls were used in the milling process.

CRYSTALLINITY
The degree of crystallinity of CNCs was examined by X-ray diffraction (XRD). XRD was generated at 40 kV using a current of 40 mA. The crystallinity index of CNCs was determined by the XRD peak height method. The crystallinity index is calculated using the following equation:

$$ I_{Cr} = \frac{I_{002} - I_{am}}{I_{002}} \times 100 $$

Where $I_{002}$ is the maximum intensity of the peak corresponding to plane having the miller indices 002 and $I_{am}$ is the minimal intensity of diffraction of the amorphous phase at $2\theta = 18^\circ$.

DISPERSION STUDIES
The dispersibility of CNC was investigated by dispersing the CNCs in deionised water. The dispersions were prepared at concentration of 2mg/ml and sonicated using water bath sonicators for 4 hours. Pictures were taken immediately after preparation and subsequently after 1 hour, 1 day and 2 days.

ZETA POTENTIAL
The zeta (ζ) potentials of the CNCs were measured at a concentration of 0.01 mg/ml with a Zetasizer analyzer. Deionised water was used as a dispersant. The ζ potential was calculated by use of the Smoluchowski equation.

Results and Discussion

Morphology and dimension
Transmission electron microscopy (TEM) was carried out to investigate the dimensions and structural morphology of CNCs. The dimensions were measured using ImageJ software by magnifying the images to identify the rice-like particles end to end with at least 10 particles measured. From the TEM images in Fig. 2 and Fig. 3, it can be seen that MCC was successfully fibrillated and deconstructed into nanocrystals via the HEBM process.

Fig. 2 Optical microscopic image (top left) of microcrystalline cellulose (MCC) before milling and TEM images of CNCs obtained via HEBM from the dispersion of 0.5 wt % MCC in deionized water
Unlike other mechanical processes\textsuperscript{30} reported, including a similar ball milling process\textsuperscript{15} (with softwood pulp sheet and alkaline solutions) where only micro- and nano-fibrillated cellulose (MFC/NFC) were observed. Here, the nanoparticles produced via our HEBM investigation exhibited rod-like or long rice-like morphology. As listed in Table 1, the aspect ratio of CNC products ranged from 20 to 26. Interestingly, the morphology and the aspect ratio values are actually quite similar to that of the CNCs produced via acid hydrolysis\textsuperscript{36, 37}. Furthermore, we found that the changes to morphology and dimensions were not significantly affected by the duration of milling (between 15 and 120 min) and the concentration (between 0.5 and 2 wt. %) of the suspension used in this study. It implies that even at 15 minutes of milling, rod-like cellulose nanocrystals can be obtained. However, according to the TEM images, the interaction between the individual CNCs is slightly altered, for example, the CNCs obtained from higher concentrations (eg. 2 wt. %) tend to interact through edges of the particles indicating the electrostatic interactions between the CNCs. The production yield (\%) (product weight over raw material weight) of CNCs from the suspension of MCC ranged between 57 and 76 %. It is to be noted that some yield reduction can be attributed to material losses occurring during handling, including withdrawal of the suspension from the mill, and filtering plus washing of the balls after the milling process. The yield \% values are relatively higher than the reported yield of CNCs obtained via acid hydrolysis (22 – 52\%) depending on sources\textsuperscript{36, 38-40}.

As a comparison, CNC was also obtained via an ultrasonication method following previously reported protocols\textsuperscript{20, 22} with some slight modifications. Fig. 4 shows the TEM images of CNCs obtained from the top layer of the suspension obtained after ultra-sonication (CNC-U) of the MCC. They also showed ‘rod-like’ or ‘rice-like’ nanocrystals with an average aspect ratio of 15 (165 ±23 nm length and 11 ±2 nm in width). However, the production yield (\%) of CNC from top layer suspension was very low, i.e. 8-10 \% of the initial weight. Meanwhile, the bottom layer had clusters or agglomerates of cellulose particles with dimensions of 100 nm to 500 nm (Figure S1 in supplementary information).

**Thermal stability**

Thermal stability of CNCs obtained via milling was measured by thermogravimetric analysis (TGA). Figure 4 compares the thermograms of MCCs and CNCs. A slight weight loss at a low temperature region (<110 °C) can be attributed to the residual water in the cellulose particles even after vacuum drying. The onset degradation temperature (T\textsubscript{onset}) for MCC was 270 °C, whereas a slight decrease in T\textsubscript{onset} was observed for
CNCs (230 - 263 °C) obtained after the milling process. This slight decrease can be attributed to either the increase in the surface area, fragmentation or decrease in crystallinity caused by the milling process.

The degradation of CNC-U starts from 250 °C which is slightly lower than the onset degradation temperature of MCC. This decrease may be associated with the increase in free cellulose chains and fragmentations brought about by ultrasonication\textsuperscript{19}. The CNCs obtained via HEBM process show higher thermal stability when compared to the thermal stability of the CNCs obtained via typical sulphuric acid hydrolysis. These start to decompose at 150 °C\textsuperscript{19, 41}. It is to be noted that the processing temperature of many thermoplastic polymers falls within the range of thermal stability exhibited by CNCs obtained via HEBM process.

**Crystallinity of CNC**

The effect of milling on the crystalline structure of MCC particles was investigated by X-ray diffraction analysis. The characteristic peaks at $2\theta = 15$ (101), 16.5 (100), 20.8 (021), 22.5 (002) and 34.3 (040) of crystalline polymorph I cellulose for MCC\textsuperscript{42} can be seen in Figure 5. These peaks can be still observed for the CNCs obtained via milling process. The crystallinity index ($I_{Cr}$) expressed as a percentage was calculated from the ratio of the crystalline peak ($I_{002}$ - $I_{am}$) and the total peak of 002 lattice plane. The $I_{Cr}$ of the initial MCC was about ~ 95 %.

CNCs obtained by the milling process showed a degree of crystallinity in the range between 85 – 95% (Table 3) with no significant trend observed upon varying concentration (0.5 - 2 wt. %) and milling time (15-60 min). The crystallinity for CNC obtained via ultrasonication was within this range, ~ 90 %, indicating a similar crystalline structure. The crystallinity range observed in this study is still higher than the earlier reported values (67 - 82 %) for CNCs obtained via acid hydrolysis\textsuperscript{5, 19}. It is also higher than the crystallinity (~32 %) reported for CNC obtained after prolonged dry milling (1-6 days) and dilute acid hydrolysis\textsuperscript{43}. Nevertheless, the maximum milling time was only 60 minutes via the wet milling conditions used in this study lead to less destruction of the crystal structure than seen with extensive dry milling.

**Stability and zeta potential of suspension**

As mentioned earlier, dispersibility is one of the key properties required for suitability as a reinforcing filler, as this property determines the ability to form stable colloidal suspensions\textsuperscript{44, 45}.

The suspensions obtained after milling are stable even after several weeks (Figure S2) unlike the suspension obtained via ultra-sonication (Figure S1 (a)), where rapid separation into two layers was observed.

However, freeze-drying affected the dispersibility of the CNC produced via HEBM (Figure S3). Further characterisation

![XRD patterns of commercial MCC and CNCs obtained (after 60 min of milling) via HEBM method showing the retainment of crystalline domains of cellulose at $2\theta = 15$ (101), 16.5 (100), 20.8 (021), 22.5 (002) and 34.3 (040)](image)
of dispersibility, was carried out by measuring the zeta potential of this CNC. As visual examination suggested, CNC dispersions had settled down after 2 days and the ζ potential recorded a value within the range of -28 and -42 mV (Table 3) indicating that HEBM CNCs are fairly stable in water and can be considered stable as compared to CNC produced via acid hydrolysis. For typical CNC obtained from sulphuric acid hydrolysis, a zeta potential of -95 mV has been achieved due to sulphate charges which can be considered excellent stability. As zirconia beads are used in the milling process, it was also necessary to know the purity of CNC preparation or the extent of metal ion contamination of the milled CNCs. The result obtained from ICP-OES analysis showed a trace of metal ions including the zirconium (Zr) (Table 3). Nevertheless, the values of ‘Zr’ did not follow any particular trend with either concentration or duration of milling.

Efficiency of CNC production from MCC via HEBM process

The preparation of CNC from commercially available MCC has been already reported by both acid hydrolysis and mechanical shear methods for nanocomposite preparation. A typical acid hydrolysis protocol involves the hydrolysis at higher temperature, with 64 % sulfuric acid, multiple dilutions and centrifugations and several days of dialysis and sonication. Table 4 provides the data (conditions and yield) obtained from published literature regarding the isolation of CNC from MCC via acid hydrolysis, where the solid to liquid ratio refers the weight of MCC over volume of 64 % acid solution used during hydrolysis. In comparison, HEBM process mainly requires the deionised water as media with a solid-to-liquid ratio of 1:200, 1:100 and/or 1:50.

It can be noted that the hydrolysis of MCC with 64 % sulphuric acid in a typical solid-to-liquid ratio of 1:10, the production yield of CNC is ~ 30 % with reference to the initial material input. On the other hand, HEBM process of MCC in deionised water with a solid-to-liquid ratio of 1:50, yielded about 58-76 % of CNC. Table 5 compares the time, energy consumption and the production yield based on a typical large scale acid hydrolysis protocol and the batch-milling process (See the supplementary information Table S1). It can be apparently evident that for the production of one kilogram of CNC via acid hydrolysis process, it requires two or threefold of raw material (MCC) and higher energy and longer time in comparison with that via an optimised HEBM process.

Influence of mild acid treatment

In order to obtain CNCs with improved thermal stability and dispersibility, the milling was also performed with a mild acid (phosphoric acid). The MCC dispersions (0.5 and 2 wt. %) were milled with 1 wt. % of phosphoric acid (H₃PO₄) at 15, 30 and 60 minutes of milling time. Figure 7 shows the TEM images and TGA thermograms of CNC obtained by this process from 0.5 wt. %. The aspect ratio of the CNCs obtained via milling with dilute phosphoric acid was higher than the CNCs obtained from milling without H₃PO₄. As can be seen in Table 6, their length and width ranged between 200 and 400 nm and 7 to 18 nm, respectively. Conversely, the remaining samples did not show distinctive shapes (Figure S4) and thus it was not possible to measure the exact dimensions of these particles. This may be presumably due to the surface swelling or dissolution by phosphoric acid depending on residence time.

With suspension of 0.5 wt. % concentration, the milling for longer times (above 30 min) showed agglomeration (Fig. S4). Compared to CNC-MC3 (Fig. 3) and CNC-MPC3 (Fig. 7), suggesting that with increasing concentration of cellulose, HEBM in presence of dilute H₃PO₄ may facilitate the surface swelling and agglomeration of CNC particles. However, milling with dilute H₃PO₄ has relatively improved the thermal stability when compared to CNCs milled without phosphoric acid; for example, the onset degradation temperature was increased to approximately 250 °C. Furthermore, the cellulose I polymorph-crystalline structure was also unaffected in the preparation (Fig. S6).

The stability of the suspension obtained from the freeze-dried CNCs obtained via milling with H₃PO₄ was also studied. (Fig. S5). Our results show that a few phosphate groups ((PO₄) - 3) might possibility attach to the surface of the cellulose structure and function as a stabilizing agent, as the amount of acid used was low. In fact, H₃PO₄ is likely to have assisted in the isolation process. However, CNCs milled with phosphoric acid recorded ζ potential between -23 to -38 mV (Table 7) showing that the CNCs have moderate stability, similar to the CNC produced via HEBM without this acid.

Table 7 also summarises the physicochemical properties of the CNCs obtained via milling with dilute phosphoric acid. The degree of crystallinity of these CNC-MPA1 and CNC-MPC3 was between 88 and 90 % indicating the crystalline structure of cellulose was not strongly affected by milling with dilute H₃PO₄ for short periods (Fig. S6). Traces of Zr ions were also detected in the suspension.

Conclusions

Isolation of cellulose nanocrystals was successfully carried out using a high energy ball milling method with and without the aid of dilute phosphoric acid. CNCs produced by this method showed distinctive rod-like or rice-like morphology with an average aspect ratio ranging between 20 and 26. The nanocrystals produced have the appropriate characteristics for reinforcing thermoplastic polymers as the higher surface area will increase the interaction between the filler and the polymer matrix. Furthermore, with the degree of crystallinity obtained, in the range of 85 to 95%, this shows a good preservation of cellulose I crystal structure which is also important in transferring the mechanical properties required in nanocomposite applications. Moreover, the thermal properties of HEBM CNCs also recorded high thermal stability values, with onset degradation temperatures of between 230°C – 263°C, thereby enabling them to be used in thermoplastic manufacturing i.e. melt compounding or reactive extrusion, which usually involves high temperature processing. In comparison of acid hydrolysis, the HEBM process significantly shows the low energy and time consumption and no/minimal use of strong acids for the production CNCs in high yield. Production of CNCs. Using the HEBM process, CNCs can be produced with a high level of scalability suggesting this method should be further explored to fulfil the industrial demand for CNCs in various applications like surface coatings, adhesives, thermoplastic manufacturing etc.
