This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. This Accepted Manuscript will be replaced by the edited, formatted and paginated article as soon as this is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Design, synthesis and thermal behaviour of a series of well-defined clickable and triggerable sulfonate polymers

Joanna Kolomanska, Priscilla Johnston, Alberto Gregori, Isabel Fraga Dominguez, Hans-Joachim Egelhaaf, Sébastien Perrier, Agnès Rivaton, Christine Dargon-Lartigau and Paul D. Topham*

In the printing industry, the exploitation of triggerable materials that can have their surface properties altered on application of a post-deposition external stimulus has been crucial for the production of robust layers and patterns. To this end, herein, a series of clickable poly(R-alkyl p-styrene sulfonate) homopolymers, with systematically varied thermally-labile protecting groups, has been synthesised via reversible addition−fragmentation chain transfer (RAFT) polymerisation. The polymer range has been designed to offer varied post-deposition thermal treatment to switch them from hydrophobic to hydrophilic. Suitable RAFT conditions have been identified to produce well-defined homopolymers (Đ, Mw/Mn < 1.11 in all cases) at high monomer conversions (> 80 % for all but one monomer) with controllable molar mass. Poly(p-styrene sulfonate) with an isobutyl protecting group has been shown to be the most readily thermolysed polymer that remains stable at room temperature, and was thus investigated further by incorporation into a diblock copolymer, P3HT-b-PiBSS, by click chemistry. The strategy for preparation of thermal modifiable block copolymers exploiting R-protected p-styrene sulfonates and azide-alkyne click chemistry presented herein allows the design of new, roll-to-roll processable materials for potential application in the printing industry, particularly organic electronics.

Introduction

Poly(p-styrene sulfonate), or poly(p-styrene sulfonic acid) (PSS), has been shown to be an extremely useful ion exchange material for a wide range of applications, such as water softening,1 medicine,2 biomaterials,3 and fuel cells.4 Most notably, perhaps, is the exploitation of PSS as a dopant for poly(3,4-ethylenedioxythiophene) (PEDOT) in organic electronic devices.5-7 Negatively charged PSS forms a complex with positively charged (p-type) PEDOT to produce hole conducting ‘buffer’ layers in organic photovoltaics (OPVs), hole injection layers in organic light emitting diodes (OLEDs) or as a possible electrode replacement for indium tin oxide (ITO).8, 9 However, PSS is a polar polymer and cannot be readily processed from organic solvents that are used typically for the deposition of the more apolar conducting materials, such as polythiophenes,10, 11 polycarbazoles12, 13 and fullerene derivatives.11, 14 Consequently, this can limit the applicability of PSS in solution-processable technologies, despite its clear relevance. Additionally, the preparation of non-polar/polar hybrid materials (such as amphiphilic block copolymers15-17) can be difficult owing to the contradictory solubilities of the disparate building blocks.

Typically, PSS is produced by the sulfonation of polystyrene using concentrated sulfuric acid,18, 19 acetyl sulfate,20, 21 or sulfur trioxide.22, 23 However, problems over control of the sulfonation level have led to the development of alternative methods. Accordingly, controlled polymerisation methods, namely nitroxide-mediated polymerisation (NMP),17, 24, 25 atomic transfer radical polymerisation (ATRP),26-28 and reversible addition-fragmentation chain transfer (RAFT) polymerisation,29-31 have been exploited to obtain sodium poly(p-styrene sulfonate). Another strategy presents ATRP of poly(ethyl p-styrene sulfonate) followed by the chemical deprotection of the ethyl ester functionality using sodium azide32 or sodium hydroxide,33 both in DMF/water cosolvent systems.

As aforementioned, and discussed across the literature, the processing of PSS from most organic solvents requires the introduction of a protecting group to remove the ionic
character of the sulfonic acid group. Deprotection of the sulfonate group is therefore essential in order to restore the ion exchange properties of PSS.\textsuperscript{32-37} Similarly, a related strategy has been employed to process conjugated polymers for use in OPV. Incorporation of alkyl side chains into the monomer (and hence pendant along the final macromolecular chain) is a widely used approach for improvement of solubility of extensive aromatic systems.\textsuperscript{38, 39} Unfortunately, however, such alkyl chains have been shown to promote degradation.\textsuperscript{40, 41} Hence, cleavage of the alkyl chains directly after processing the polymers is recommended to overcome this problem. Several investigations concerning chemically- and thermally-assisted removal have been undertaken.\textsuperscript{42-45} Chemical routes profit from high side chain cleavage efficiency. However, in roll-to-roll technology, widely used in the application of coatings (particularly pertinent for the industrial production of many organic electronic devices), chemical modification is undesirable as a processing technique because of the cost, complications of washing, chemical waste and possible damage to other materials in the system. The use of thermally-assisted deprotection of functional groups significantly diminishes these issues. Nonetheless, caution must be exercised with this approach, as excessive temperatures lead to lower OPV performances and damage to the flexible plastic substrates.\textsuperscript{46, 47} Indeed, acid-catalysed cleavage can allow a decrease in processing temperature,\textsuperscript{48} however, the removal of the catalyst following deprotection could be necessary for certain applications (particularly organic electronics, where trace amounts of contaminants can severely impact device performance). To this end, use of a thermolabile neopentyl group for the preparation of a PSS precursor has been previously reported.\textsuperscript{36, 37, 49}

Most pertinently, our group has synthesised poly(3-hexylthiophene)-b-poly(neopentyl styrene sulfonate) (P3HT-b-PNSS) as a potential interlayer for adhesion improvement in OPVs.\textsuperscript{50} Conditions required for neopentyl group removal both from PNSS homopolymer and P3HT-b-PNSS copolymer have been studied. The results showed that the presence of P3HT leads to longer deprotection times of the PNSS block, limiting the application of this material in OPVs. As aforementioned, prolonged high temperature treatment should be avoided during OPV processing as it can cause degradation of cells and a loss of performance.

In the quest for more suitable material, herein, we have selected and synthesised a systematic range of styrene sulfonate monomers bearing different linear and branched aliphatic protecting groups, namely: n-propyl (2), isopropyl (3), n-butyl (4), isobutyl (5), n-pentyl (6) and neopentyl (7) (see Figure 1).\textsuperscript{34, 50-53} These monomers have been polymerised via RAFT\textsuperscript{54-56} using an azide-functionalised CTA, to the best of our knowledge, is the first report of not only radical, but also controlled radical polymerisation of 2, 4, 5 and 6. It should be noted that photochemically-initiated radical polymerisation of 3,\textsuperscript{52} and NMP\textsuperscript{57, 58}, ATRP\textsuperscript{54-57} and RAFT\textsuperscript{50} of 7 have been reported. In this submission, the thermal lability of the various protecting groups is systematically assessed using thermogravimetric analysis (TGA) to identify a well-defined, readily processable poly(p-styrene sulfonate) precursor.

Appropriate synthetic conditions have been identified to successfully polymerise all of these monomers with relatively high conversion (> 80 %, for all but the isobutyl derivative) and low molar mass dispersity (D < 1.11). The thermal modification of the resultant polymers is shown to be more facile for branched protecting groups rather than linear ones. Moreover, owing to the azide-functionalised CTA used in the RAFT polymerisations, all the synthesised polymers bear a terminal azide group which, as demonstrated herein, can be exploited for the construction of diblock copolymers using azide-alkyne click chemistry.

### Experimental

#### Materials

Methanol (MeOH), dichloromethane (DCM), hexane were purchased from Fisher Scientific and used as supplied. 1,4-Diazabicyclo[2.2.2]octane (DABCO, 98 %), sodium chloride (99 %), anhydrous magnesium sulfate (99.5 %), isobutanol (≥ 99 %) were purchased from Alfa Aesar and used as received. Propan-2-ol (99.5 %), butan-1-ol (≥ 99 %), pentan-1-ol (≥ 99 %) and anhydrous tetrahydrofuran (THF) (≥ 99.9 %) were purchased from Sigma Aldrich and used as received without further purification. Chloroform-d (99.8 % At + 0.05 % TMS, Goss Scientific) and 2,2’-Azobis(isobutyronitrile) (AIBN, TCI), propan-1-ol (≥ 99 %, Lancaster Synthesis) were used as supplied. 2-azidoethyl 2-(dodecylthiocarbonothioylthio)-2-methylpropionate (CTA-N<sub>3</sub>, Figure S1, ESI)\textsuperscript{51} and P3HT-ethynyl (D<sub>n</sub> = 50, estimated from <sup>1</sup>H NMR)\textsuperscript{50}, p-styrene sulfonol chloride (1)\textsuperscript{52} were synthesised according to the relevant literature procedures. A poly(styrene sulfonic acid) solution (M<sub>n</sub>, 75000 g/mol, 18 wt% in H<sub>2</sub>O) was obtained from Sigma Aldrich and was lyophilised prior to use.

#### Methods

##### Synthesis of monomers

p-Styrene sulfonol chloride (1, 8.0 g, 39 mmol) was added dropwise at 0 °C to a stirring solution of DABCO (1.2 eq.) and ROH (1.5 eq.) in DCM (100 ml). The reaction mixture was allowed to warm up to room temperature and was then stirred...
overnight. After which, 100 ml water was added and the layers were separated. The organic layer was washed with water (3 x 150 ml) and brine (200 ml). After drying over magnesium sulfate, the solvent was removed and hexane (250 ml) was added to the residues. The mixture was heated to 65 °C, stirred for 15 minutes and the solution was separated from the solids by decantation. Hexane was removed under vacuum to afford the product as a yellow oil. 1H and 13C NMR spectra for all monomers are provided in the ESI (Figures S2 – S7).

n-Propyl p-styrene sulfonate (2)

The general procedure was followed to give 2 (32 %). 1H NMR in CDCl3 (δ, ppm): 0.89 (t, 3H, J = 9.0 Hz), 1.67 (sextet, 2H, J = 8.1 Hz), 4.00 (t, 2H, J = 7.8 Hz), 5.45 (d, 1H, J = 13.2 Hz), 5.90 (d, 1H, J = 21.0 Hz), 6.75 (dd, 1H, J = 13.0 Hz), 7.54 (d, 2H, J = 9.9 Hz), 7.85 (d, 2H, J = 10.2 Hz). 13C NMR in CDCl3 (δ, ppm): 9.9, 22.4, 72.3, 118.0, 126.8, 128.3, 135.2, 142.7.

Isopropyl p-styrene sulfonate (3)

The general procedure was followed to give 3 (41 %). 1H NMR in CDCl3 (δ, ppm): 1.26 (d, 6H, J = 6.3 Hz), 4.37 (septet, 1H, J = 6.3 Hz), 5.44 (d, 1H, J = 10.8 Hz), 5.89 (d, 1H, J = 17.7 Hz), 6.74 (dd, 1H, J = 7.4, 12.0 Hz), 7.53 (d, 2H, J = 8.4 Hz). 13C NMR in CDCl3 (δ, ppm): 22.7, 77.4, 117.9, 126.8, 127.9, 135.2, 136.2, 142.6.

n-Butyl p-styrene sulfonate (4)

The general procedure was followed to give 4 (22 %). 1H NMR in CDCl3 (δ, ppm): 0.859 (t, 3H, J = 9.0 Hz), 1.34 (m, 2H), 1.60 (m, 2H), 4.04 (t, 2H, J = 7.8 Hz), 5.46 (d, 1H, J = 12.0 Hz), 5.90 (d, 1H, J = 21.0 Hz), 6.76 (dd, 1H, J = 13.9 Hz), 7.55 (d, 2H, J = 9.9 Hz), 7.85 (d, 2H, J = 9.3 Hz). 13C NMR in CDCl3 (δ, ppm): 13.4, 18.6, 30.8, 70.6, 118.0, 126.8, 128.2, 135.2, 142.8.

Isobutyl p-styrene sulfonate (5)

The general procedure was followed to give 5 (25 %). 1H NMR in CDCl3 (δ, ppm): 0.87 (d, 6H, J = 8.1 Hz), 1.93 (septet, 1H, J = 8.1 Hz), 3.79 (d, 2H, J = 7.8 Hz), 5.44 (d, 1H, J = 12.9 Hz), 5.90 (d, 1H, J = 21.0 Hz), 6.74 (dd, 1H, J = 21.0, 12.0 Hz), 7.53 (d, 2H, J = 9.9 Hz), 7.83 (d, 2H, J = 10.2 Hz). 13C NMR in CDCl3 (δ, ppm): 18.6, 28.0, 76.5, 118.0, 126.7, 128.3, 135.2, 142.8.

n-Pentyl p-styrene sulfonate (6)

The general procedure was followed to give 6 (30 %). 1H NMR in CDCl3 (δ, ppm): 0.83 (m, 3H), 1.27 (m, 4H), 1.64 (m, 2H), 4.03 (t, 2H, J = 7.8), 5.45 (d, 1H, J = 12.9 Hz), 5.90 (d, 1H, J = 21 Hz), 6.75 (dd, 1H, J = 21.0, 15.0 Hz), 7.54 (d, 2H, J = 10.2 Hz), 7.85 (d, 2H, J = 9.9 Hz). 13C NMR in CDCl3 (δ, ppm): 13.9, 22.0, 27.4, 28.5, 70.9, 118.1, 126.8, 128.2, 135.2, 142.8.

Neopentyl p-styrene sulfonate (7) synthesis

NSS was prepared according to the literature procedure.53

RAFT polymerisation of monomers

General procedure for the synthesis of R-protected polymers (8-13)

Polymerisation reactions were performed using Carousel 12 Plus, a set up for parallel syntheses from R. B. Radley Co. Ltd. Monomer (2-7) (1.0 g), AIBN (0.01 eq.) and RAFT agent (CTA-N3, 0.05 eq.) were added to the reaction tubes. The system was degassed three times via vacuum and nitrogen cycles, before anhydrous THF (2.7 ml) was added and the resulting mixture was then degassed again. To start the polymerisation, the system was heated to 60 °C and then allowed to proceed for approximately 120 hours. Reaction progress was monitored by collecting samples periodically and analysing by 1H NMR and GPC. The reaction was stopped after 120 hours by cooling down the system to room temperature. For purification, the reaction mixture was diluted with THF (2 ml) and reprecipitated into methanol (200 ml). The polymer was filtered off and dried under vacuum to afford the product as a dark yellow oil. 1H and 13C NMR spectra for all monomers are provided in the ESI (Figures S2 – S7).

Poly(n-propyl p-styrene sulfonate) (8): Mn = 3300 g/mol, D = 1.09. 1H NMR in CDCl3 (δ, ppm): 0.90 (br, 3H), 1.22 (br, 20H from CTA-N3 moiety), 1.71 (br, 5H), 4.05 (br, 2H), 6.70 (br, 2H), 7.69 (br, 2H).

Poly(isopropyl p-styrene sulfonate) (9): Mn = 3800 g/mol, D = 1.08. 1H NMR in CDCl3 (δ, ppm): 1.30 (br, 6H from iPSS and 20H from CTA-N3 moiety), 1.62 (br, 3H), 4.83 (br, 1H), 6.69 (br, 2H), 7.72 (br, 2H).

Poly(n-butyl p-styrene sulfonate) (10): Mn = 3800 g/mol, D = 1.08. 1H NMR in CDCl3 (δ, ppm): 0.86 (br, 3H), 1.23 (br, 20H from CTA-N3 moiety), 1.37 (br, 3H), 1.68 (br, 4H), 4.09 (br, 2H), 6.71 (br, 2H), 7.70 (br, 2H).

Poly(isobutyl p-styrene sulfonate) (11): Mn = 3000 g/mol, D = 1.08. 1H NMR in CDCl3 (δ, ppm): 0.92 (br, 6H), 1.24 (br, 20H from CTA-N3 moiety), 1.64 (br, 3H), 2.00 (br, 1H), 3.87 (br, 2H), 6.72 (br, 2H), 7.74 (br, 2H).

Poly(n-pentyl p-styrene sulfonate) (12): Mn = 3900 g/mol, D = 1.08. 1H NMR in CDCl3 (δ, ppm): 0.84 (br, 3H), 1.17 (br, 20H from CTA-N3 moiety), 1.20 (br, 5H), 1.67 (br, 4H), 4.05 (br, 2H), 6.68 (br, 2H), 7.67 (br, 2H).

Poly(neopentyl p-styrene sulfonate) (13): Mn = 3500 g/mol, D = 1.11. 1H NMR in CDCl3 (δ, ppm): 0.90 (br, 9H), 1.23 (br, 20H from CTA-N3 moiety), 1.62 (br, 2H), 1.82 (br, 1H), 3.75 (br, 2H), 6.71 (br, 2H), 7.71 (br, 2H).

Synthesis of poly(isopropyl p-styrene sulfonate) macroCTA (PiBSS)

The preparation of poly(3-hexylthiophene)-block-poly(isobutyl p-styrene sulfonate) (P3HT-b-PiBSS) PiBSS-N3 was prepared according to the general procedure for the synthesis of R-protected polymers (8-13) with some modifications. In order to shorten the reaction time and limit possible side reactions, the synthesis was performed using more concentrated reaction mixture (1 g of iBSS/1 ml of THF) than that used for synthesis of the aforementioned polymer series (8-13), and the reaction was stopped after 72 h. Mn = 3900 g/mol; D = 1.16; Dp = 14, estimated from GPC against polystyrene standards. This homopolymer was also used in the TGA experiment using PSS-doped PiBSS.

Synthesis of poly(3-hexylthiophene)-block-poly(isobutyl p-styrene sulfonate) (P3HT-b-PiBSS)
bubbling \( \text{N}_2 \) for 0.5 h) and THF (20 ml) were charged to a 50 ml round-bottomed flask, evacuated for 10 minutes and backfilled with nitrogen (3 cycles). The flask was then kept at 50 °C for 48 hours, following which, the solution was passed through a neutral alumina column to remove the copper catalyst. After concentrating the solution in vacuo, the product was recovered by precipitation in methanol, dried under reduced pressure, and then subjected to soxhlet purification with methanol and acetone, respectively. The product was finally extracted with chloroform, concentrated under reduced pressure and dried under vacuum overnight to yield the block copolymer.

Recovery: 76.8 %; \( M_n = 19300 \text{ g/mol}; D = 1.27 \); Selected IR bands: 2961 m (sh.), 2926 s, 2861 s, 1735 w, 1597 w, 1578 w, 1506 w, 1455 m, 1357 m, 1274 w, 1176 s, 1100 w, 972 m, 938 m, 822 s, 718 w, 662 w. \(^1\)H NMR: See Figure S22, ESI for spectrum and assignment.

TGA Study of polymers

3-4 mg sample of polymer (8-13) was placed in a TGA pan and measurements were performed in two modes; a temperature sweep from 25 to 500 °C (at a rate of 10 °C/min) (Figure 4(a)) and an isothermal profile (150 °C) for 120 minutes (Figure 4(b)). Samples after the isothermal measurements were further analysed by FTIR ATR (Figure S14, ESI).

TGA Study of PSS-catalysed thermolysis of PBiSS

PBiSS and PSS were ground together using a mortar and pestle to produce homogeneous PBiSS samples containing 11.9, 26.2, 41.1 and 52.2% (w/w) PSS. Approximately 5-10 mg of each mixed sample was then subjected to isothermal thermogravimetric analysis (150 °C, 2h).

Characterisation

\(^1\)H (300 MHz) and DEPT \(^{13}\)C NMR (75 MHz) Spectroscopy (positive peaks correspond to \(-\text{CH}_2\) and \(-\text{CH}_3\) groups and negative peaks to \(-\text{CH}^\cdash\) groups) was carried out on a Bruker Avance Spectrometer, where R-protected monomers and polymers were dissolved in CDCl\(_3\) and PSS-doped PBiSS in d\(_2\)-DMSO. \(^1\)H NMR Spectroscopy was also used to calculate monomer conversion during RAFT polymerisation. Relative number-average molecular weight (\(M_n\)) and dispersity (\(M_w/M_n\), \(D\)) were measured by Gel Permeation Chromatography (GPC) (flow rate 1 ml/min, 40 °C) using a Varian GPC spectrophotometer comprising three PL gel 5 \(\mu\)m 300 x 7.5 mm mixed-C columns and a degassed THF eluent system containing triethylamine (2 % v/v) and BHT (0.05 % w/v). The samples were calibrated with narrow polystyrene standards (\(M_p\) range = 162 to 6 035 000 g/mol) and analysed using PL Cirrus software (version 2.0) supplied by Agilent Technologies. Fourier transform infrared (FTIR) spectra of all the samples were obtained using attenuated total reflectance (ATR) on a Thermo Nicolet 380 FTIR spectrophotometer over the range 4000-500 cm\(^{-1}\) for 8 scans with a resolution of 4 cm\(^{-1}\). Thermogravimetric analysis (TGA) was obtained using a Pyris 1 Thermogravimetric analyser under nitrogen atmosphere (flow rate 25 ml/min). The contact angles of water on PBiSS-N\(_2\) and PBiSS-b-P3HT substrates were measured using a Krüss Drop Shape Analyser (DSA 10, Krüss GmbH, Hamburg, Germany).

Contact angles were obtained by releasing a drop of deionised \(\text{H}_2\text{O}\) (3 \(\mu\)l) onto the sample surface, and the values reported herein represent an average of 3 measurements taken at 3 locations across the substrate surface.

Results and discussion

Recently, the polymerisation of neopentyl \(p\)-styrene sulfonate has been studied in depth in our laboratory.\(^63\) Herein to improve the processability of the final polymer, broader research on a series of R-protected \(p\)-styrene sulfonates is presented, comprising synthesis and RAFT polymerisation of systematically varied monomers (2-7). R-protected \(p\)-styrene sulfonate monomers (2-7) were synthesised in a two-step process from sodium \(p\)-styrene sulfonate as presented in Scheme 1. Each monomer in the series was then polymerised via RAFT using AIBN and CTA-N\(_2\) in THF at 60 °C.

Introduction of terminal azide functionality into the chain transfer agent enables the polymers to be further used as building blocks in the production of more complex materials (such as block copolymers) via click chemistry.\(^{64-66}\) Of note, caution should be taken when employing azide-functionalised moieties in thermally-driven polymerisations due to unwanted reaction with electron-poor olefinic monomers, such as acrylamides and (meth)acrylates.\(^67\) Styrenic monomers, on the other hand, have been shown not to be particularly susceptible to this phenomenon.\(^5\) Polymisations were performed in THF (37 % w/v) at 60 °C for 120 h. To follow the progress of each reaction, samples were taken after 2, 8, 24, 32, 48, 56, 72, 120 h and analysed by GPC and \(^1\)H NMR spectroscopy. High monomer conversion after 120 h (> 80 %) was observed in all reactions, except the polymerisation of isobutyl \(p\)-styrene sulfonate (5), where an acceptable 69 % was reached. In most of the reactions (3-7), a plateau was observed after 72 h (Figure 2a), showing no further significant polymerisation was occurring after this point. It is noteworthy that partial removal of the isopropyl protecting group was observed during polymerisation after 120 h at this temperature. To obtain poly(isobutyl \(p\)-styrene sulfonate) of a similar molar mass to the remaining polymers in the series, polymerisation of 3 was repeated using 0.04 eq. CTA (target \(D_p = 25\)) and stopped after 72 h to avoid premature thermolysis. Indeed, GPC analyses show that the attained molar masses for all polymers were within 3000 to 3900 g/mol (Table 1). All products displayed...
unimodal GPC traces (Figure 2b) with low molar mass dispersions ($\bar{D} \leq 1.11$, Table 1). Interestingly, although AIBN has a half-life of approximately 20 hours at 60 °C, propagation continued up to approximately 72 hours in most cases and is attributed to thermally-induced self-polymerisation of styrenic monomers.

To demonstrate the control of molar mass in RAFT polymerisations, the evolution of the molar mass and dispersity is presented in Figure 3. A linear increase of molecular mass versus conversion for all polymerised monomers was observed, and the dispersity remained low throughout the reactions ($\bar{D} \leq 1.12$ in all cases). Semi-logarithmic first order plots and corresponding GPC traces throughout each polymerisation have been included in the ESI (Figures S15 a-f and Figure S16).

**Thermolysis**

TGA has been employed to examine the thermal modification profiles of our polymers (8-13) to produce poly(p-styrene sulfonate), PSS. Measurements were performed in two modes; a temperature sweep from 25 to 500 °C (at a rate of 10 °C/min) [Figure 4(a)] and an isothermal profile (150 °C) for 120 minutes [Figure 4(b)]. The data clearly show that the weight loss of the branched polymers, occurring at approximately 150 °C (9) and 200 °C (11, 13) in the temperature sweep experiment [Figure 4(a)], occurs more readily than the weight loss in the linear counterparts (8, 10, 12), observed at approximately 230 °C. For the isothermal (150 °C) treatment, the significant weight loss is observed after 7 min for 9, 30 min for 11 and 80 min for 13, whereas for the linear polymers only a minor decrease of weight is observed after 120 minutes. The observed weight loss is attributed to removal of the protecting group from the sample. However, it is noteworthy that the initial obtained weight loss percentage observed in Figure 4(b).

(a) Target degree of polymerisation, $D_p = 20$, with the exception of product 9 (target $D_p = 25$), which required a higher final target to achieve a similar $M_n$ to the others in the study because prolonged polymerisation times (> 72 h) induced thermal deprotection of the polymer; (b) Determined by $^1$H NMR spectroscopy; (c) Determined by THF GPC (PS standards); (d) calculated for 0-72 h (Figure S16, ESI); (e) k$_1$ for 0-44h, k$_2$ for 44-72 h; (f) k$_1$ for 0-32h, k$_2$ for 32-72 h.
differs from the theoretically calculated values in the case of isobutyl and neopentyl derivatives; 11% and 12% compared to 21% and 25% theoretical values for 11 and 13 (including release of nitrogen from the azide group), respectively. This difference is attributed to a Friedel-Crafts side reaction which results in attachment of some of the alkyl protecting groups to the aromatic ring of the polymer at the meta position. Observation of this phenomenon has already been described for poly(neopentyl p-styrene sulfonate).  

Interestingly, the observed weight loss closely matches the theoretically calculated values for the polymer with isopropyl protecting group (9). Isothermal TGA [Figure 4(b)] shows the differences in the time required for protecting group removal, indicating the ease of deprotection in the following order (starting with the most readily deprotected): isopropyl (9) > isobutyl (11) > neopentyl (13). Owing to the fact that the isopropyl group is easily cleavable, the degradation of 9 was observed during storage at room temperature. This highlights that the design of polymers with fast cleavable groups, for processes where sustained thermal treatments are undesired, requires a compromise between lability (for application) and stability (for synthesis and short-term storage) of protecting groups. Hence, the isobutyl group providing both features was investigated further for its thermal processing behaviour and as the switchable component in P3HT-b-PIBSS copolymer.

Aqueous solubility studies of the polymers after isothermal treatment (2 h at 150°C) indicated that the branched protected polymers (9, 11, 13) change from being hydrophobic to hydrophilic following deprotection, as expected, whereas polymers with linear protecting groups (8, 10, 12) remained hydrophobic. More pertinently, these results have been confirmed by FTIR spectroscopy (Figure S14, ESI). FTIR spectra of poly(isobutyl p-styrene sulfonate), 11, before and after deprotection, are shown in Figure 5 as an exemplar.

A huge reduction in intensity of the band associated with alkyl chains [δ(C-H) ~ 2900 cm⁻¹] and a disappearance of the sharp signal at 1350 cm⁻¹ (related to sulfonate ester) are clearly observed. Simultaneously, a broad band appears in the region of 3500 cm⁻¹, indicative of the presence of the unprotected sulfonate group. It is noteworthy that the data also show a loss of azide functionality (2100 cm⁻¹) in our polymers following thermal treatment, demonstrating the instability of this functional end group in line with the literature. Consequently, should coupling (via click chemistry) be required to produce more sophisticated materials, such as block copolymers or hybrid materials, it should be carried out prior to thermal deprotection. As expected from the TGA results, the IR spectra of polymers with linear protecting groups show only minor deprotection. A low-intensity peak in the region of 3500 cm⁻¹ was observed suggesting the presence of a small amount of sulfonic acid groups, however the decrease in intensity of the peaks at 1350 cm⁻¹ and 2900 cm⁻¹ was negligible. This confirms that the removal of the protecting groups was marginal and the majority of protecting groups were not affected by the thermal process.

All of the synthesised polymers have similar dispersity (1.08 < D < 1.11) and all molar masses are in the range of 3000 – 3900 g/mol. In order to study the effect of molar mass on deprotection profiles, a series of poly(isobutyl p-sulfonate styrenes) with systematically varied Mₙ was synthesised and probed by TGA. The results presented in Figure 6 show that the overall rate of deprotection (k_dep) increases together with molar mass of polymer up to 6000 g/mol in the following order: k_dep, 2400 < k_dep, 4600 < k_dep, 6000 ≈ k_dep, 7000. It suggests that presented deprotection is an autocatalytic process, in which thermal removal of the first group and generation of a free sulfonic group catalyses cleavage of protecting groups (Figure 7). Similar behaviour was previously reported for acetoxacetate derivatives containing (tosyloxy)methyl or (mesyloxy)methyl residues. The authors proved that the tert-butyl carbonate

deprotection initiated by addition of a small amount of TsOH or MsOH is subsequently catalysed by TsOH or MsOH generated as fragmentation by-products. The dependence of the deprotection rate on molar mass shown herein could be related to the differences in mobility between short and long polymer chains. Low molar mass polymers with higher mobility are less susceptible to removal of the protecting group due to their ability to migrate and reduce contact with the highly hydrophilic, isolated sulfonic acid groups, sporadically situated along the polymer backbone, which catalyse the deprotection process. Such migration is driven by the concomitant sudden increase in the Flory-Huggins interaction parameter (\(\chi_{iBSS}\)) between the disparate repeat units on the polymer backbone. In contrast, polymers with high molar mass are less mobile and hence less capable of significant migration away from the hydrophilic acidic groups along the backbone. Consequently, a “nuclei” of acidic groups will begin to form, spreading throughout the bulk of the polymer. Clearly, a threshold molar mass is reached whereby a maximum rate of auto-catalysed deprotection is reached.

In order to investigate whether free sulfonic acid groups increase the rate of deprotection of the sulfonate ester groups in PiBSS, an additional experiment was performed. Here, mixed samples containing known mass ratios of PiBSS (\(M_n = 3900\) g/mol, \(\bar{D} = 1.16\)) and PSS (\(M_n = 75000\) g/mol) homopolymers, were subjected to isothermal thermogravimetric analyses (150 °C, 2 h, Figure 8, Figure S18) TGA thermograms of PiBSS (control) and PiBSS doped with PSS at 11.9, 26.2, 41.1 and 52.2 % (w/w) are presented in Figure 8. A minor increase in the deprotection rate was observed for the highest loadings of PSS (52.2 and 41.1 %) PSS-doped PiBSS, whereas the control sample, 11.9 and 26.2 % PSS-doped PiBSS presented similar behaviour. Expected weight loss for PSS-doped PiBSS was calculated assuming that PiBSS weight loss will be at the same level as for the control sample (i.e. 9 % after 50 min of heating). The obtained numbers closely matched the experimental results showing that the addition of PSS has no influence on the extent of isobutyl group removal and side rearrangements. Overall, these results suggest that indeed the presence of PSS, created during the thermolysis of PiBSS, does speed up the deprotection rate and gives credence to our speculations as to the effect of molar mass on the thermolysis profiles. The somewhat meagre effect on the rate of adding free PSS (shown in Figure 8) is attributed to enhanced ability of iBSS groups to migrate away from free PSS in a blend than anchored SS groups located along its backbone.

**Synthesis, characterisation and thermal modification of P3HT-b-PiBSS**

To further confirm fidelity of the terminal azide functionality of the PiBSS polymer (PiBSS-N\(_3\), \(M_n = 3900\) g/mol, \(\bar{D} = 1.16\)) and to fabricate a thermally modifiable material for future use in organic photovoltaic devices, a P3HT-b-PiBSS diblock copolymer was synthesised via click coupling of alkylene-functionalised P3HT (P3HT-ethynyl) and PiBSS-N\(_3\), according to the method previously reported (Scheme S17, ESI). Figure 9 shows the GPC traces and FTIR spectra obtained for PiBSS-N\(_3\) and P3HT-ethynyl building blocks, along with those obtained for the resultant diblock copolymer, P3HT-b-PiBSS (1H NMR spectra are provided in the ESI, Figures S20-S22). The GPC traces clearly reveal the expected unimodal increase to higher molar mass of the diblock material (\(M_n = 19500\) g/mol; \(\bar{D} = 1.27\)) while the FTIR spectrum of P3HT-b-PiBSS shows a combination of the individual building blocks, accompanied by the expected absence of azide and alkyne bands (2113 cm\(^{-1}\) in PiBSS-N\(_3\) and 2141 cm\(^{-1}\) in P3HT-ethynyl, respectively) (Figure 9).

The thermal modification behaviour of the PiBSS-N\(_3\) homopolymer and corresponding P3HT-b-PiBSS diblock copolymer were investigated by isothermal TGA (150 °C, 3 h), water contact angle measurements and FTIR spectroscopy (before and after thermal treatment) as shown in Figure 10. TGA confirmed complete removal of the isobutyl group (Figure 10a) from P3HT-b-PiBSS (observed 6.5 % weight loss, expected 6.3% weight loss for complete deprotection). The water contact angle of a film of the diblock copolymer concomitantly changed from 99.4° to 89.7° after heating at 150 °C for 3 h, indicating the expected increase in surface hydrophilicity due to the formation of free sulfonic acid groups in the block copolymer. It is important to note that replacing the neopentyl group in P3HT-SS-b-PNSS\(_{5}\) with the isobutyl protecting group used in the current diblock material (P3HT-b-PiBSS-N\(_3\)), resulted in a decrease in the required deprotection time (at 150 °C) from 3 h (for P3HT-SS-b-PNSS\(_{5}\)) to around 45 minutes.

(for P3HT<sub>b</sub>-PIBSS<sub>14</sub>). The reduction of time needed for removal of protecting groups is crucial for industrial application of P3HT-<i>b</i>-PIBSS where long thermal treatment at elevated temperature is undesired (e.g. roll-to-roll production of OPV). Consistent with the aforementioned isothermal experiments (Figure 6), the control PIBSS-<i>N</i><sub>3</sub> homopolymer only underwent 49.8 % of the expected mass loss (observed to the Friedel-Crafts rearrangement occurring in PiBSS). Thermal studies of the polymers showed the extent of deprotection observed by TGA for thermal treatment (150 °C, 3 h).

In summary, a series of R-protected monomers have been synthesised and polymerised by RAFT. The conditions applied resulted in high quality polymers characterised by low molar mass dispersities and unimodal GPC traces. Additionally, the use of an azide functionalised chain transfer agent allowed preparation of potential building blocks for click chemistry. Thermolysis of linear alkyl group protected polymers at 150 °C caused only partial depolymerisation whereas thermal treatment of branched alkyl group protected products yielded hydrophilic polymer, poly(6-styrene sulfonate). Thermal studies of the polymers showed the deprotection rate followed the order (starting with the most readily deprotected): isopropyl > isobutyl > neopentyl; however the spontaneous degradation of the isopropyl-

protected polymer was observed during short-term storage. Thus, the isobutyl group proved to be the most thermally labile protecting group that was storage stable at room temperature. The synthesis of P3HT-<i>b</i>-PIBSS from P3HT-ethynyl and PIBSS-azide demonstrated the success of azide-alkyne strategy and subsequent thermal studies of the copolymer showed that the deprotection time can be shortened by judicious selection of the PSS protecting group. The conducted studies provide a strategy for the <i>in situ</i> fabrication of amphiphilic polymers, cast from organic solvents, where chemical cleavage of protecting groups is undesirable.
