We report large photoluminescence (PL) enhancement of green-emitting  $\text{Ba}_2\text{SiO}_4:\text{Eu}^{2+}$  phosphor prepared in an eutectic  $\text{Li}_2\text{CO}_3$  melt as a flux. Among the phosphor materials synthesized using low-purity precursors (99%-pure  $\text{BaCO}_3$  and 99.6%-pure  $\text{SiO}_2$ ), the emission intensity of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02},\text{Eu}_{0.02})$  (Li = 200% excess) is found to be 470% as high as that of  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  (no-Li) and in fact is almost equivalent to that of Li-undoped  $\text{Ba}_2\text{SiO}_4:\text{Eu}^{2+}$  synthesized using ultrapure precursors (99.98%-pure  $\text{BaCO}_3$  and 99.995%-pure  $\text{SiO}_2$ ). In combination with the results from PL measurements and inductively coupled plasma mass spectrometry (ICP-MS), the elemental distribution of the products and melts found from time-of-flight secondary ion mass spectrometry (TOF-SIMS) directly indicates that the excess  $\text{Li}_2\text{CO}_3$  autonomously removes the impurities that were originally contained in the low-purity precursors, in particular  $\text{SiO}_2$ , and thus critically improves the photoluminescence efficiency of the material. The newly found Li flux effect of large PL enhancement may not only contribute to more economic production of phosphors but provide a platform in discovery of new efficient phosphors for solid state lighting.

### 1 Introduction

In search for highly efficient solid state lighting materials, Li-codoping have been very successful in improving luminescence properties of rare earth-doped phosphors.<sup>1-12</sup> It is generally accepted that the  $\text{Li}^+$  ions doped in the host lattices play important roles in the enhanced luminescent property of phosphors. The enhanced luminescence of the Li-codoped phosphors has been explained, as follows: i) copresence of  $\text{Li}^+$  ions favorably modifies the local structure of the activator ions and their special distribution;<sup>1-4</sup> ii) codoping of  $\text{Li}^+$  ions creates oxygen vacancies which might act as a sensitizer for the energy transfer to activator ions;<sup>5,7,9,10</sup> iii) Li precursors such as  $\text{Li}_2\text{CO}_3$  or LiF act as a flux which promotes incorporation of the activator ions into the host lattice and also enhances crystal growth during the firing process at high temperatures;<sup>5,6,12</sup> and iv) Li-codoping provides to the product particles a morphology that is more desirable in reducing internal reflection.<sup>5,6</sup> Among those possible mechanisms of the luminescence enhancement by Li-codoping, the flux effect (i.e., iii)) has been found to play

a minor role. In the studies of Li-codoping in  $\text{Y}_2\text{SiO}_5:\text{Pr}^{3+}$ ,<sup>12</sup> for example, the flux effect was responsible to ~5% of the total enhancement of the emission, while the structural effect including increased  $\text{Pr}^{3+}$  separation and phase change was accountable for the rest (95%). Herein we report that the flux effect can be much more significant via a newly discovered mechanism, that is, autonomous impurity purification, by using green-emitting  $(\text{Ba},\text{Sr})_2\text{SiO}_4:\text{Eu}^{2+}$  phosphor system. Green-emitting  $(\text{Ba},\text{Sr})_2\text{SiO}_4:\text{Eu}^{2+}$  phosphor is promising for UV-LEDs because of its short decay time and high luminescence characteristics under UV excitation. Furthermore, the chromaticity of the  $(\text{Ba},\text{Sr})_2\text{SiO}_4:\text{Eu}$  phosphor can be controlled from the near UV (NUV) to the red by changing the crystal field splitting or covalency of the host lattice through Li-codoping, for example.<sup>13,14</sup> The electronic configuration of  $\text{Eu}^{2+}$  is  $[\text{Xe}]4f^7$ , and its lowest excited state of 4f levels is located at  $28 \times 10^3 \text{ cm}^{-1}$  and it is in higher energy than that of the  $4f^65d^1$  in most compounds, so that  $\text{Eu}^{2+}$  usually exhibits broad-band emission associated with f-d transitions. As the  $\text{Eu}^{2+}$  activator is incorporated in  $\text{Ba}^{2+}$  sites, a new interaction between  $[\text{SiO}_4]^{4-}$  and  $\text{Eu}^{2+}$  activator probably occurs,  $-\text{[O-Si-O]-Eu}^{2+}-\text{[O-Si-O]}$ . Thus, by  $\text{Li}^+$  codoping, the change of covalency as well as crystal field strength in the host lattice may give rise to the modification of the characteristic of  $\text{Eu}^{2+}$  emission, which results in the improved luminescent intensity of  $\text{Ba}_2\text{SiO}_4:\text{Eu}^{2+}$  phosphor. Additional Li-codoping effect has not been reported so far in enhancing the luminescent property of the phosphors or for  $\text{Eu}^{2+}$ -activated phosphors in general, although such

enhancement from a flux effect for  $\text{Eu}^{2+}$ -activated phosphors have been discovered by one of the authors.<sup>5,6</sup>

## 2 Experimental

Li-codoped  $\text{Ba}_2\text{SiO}_4:\text{Eu}^{2+}$  materials were synthesized via a solid-state reaction with stoichiometric or excessive amounts of  $\text{Li}_2\text{CO}_3$ . The stoichiometric amounts of  $\text{BaCO}_3$  (Aldrich, 99% and 99.98%),  $\text{SiO}_2$  (Aldrich, 99.6% and 99.995%)  $\text{Li}_2\text{CO}_3$  (Aldrich, 99.99%), and  $\text{Eu}_2\text{O}_3$  (Aldrich, 99.9%) were mixed and pulverized, then heated at  $1250^\circ\text{C}$  for 6h in air using alumina boats for the regular syntheses. The obtained powders with white body color were fired at  $1250^\circ\text{C}$  for 6h in mild reducing atmosphere (4%  $\text{H}_2/\text{Ar}$ ). After the reduction of the material, the white colored powder was changed into a white-greenish powder. Additionally, in the weighing step,  $\text{Li}_2\text{CO}_3$  was added excessively between 100 and 300% excess relative to the stoichiometric one. Thermogravimetry and differential scanning calorimetry (TG/DSC, SDT Q 600 model) were used to determine the weight loss of starting materials, such as  $\text{BaCO}_3$ ,  $\text{SiO}_2$ ,  $\text{Eu}_2\text{O}_3$ , and  $\text{Li}_2\text{CO}_3$ . A heating rate of  $10^\circ\text{C}/\text{min}$  was used for measurements from room temperature to  $1200^\circ\text{C}$  in air. The structures of  $\text{Ba}_2\text{SiO}_4(\text{Li},\text{Eu})$  compounds were characterized using a X-ray diffractometer (XRD 6000 model, Shimadzu) using Cu-K $\alpha$  radiation at 30 kV and 30 mA. The unit-cell parameters were obtained using a nonlinear least-squares cell refinement program (UnitCell). The luminescent spectra were measured at room temperature using a fluorescent spectrophotometer (Scinco, FluoroMate FS-2). The reflectance spectra of phosphors were recorded using UV-visible spectrophotometer (UV-2600, Shimadzu) with  $\text{BaSO}_4$  as a reference. Elemental analysis was performed using an inductively coupled plasma mass spectrometer (ICP-MS, ELAN DRC II model, Perkin Elmer). TOF-SIMS experiments were performed with a TOF-SIMS V (ION-TOF GmbH, Münster, Germany) instrument in KBSI, Busan center by using a pulsed 30 keV  $\text{Bi}^+$  primary beam with a current 1 pA. The analyzed area used in this work was a square of  $100\ \mu\text{m} \times 100\ \mu\text{m}$  and the data acquisition time was 100 s. In order to prepare SIMS samples, the high purity indium metal (99.995% purity) was cut and pressed loosely using a pelletizer ( $\phi = 8\ \text{mm}$ ), and subsequently the powder sample was placed over the indium metal disc and pressed. The particulates were homogeneously embedded in the indium metal disc. Positive ion spectra were internally calibrated using  $\text{H}^+$ ,  $\text{H}_2^+$ ,  $\text{CH}_3^+$ ,  $\text{C}_2\text{H}_5^+$ , and  $\text{C}_3\text{H}_7^+$  peaks and normalized to the respective secondary total ion yields. The chemical images of the analyzed area were recorded with  $128 \times 128$  pixel resolution during the data acquisition. Charge effects were compensated by means of an interlaced pulsed electron flood gun ( $E_k = 20\ \text{eV}$ ). The brightness of phosphor materials was measured using a CHROMA METER CS-100A model (MINOLTA). PL quantum yields of  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  phosphor materials before and after Li-doping were measured using a PL spectrometer with an integrating sphere (Hamamatsu Photonics: Quantum Yield Measurement system C9920-02) at room temperature.

## 3 Results and discussion

### 3.1 TG/DSC of Li-Compounds as a $\text{Li}^+$ -Ion Source and Structural Characterization.

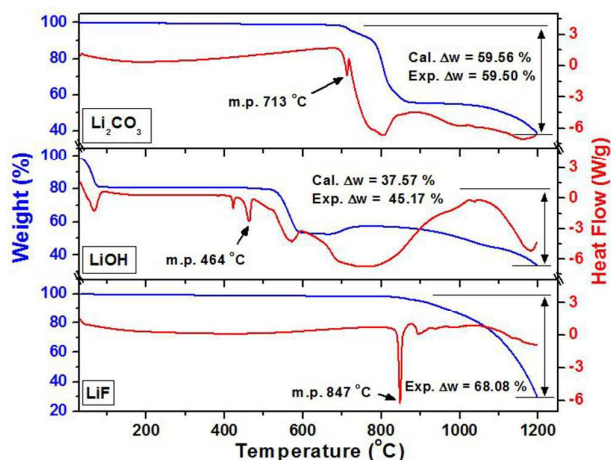

Fig. 1 TG and DSC curves of  $\text{Li}_2\text{CO}_3$ ,  $\text{LiOH}$ , and  $\text{LiF}$ .

Fig. 2 XRD patterns of  $\text{Ba}_2\text{SiO}_4(\text{Li},\text{Eu})$  phosphors.

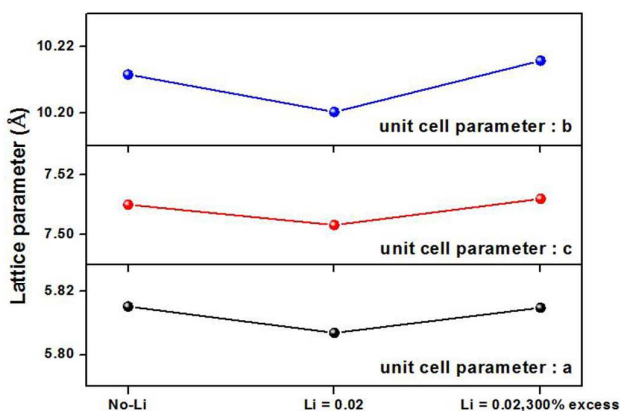

Fig. 3 Variation of unit cell parameters in  $\text{Ba}_2\text{SiO}_4(\text{Li},\text{Eu})$  phosphors as a function of Li content.

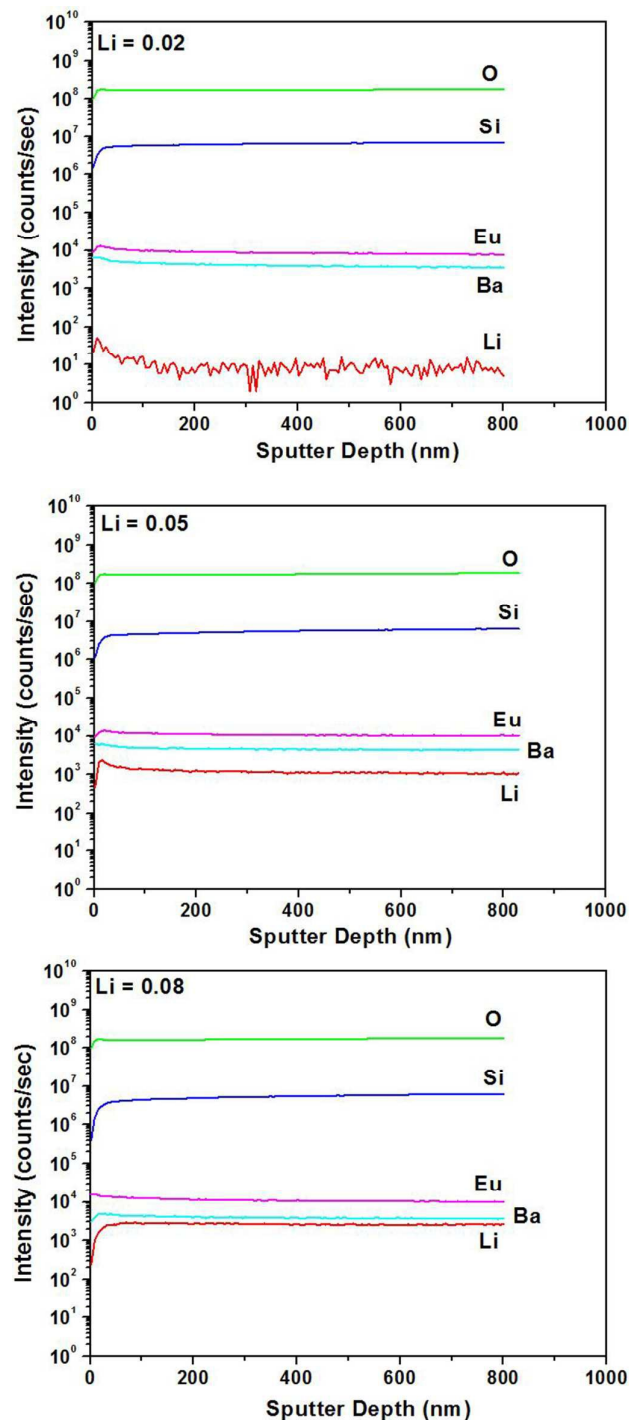

Fig. 4 Atomic intensity versus sputtered depth of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_x, \text{Eu}_{0.02})$  as a function of Li content.

TG and DSC were performed to examine the thermal behavior of the  $\text{Li}_2\text{CO}_3$ ,  $\text{LiOH}$ , and  $\text{LiF}$  as a  $\text{Li}^+$ -ion source as shown in Fig. 1. The additional TG/DSC curves of  $\text{BaCO}_3$ ,  $\text{SiO}_2$ , and  $\text{Eu}_2\text{O}_3$  are presented in Fig. S1 (Supporting Information). The weight loss of  $\text{Li}_2\text{CO}_3$  begins at around  $700^\circ\text{C}$  and is complete

at  $800^\circ\text{C}$  with the melting point at  $713^\circ\text{C}$  in DSC curve and subsequently the additional weight loss restarts up to  $1200^\circ\text{C}$  corresponding to the decarbonation of  $\text{Li}_2\text{CO}_3$ , in which the experimental weight loss (59.5%) is in good agreement with the theoretical value (59.6%). For  $\text{Li}_2\text{O}$ , the continuous weight loss above  $1000^\circ\text{C}$  may be due to slow evaporation of  $\text{Li}_2\text{O}$ .  $\text{LiOH}$  dehydroxylates to form  $\text{Li}_2\text{O}$  above  $\sim 500^\circ\text{C}$  and the formed  $\text{Li}_2\text{O}$  gradually evaporates at the high temperature region. However, the origin of the slight weight gain between  $680$  and  $960^\circ\text{C}$  is not clear. The TG thermogram of  $\text{LiF}$  indicates that evaporation of  $\text{LiF}$  starts at  $\sim 840^\circ\text{C}$  and is significant in our firing condition (at  $1250^\circ\text{C}$  for 6h in air). Based on the TG and DSC thermograms, therefore,  $\text{Li}_2\text{CO}_3$  is the best candidate as a  $\text{Li}^+$ -ion source in examining the Li-doping effect of the host materials. The X-ray diffraction (XRD) patterns of three products with different amounts of  $\text{Li}_2\text{CO}_3$  are shown in Fig. 2 and they are consistent with the XRD pattern of  $\text{Ba}_2\text{SiO}_4$  with a primitive orthorhombic cell (*Pmcn*).<sup>15</sup> The refined unit cell parameters are as follows: for  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  (no-Li),  $a = 5.815 \text{ \AA}$ ,  $b = 10.211 \text{ \AA}$ ,  $c = 7.510 \text{ \AA}$ ; for  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02}, \text{Eu}_{0.02})$  (nominal-Li),  $a = 5.807 \text{ \AA}$ ,  $b = 10.200 \text{ \AA}$ ,  $c = 7.503 \text{ \AA}$ ; and for  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02}, \text{Eu}_{0.02})$  (Li-300% excess),  $a = 5.815 \text{ \AA}$ ,  $b = 10.216 \text{ \AA}$ ,  $c = 7.512 \text{ \AA}$ . It is noted that the unit cell parameters of the Li doped compound,  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02}, \text{Eu}_{0.02})$  (nominal-Li) are slightly reduced compared with those of  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  (no-Li), which is probably due to the formation of the oxygen defects associated with the volatility of  $\text{Li}_2\text{O}$  at high temperature. At a higher Li doping level (300% excess), the unit cell parameters are close to those of  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  (no-Li) compound as shown in Fig. 3. SIMS studies were carried out in order to examine the content of Li as well as other elements present,<sup>16,17</sup> and the depth profile of secondary ion intensities (for Ba, Si, Eu, Li, and O atom) of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_x, \text{Eu}_{0.02})$ ;  $x = 0.02, 0.05$  and  $0.08$ ) are shown in Fig. 4. The sample with a larger Li content shows a larger signal intensity in the Li channel and somewhat smaller intensity for the Ba while the rest of the elements (Si, and O) have the nearly the same intensities. Evidently, the SIMS intensity of Ba is gradually diminished with increasing Li-content because Li-ions occupy Ba sites in the  $\text{Ba}_2\text{SiO}_4$  crystal lattice with an orthosilicate-type structure as depicted in  $\text{Ba}_{2-x}\text{Li}_x\text{O}_4$  chemical formula. In addition, the signal intensities of the elements are constant from near the surface to the interior (ca. 800 nm) of the grains for all the samples, indicating that the individual particles are atomistically homogeneous throughout the body, as desired.

### 3.2 Photoluminescence Spectra of Li-doped $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$

#### Materials.

Fig. 5 shows the PL spectra and emission spectra ( $\lambda_{\text{ex}} = 370 \text{ nm}$ ) of  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  and its Li-codoped samples synthesized using  $\text{BaCO}_3$  (99% purity),  $\text{SiO}_2$  (99.6% purity),  $\text{Eu}_2\text{O}_3$  (99.9% purity) and  $\text{Li}_2\text{CO}_3$  (99.99% purity), in which  $x$  is the nominal amount of Li ( $x = 0.02, 0.05$  and  $0.08$ ). All the samples exhibit a broad absorption band from 220 to 470 nm, which may be ascribed to the spin allowed  $4f^7(^8\text{S}_{7/2})-4f^65d$  transitions of  $\text{Eu}^{2+}$ .<sup>18-22</sup> The emission spectra show symmetric bands centered at 503 nm, associated with a green-emission. The emission

Fig. 7 PL spectra of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02}, \text{Eu}_{0.02})$  synthesized with Li-excess.

Fig. 6 Diffuse reflectance spectra of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_x, \text{Eu}_{0.02})$  as a function of Li content.

Table 1 Li Contents of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_x, \text{Eu}_{0.02})$  Determined by ICP.

Li (x)	Li content, ppm (nominal composition, ppm)	Li defect ( $\times 10^{-2}$ )
0.02	1.06 (380.93)	1.99
0.05	41.49 (962.6)	4.75
0.08	155.63 (1557.16)	7.20

intensity is increased with higher  $\text{Li}^+$  concentration, and the maximum intensity at  $\text{Li} = 0.02$  is observed, indicating that the optimal concentration of  $\text{Li}^+$ -ion is 0.02. It should be mentioned that the defect-related luminescent materials have been prepared and characterized, such as nanocrystal  $\text{SiO}_2$ ,<sup>23</sup>  $\text{MoS}_2$ ,<sup>24</sup>  $\text{Gd}_2\text{O}_3:\text{Dy}$ ,<sup>25</sup>  $\text{ZnO}$  quantum dots,<sup>26</sup>  $\text{Y}_2\text{O}_3:\text{Eu}$ <sup>27</sup> etc. As shown in Table 1, the considerable amounts of Li-defects are observed due to the volatility of  $\text{Li}_2\text{O}$  in the firing step at  $1250^\circ\text{C}$ . It is presumed that the cationic defects induced by the  $\text{Li}^+$ -ions introduced into the  $\text{Ba}^{2+}$ -sites have an effect on the effective energy transfer from the host-lattice ( $\text{Ba}_2\text{SiO}_4$ ) to the  $\text{Eu}^{2+}$ -activator ions as revealed in the diffuse reflectance spectra (Fig.

Fig. 8 XRD patterns of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02}, \text{Eu}_{0.02})$  phosphor ( $\text{Li} = 300\%$  excess) synthesized using zirconia crucible.

6). For the  $\text{Ba}_2\text{SiO}_4:(\text{Li}_x, \text{Eu}_{0.02})$  phosphor materials, the maximum emission intensity corresponds to the optimal concentration of  $\text{Li}^+$ -ion ( $x = 0.02$ ). It is remarkable that the emission intensity of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02}, \text{Eu}_{0.02})$  phosphor is about 3.2 times higher than that of  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  phosphor even in very small quantity of Li. Fig. 6 presents the diffuse reflectance spectra of  $\text{Ba}_2\text{SiO}_4$ ,  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$ , and Li-codoped  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  phosphors. As the  $\text{Eu}^{2+}$  ions are doped into the  $\text{Ba}_2\text{SiO}_4$  host lattice, the broad absorption bands are manifested in the range of 300–450 nm. It might be assured that the broad absorption bands around 300 and 450 nm in  $\text{Ba}_2\text{SiO}_4:\text{Eu}^{2+}$  phosphor are associated with the  $4f \rightarrow 5d$  transition of  $\text{Eu}^{2+}$  because the absorption band of the  $\text{Ba}_2\text{SiO}_4$  host material is absent in this wavelength range. Furthermore, the absorption bands of the Li-doped  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  are still stronger than that of  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  without Li-doping, which is well coincident with the excitation spectra as previously presented in Fig. 5.

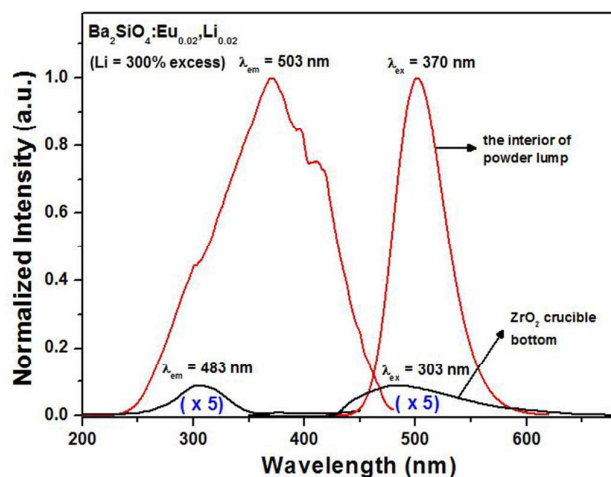

Fig. 9 Excitation and emission spectra of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02},\text{Eu}_{0.02})$  phosphor (Li = 300% excess) synthesized using zirconia crucible.

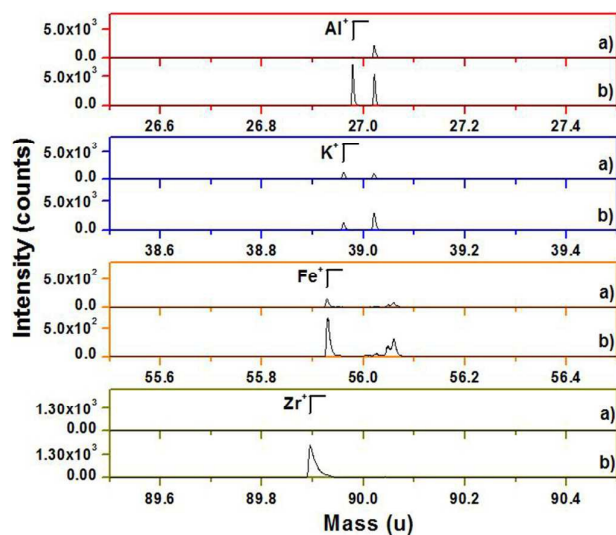

Fig. 10 TOF-SIMS mass spectra of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02},\text{Eu}_{0.02})$  synthesized using Li-300% excess. In each secondary ion, the spectrum in the upper part (a) corresponds to the powder sample and that in the lower part (b) corresponds to the bottom of the zirconia crucible.

The remarkable PL enhancement by Li-codoping warrants further examination of the materials in search for its origin. One may presume that the  $\text{Li}^+$  ions introduced into the  $\text{Ba}^{2+}$ -sites in  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  crystal lattice create the cation vacancies as well as the oxygen vacancies for charge balance, which might act as a sensitizer for the effective energy transfer from the host lattice ( $\text{Ba}_2\text{SiO}_4$ ) to the activator ions ( $\text{Eu}^{2+}$ ). As shown in Table 1, ICP results indicate that the materials do have a considerable amount of Li defects probably due to the volatility of  $\text{Li}_2\text{O}$  in the firing step, at  $1250^\circ\text{C}$  for 12h in air and 4%  $\text{H}_2/\text{Ar}$ . In contrast to our expectation, however, the increase in the nominal content of Li improves the PL of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02},\text{Eu}_{0.02})$  synthesized using the excess  $\text{Li}_2\text{CO}_3$  (100%, 200%, and 300%) as shown in Fig. 7. Namely, the PL intensity is much higher when the samples were prepared with

an excess amount of  $\text{Li}_2\text{CO}_3$ , indicating that the presence of the Li defects is not the critical cause for the PL enhancement. In understanding the origin of the PL enhancement, a critical clue is evident in TOF-SIMS results for the  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02},\text{Eu}_{0.02})$  (Li = 300% excess) product which was synthesized using  $\text{SiO}_2$  (99.6% purity),  $\text{BaCO}_3$  (99% purity),  $\text{Li}_2\text{CO}_3$  (99.99% purity), and  $\text{Eu}_2\text{O}_3$  (99.9% purity). After firing, two different samples were collected in the zirconia crucible, in first the interior of the cohesive powder-lump, in second the fused part remained at the bottom of the zirconia crucible. XRD pattern of the powder in the interior of the powder-lump shows that of  $\text{Ba}_2\text{SiO}_4$  with a pure single phase, whereas the impurity phases such as  $\text{BaZrO}_3$ ,  $\text{LiAlSiO}_4$ ,  $\text{KAlSiO}_4$ , and  $\text{ZrO}_2$  are manifested at the bottom of zirconia crucible as presented in Fig. 8. The PL properties between two samples are compared in Fig. 9. The excitation and emission spectra of the impurity phases at the bottom of zirconia crucible are quite different from those of  $\text{Ba}_2\text{SiO}_4:\text{Eu}^{2+}$  and its intensities are very low. Fig. 10 presents TOF-SIMS positive secondary ion mass spectra of the two samples. Interestingly, three main impurities determined by ICP-MS (see Table S1) are present much more significantly in the sample from the bottom. Moreover, the  $\text{Zr}^+$  secondary ion is present only in the sample from the bottom, whereas there is no  $\text{Zr}^+$  ion in the sample from the upper part. Fig. 11 shows the images of the  $\text{Al}^+$ ,  $\text{K}^+$ ,  $\text{Fe}^+$ , and  $\text{Zr}^+$  secondary ion in which the specific elemental topography of each ion in the samples are presented in a linear color scale bar with color range from black to white, where black corresponds to the zero counts and white to the maximum intensity (e.g.  $2.972 \times 10^3$  counts for  $\text{Al}^+$  at the left in the top in Fig. 11). Images of TOF-SIMS collected from the different positions of the powder sample coincide well with the intensities of the secondary cations as presented in Fig. 11. It should be noted that the intensities of the secondary cation in the sample collected from the bottom of the crucible are still stronger than those from the upper part. Since the target product particles remain in the upper part of the crucible, it is reasonable to say that the products have impurities much less than what we would expect from the amount of the impurities of the starting precursors and that the added  $\text{Li}_2\text{CO}_3$  as a  $\text{Li}^+$  ion source effectively removes the impurities in the precursors. This is supported by the fact that in Fig. 7 all the products prepared with excess  $\text{Li}_2\text{CO}_3$  (100, 200 and 300%) show nearly the same PL intensity. It should be noted that the liquid-phase sintering is usually considered to occur in three stages which are rearrangement, solution precipitation, and Ostwald ripening.<sup>28</sup> As the temperature is raised above  $710^\circ\text{C}$ , the  $\text{Li}_2\text{CO}_3$ - $\text{Li}_2\text{O}$  mixture melts and reacts with  $\text{BaCO}_3$ ,  $\text{SiO}_2$ , and  $\text{Eu}_2\text{O}_3$  to form a eutectic liquid. Assuming that there is good wetting between the liquid and the particulate solids, the impure solids dissolve at the solid/liquid interfaces, diffuse through the liquid and precipitate on the particles at another site which is the bottom of the zirconia crucible in our system. In essence, the excess amount of  $\text{Li}_2\text{CO}_3$  as a  $\text{Li}^+$ -source plays an important role as a molten flux medium that effectively traps impurities in the melt and thus result in a low impurity level in the phosphor product. This proposition is further substantiated when we

Fig. 11 TOF-SIMS images of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02}, \text{Eu}_{0.02})$  synthesized using Li-300% excess. The images in the upper part correspond to the powder sample and those in the lower part correspond to the bottom of the zirconia crucible.

Fig. 12 PL spectra of  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  synthesized using the starting chemicals with the high and low purity.

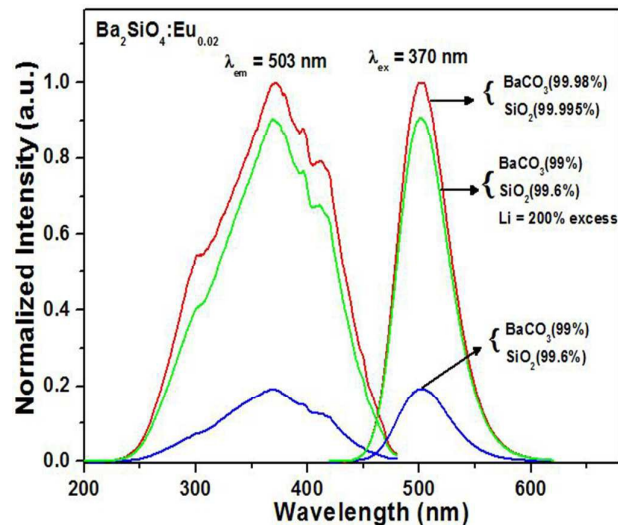

Fig. 13 Comparison of PL property between  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  (using the high purity) and  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02}, \text{Eu}_{0.02})$  (using the low purity and Li-200% excess).

compare the PL intensities of the Li-codoped products with another set of products prepared without Li-codoping but instead with high-purity precursors. Fig. 12 shows the excitation and emission spectra of  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  products with

precursors of varied purities. From the trend in the PL intensity, it is evident that the PL efficiency is strongly dependent of the chemicals purities of the precursors, with the maximum emission intensity from the highest-purity  $\text{BaCO}_3$  (99.98%) and

**Table 2** Luminescent Properties of Ba<sub>2</sub>SiO<sub>4</sub>:(Li<sub>0.02</sub>,Eu<sub>0.02</sub>) Phosphor Materials.

Starting material	Maximum $I_{em}$ ratio (%) <sup>a</sup>	Emission peak area ratio (%) <sup>a</sup>	Relative brightness, cd/m <sup>2</sup> (%) <sup>a</sup>	Quantum Yield (%)
BaCO <sub>3</sub> (H) <sup>b</sup> , SiO <sub>2</sub> (H) <sup>b</sup> No-Li addition	100	100	100	63.9
BaCO <sub>3</sub> (L) <sup>b</sup> , SiO <sub>2</sub> (L) <sup>b</sup> Li : 200% excess	90.8	91.4	92.6	69.0
BaCO <sub>3</sub> (L) <sup>b</sup> , SiO <sub>2</sub> (L) <sup>b</sup> Li : 300% excess	88.4	88.8	91.3	63.2
BaCO <sub>3</sub> (L) <sup>b</sup> , SiO <sub>2</sub> (L) <sup>b</sup> Li : No-excess	60.9	61.7	63.2	53.9
BaCO <sub>3</sub> (L) <sup>b</sup> , SiO <sub>2</sub> (L) <sup>b</sup> No-Li addition	19.3	19.5	22.3	31.5

<sup>a</sup> Property of Ba<sub>2</sub>SiO<sub>4</sub>:Eu<sub>0.02</sub> material synthesized with BaCO<sub>3</sub>(H) and SiO<sub>2</sub>(H) is located to 100%.

<sup>b</sup> BaCO<sub>3</sub>(H) corresponds to BaCO<sub>3</sub>(99.98% purity), SiO<sub>2</sub>(H) to SiO<sub>2</sub>(99.995% purity), BaCO<sub>3</sub>(L) to BaCO<sub>3</sub>(99% purity), and SiO<sub>2</sub>(L) to SiO<sub>2</sub>(99.6% purity).

**Fig. 14** Relative brightness of Phosphor Materials; Ba<sub>2</sub>SiO<sub>4</sub>:Eu<sub>0.02</sub> (a), Ba<sub>2</sub>SiO<sub>4</sub>:(Li<sub>0.02</sub>,Eu<sub>0.02</sub>) (b), Ba<sub>2</sub>SiO<sub>4</sub>:(Li<sub>0.02</sub>,Eu<sub>0.02</sub>) (c), Ba<sub>2</sub>SiO<sub>4</sub>:(Li<sub>0.02</sub>,Eu<sub>0.02</sub>) (d), Ba<sub>2</sub>SiO<sub>4</sub>:(Li<sub>0.02</sub>,Eu<sub>0.02</sub>) (e), Ba<sub>2</sub>SiO<sub>4</sub>:Eu<sub>0.02</sub> (f). Brightness of Ba<sub>2</sub>SiO<sub>4</sub>:Eu<sub>0.02</sub> (a) is located to 100%.

SiO<sub>2</sub> (99.995%) precursors being 5.2 times higher than that from the lowest-purity BaCO<sub>3</sub> (99%) and SiO<sub>2</sub> (99.6%) precursors. The emission intensity from BaCO<sub>3</sub> (99%) and SiO<sub>2</sub> (99.995%) precursors is 4.7 times higher than that from BaCO<sub>3</sub> (99%) and SiO<sub>2</sub> (99.6%), indicating that the emission intensity is more sensitive to the purity of SiO<sub>2</sub> than that of BaCO<sub>3</sub>. A Ba<sub>2</sub>SiO<sub>4</sub>:Eu<sub>0.02</sub> product prepared with the aqua regia-purified SiO<sub>2</sub> and BaCO<sub>3</sub> (99%) shows a PL intensity 2.5 times higher than that of Ba<sub>2</sub>SiO<sub>4</sub>:Eu<sub>0.02</sub> using BaCO<sub>3</sub> (99%) and the as-received SiO<sub>2</sub> (99.6%). Remarkably, Fig. 13 shows that the PL intensities are quite comparable between Li-codoped Ba<sub>2</sub>SiO<sub>4</sub>:(Li<sub>0.02</sub>,Eu<sub>0.02</sub>) synthesized using the lowest-purity BaCO<sub>3</sub> (99%) and SiO<sub>2</sub> (99.6%) but with 200%-excess Li<sub>2</sub>CO<sub>3</sub>, and Ba<sub>2</sub>SiO<sub>4</sub>:Eu<sub>0.02</sub> synthesized using the highest-purity BaCO<sub>3</sub> (99.98%) and SiO<sub>2</sub> (99.995%) precursors. As shown in Table S1, further ICP-MS analysis showed that the low-purity SiO<sub>2</sub> (Aldrich, 99.6% purity) contain three main impurities: Al (3891 ppm), K (1312 ppm), and Fe (478 ppm). After treating the SiO<sub>2</sub> with a hot aqua regia, the concentrations of three main

impurities are also reduced: Al (2288 ppm), K (186 ppm), and Fe (102 ppm). Fig. 14 shows the relative brightness monitored under 365 nm UV-light, which is in good agreement with PL results as presented in Fig. 7 and Fig. 13. Luminescent properties obtained from the emission spectra and quantum yields of Ba<sub>2</sub>SiO<sub>4</sub>:Eu<sub>0.02</sub> phosphor materials before and after Li-doping are summarized in Table 2. The photoluminescence quantum yield (QY), which is the probability that a chromophore emits a photon upon its return from the excited to the ground state, can be represented as the ratio of its radiative to the non-radiative rate,<sup>29-32</sup>

$$\Phi = k_{\text{rad}} / (k_{\text{rad}} + k_{\text{nr}}) \quad (1)$$

where  $k_{\text{rad}}$  and  $k_{\text{nr}}$  are the rate constant for radiative emission and non-radiative deexcitation to the ground state, respectively. As presented in Table 2, the luminescent properties (maximum  $I_{em}$  ratio, emission peak area ratio, and relative brightness) associated with the radiative process have the similar values, while the QY values (related with radiative and non-radiative process) are somewhat different, i.e., the smaller differences compared to those of radiative process. Evidently, the discrepancy between three-radiative and QY values may be attributed to the energy losses due to the non-radiative process.

#### 4 Conclusions

Large photoluminescence enhancement up to 470% has been achieved for the green emitting (Ba,Sr)<sub>2</sub>SiO<sub>4</sub>:Eu<sup>2+</sup> phosphor material via Li-codoping using Li<sub>2</sub>CO<sub>3</sub> as a flux, when low-purity precursors were employed. By examining the elemental distribution in the reaction products and flux after the Li-codoping experiment, it was discovered that the excess Li condition results in extraction of Al, K and Fe impurities from the low-purity precursors, hence decreasing impurity concentrations in the phosphor product. This effect was further verified by comparing the photoluminescence efficiency of the Li-codoped phosphors with that of Li-undoped phosphors that were prepared with high-purity precursors. This newly-discovered mechanism of photoluminescence enhancement upon Li-codoping may lead to more economical adoption of solid state lighting for energy efficiency. This also provides an

efficient synthetic route aiming alleviation of the undesired luminescent quenching by impurities and thus allows us to explore new phosphors that are particularly susceptible to such impurity effect.

### Table of contents (Graphical Abstract)

The emission intensity of  $\text{Ba}_2\text{SiO}_4:(\text{Li}_{0.02},\text{Eu}_{0.02})$  (200% excess Li) synthesized using low purity precursors (99%-pure  $\text{BaCO}_3$  and 99.6%-pure  $\text{SiO}_2$ ), is found to be 470% as high as that of  $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}$  (no-Li). The excess  $\text{Li}_2\text{CO}_3$  autonomously removes the impurities that were originally contained in the low purity precursors, in particular  $\text{SiO}_2$ , and thus critically improves the photoluminescence efficiency of the material.
