This is an *Accepted Manuscript*, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. This *Accepted Manuscript* will be replaced by the edited, formatted and paginated article as soon as this is available.

You can find more information about *Accepted Manuscripts* in the [Information for Authors](#).

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard [Terms & Conditions](#) and the [Ethical guidelines](#) still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this *Accepted Manuscript* or any consequences arising from the use of any information it contains.

**Synthesis of Polyacrylamides Hydrophobically Modified with Butyl Acrylate
Using a Nanoclay with Interlayer Spaces for Butyl Acrylate Aggregation: Studies
on the Microstructure and Aqueous Solution Viscosity**

Abstract

Aqueous solution free-radical copolymerization of acrylamide with hydrophobic butyl acrylate (BA) was performed by potassium persulfate as an initiator in the presence of nanoclay. Effect of two nanoclays with different natures, i.e. hydrophilic Cloisite Na⁺ and hydrophobic Cloisite 30B, on the microstructure and aqueous solution viscosity of the synthesized copolymers were studied. It was found from microstructural studies by NMR that copolymerization with Cloisite Na⁺ may proceed via a mechanism similar to the heterogeneous mechanism, while those with Cloisite 30B may proceed simultaneously with both the micellar and heterogeneous mechanisms with a relatively high tendency toward micellar method. These findings were further confirmed by the water solubility, XRD, TEM, dynamic light scattering (DLS) and viscosity analyses. Significant intercalation of the chains into the clay galleries was observed only with Cloisite Na⁺. Results of the DLS analysis as well as the aqueous solution viscosity versus copolymer composition, NaCl concentration and temperature revealed intermolecular aggregation of the BA groups especially for multiblock structured copolymers synthesized with emulsifier or Cloisite 30B.

Introduction

Due to its high molecular weight, polyacrylamide (PAM) is of interesting polymer as thickening agent and rheological modifier in the aqueous solutions [1-4]. To improve rheological properties such as resistance to the shear rate, salt tolerance and thermal stability, PAMs have been hydrophobically modified by incorporating a small amount of the hydrophobic comonomers into the main chain, resulting in water-soluble polymers so called hydrophobically modified polyacrylamides (HMPAMs) [2-5]. Linear alkyl or alkylaryl acrylamides and alkyl acrylates are commonly used hydrophobic comonomers [1,2,4]. These polymers have found applications in various fields such as enhanced oil recovery, drilling fluid, coatings and paints [2,4]. To be applicable in the above-mentioned applications, synthesized HMPAMs should have suitable rheological properties such as thickening behavior with increasing polymer concentration in the aqueous solution, shear-thinning behavior, resistance to the shear fields and stability against high concentration of the salts and high temperature to maintain their viscosities [1-8].

There is a direct relationship between the thickening and rheology modification properties and chemical microstructure of the HMPAMs [2-5]. Molecular weight and its distribution and copolymer composition and its distribution (i.e. comonomers sequence length) are of important (micro)structural characteristics which have significant effects on the association of hydrophobic groups and rheological properties [1-5,8-10]. Mark-Houwink relationship established for the PAM homopolymer can be used to estimate molecular weight of the HMPAMs where mole fraction of the hydrophobic comonomer in the copolymer is very low relative to the hydrophilic main monomer, i.e. acrylamide [2,8-12]. On the other hand, ¹H-NMR method can give reliable results on the copolymer composition providing that mole fraction of the hydrophobic comonomer incorporated into the copolymer chains is high

enough (> 2 mole %) or hydrophobic comonomer contains two terminal methyl groups (N,N-dihexylacrylamide, for example) [2,5,13].

There are different methods to synthesize HMPAMs such as heterogeneous, homogeneous and micellar copolymerizations [1-5,13]. HMPAMs can be synthesized via free-radical copolymerization technique without any additive (heterogeneous method) [5,13]. On the other hand, it is possible to dissolve the hydrophobic comonomer in the aqueous solution using a co-solvent (homogeneous method) or an emulsifier (micellar method) [2,5,13]. Studies on the heterogeneous and homogeneous methods have revealed that hydrophobic comonomer incorporates randomly into the copolymer chain with a sequence length equal to about unity. On the other hand, emulsifier with a concentration much higher than its critical micelle concentration (CMC) is used in the micellar method; resulting in the hydrophobic monomer swollen micelles. The entrance into, propagate inside and exit from the micelles of the propagating macroradicals in the aqueous solution can repeat several times for a single propagating macroradical before its termination, resulting in a multi-block microstructure [2,4,13]. It can be attributed to a relatively high lifetime of propagating polyacrylamide macroradicals due to the high ratio of the propagation to termination rate constants and to the small chain transfer constant in the water [1].

Copolymerization of the acrylamide (AM) and a small amount of fluorinated (meth)acrylate has been reported for synthesizing HMPAMs where association behavior of the hydrophobic groups has been observed [14]. Preparation of hydrophobically modified polyelectrolytes by precipitation copolymerization of acrylic acid and 3-[tris(trimethylsilyloxy)silyl] propyl methacrylate in the supercritical carbon dioxide has been reported [15]. Acrylic acid/ alkyl acrylate (alkyl chain with a length of 8, 12, 14, 16 or 18) copolymer has been synthesized via precipitation polymerization and a random distribution of the alkyl acrylate in the copolymer has been reported [16]. These copolymers exhibited strong association behavior in the

aqueous solution.

Although homogeneous and microemulsion radical copolymerization of AM and n-butyl acrylate (BA) has been reported [17-20]; however, these studies have not intended to prepare water-soluble HMPAMs or study their physical properties in the aqueous solutions. More recently, two works have been reported on the use of wide accessible, low cost and hydrophobic BA comonomer for synthesis of the HMPAMs [13,21]. The aggregation behavior in aqueous solution of hydrophobically modified polyacrylates synthesized by atom transfer radical polymerisation (ATRP) of a mixture of alkyl acrylate and t-butyl acrylate (tBA) and subsequent hydrolysis of the tBA has been investigated [21]. The hydrophobicity of polyacrylates has systematically been varied by the amount of alkyl acrylate and in particular by the length of the hydrocarbon moiety where n-butyl, hexyl, isooctyl, and dodecyl acrylates have been used. Acrylates were randomly distributed along the polyelectrolyte backbone. Results showed formation of the hydrophobic aggregation domains whose size increases with the length of the alkyl chain.

AM and BA have been copolymerized via heterogeneous and micellar methods in the aqueous solution without and with, respectively, SDS as an emulsifier [13] and BA-modified PAMs with random and multi-block, respectively, microstructures with molecular weights in the range of about 10^6 gmol^{-1} have been prepared. Results showed that it is possible to establish a reasonable microstructure-water solubility relationship for the AM/BA copolymers synthesized by different methods. For example, length of BA blocks per micelle higher than about 10 was found to limit water solubility of the copolymers.

Beneficial effect of the organically modified clays, i.e. Cloisite 30B, on the polymerization rate of controlled radical polymerization of (meth)acrylates has been reported [22-24]. These observations have been found to be due to a definite interaction between the hydroxyl moiety (Al-O-H) of organoclay and carbonyl group ($>\text{C}=\text{O}$) of the (meth)acrylates [22-24]. Therefore,

(meth)acrylates can diffuse into the clay galleries, resulting in the increased basal spacing (d_{001}) of the organoclay.

According to the above explanations, interlayer spaces of organoclays are expected to be suitable loci for association of the hydrophobic interacting (meth)acrylates such as BA. On the other hand, due to the fully exfoliation of layers [25,26], pristine clays cannot provide spaces for BA association; hence, random distribution with a sequence length of about 1 for BA is expected. Hence, in continuum of the previous work [13], AM and BA are copolymerized in the present work via free radical aqueous solution copolymerization in the presence of nanoclay. The aim of this work is to investigate effect of the dispersion state of the two different nanoclays, i.e. hydrophilic Cloisite Na⁺ pristine clay with a fully exfoliation of the layers in the aqueous solution [25,26] or hydrophobic Cloisite 30B organoclay with a slightly intercalation of the layers only by BA [22-24], on the copolymerization mechanism, microstructure and aqueous solution viscosity, i.e. establishing the synthesis-structure-property relationship, of the AM/BA copolymers. Accordingly, chemical structure of the synthesized copolymers is characterized by ¹H NMR and ¹³C NMR spectroscopies. Then, microstructure and hydrophobic aggregation behavior are then evaluated using water solubility test, ¹H NMR spectroscopy (for copolymer composition determination), intrinsic viscosity measurement (for calculation of the molecular weight) and dynamic light scattering (DLS) (for calculation of the hydrodynamic radius, R_h , of the copolymer chains in the aqueous solution). Morphology of the polymer/ clay (nano)composites is investigated by X-ray diffraction (XRD) and transmission electron microscopy (TEM). Viscosity of the aqueous solutions containing AM/BA copolymers is investigated as a function of copolymer concentration, sodium chloride (NaCl) concentration and temperature.

Experimental

Materials

The AM (Merck, for synthesis) was recrystallized twice in the acetone. BA (Merck, for synthesis) was purified via passing through a basic alumina column. Potassium persulfate (KPS) from Merck were used without further purification. Cloisite Na⁺ and Cloisite 30B (both from Southern Clay Products Inc.) as a pristine and organically modified (modifier: (bishydroxyethyl)methyl tallow quaternary ammonium cation) nanoclays, respectively, with cation exchange capacities of 92 and 90 meq/100 g clay, respectively, were dried under reduced pressure at 70 °C for 24 h before use. NaCl (purity>99%) and acetone (purity>99%) were purchased from Dr. Mojallali Co. (Iran). Deionized water and nitrogen (purity > 99.9%) were used in all experiments.

Synthesis

In the previous research, micellar (experiment AB-1) and heterogeneous (experiment AB-2) methods were used for synthesis of the AM/BA copolymers where SDS (1.2 g in the case of micellar method) and KPS (0.05 wt% relative to the aqueous phase in the both methods) were employed as emulsifier and initiator, respectively [13]. 1.056 g (93 mol%) and 0.144 g (7 mol%) of AM and BA, respectively were used in the above-mentioned reactions. In the present work, similar procedure of the micellar copolymerization was also used except that nanoclay was used instead of the SDS (Table 1). A 50 ml ampoule containing 40 ml deionized water was used as a reaction chamber. By using a magnet stirrer (in the case of Cloisite Na⁺) or ultrasonic homogenizer (in the case of Cloisite 30B) for 30 min, the predefined amount of clay (Table 1) was dispersed in the aqueous phase and given amounts of the AM (1.056 g) and BA (0.144 g) were then added to the reaction mixture. The resulting mixture was further mixed for 1 h. It has been reported that layers of the Cloisite Na⁺ can readily be separated to single layers in the water with a concentration as high as 10 wt%, forming a stable dispersion for a long time period [25,26]. However, Cloisite 30B is a

hydrophobic clay and precipitates immediately in the aqueous phase; hence, it was dispersed in the aqueous phase in the presence of hydrophobic BA comonomer by using an ultrasonic homogenizer.

The reaction mixture was immersed in a water/ice bath followed by bubbling with nitrogen for 30 min under magnetic stirring to remove air, and then a given amount of KPS was added (Table 1). The reaction chamber was immersed in a 50 °C water bath for 8 h while reaction mixture was mixed with a magnetic stirrer, after which, copolymer and clay were precipitated together by adding excess amount of the acetone. The precipitated product was again dissolved in the water, then precipitated using the excess acetone and dried in a vacuum oven at 60 °C for 24 h. Dried product was directly subjected to the XRD analysis. To separate copolymer and clay, dried product was dissolved in the water; clay was then precipitated by an ultracentrifugation at 14000 rpm and separated by filtration from upper clear aqueous solution containing copolymer. Finally, copolymer was precipitated from clear aqueous solution by adding excess amount of the acetone, filtered, and dried under vacuum at 60 °C for 24 h. Purified copolymer was then used in the NMR, DLS and viscosity measurements. Conversion of the AM and BA monomers to the copolymer was measured gravimetrically.

Table 1

Characterization

To study the copolymer composition and chemical microstructure, ¹H-NMR and ¹³C-NMR spectra were recorded using Bruker Avance 400 MHz NMR spectrophotometer. Purified copolymer with a concentration of about 3 wt% was dissolved in the D₂O solvent and used for analysis.

Water solubility of the purified copolymers was evaluated visually via dissolution of a given amount of copolymer in the water where rapid and slow dissolutions were defined as excellent and good, respectively, water solubility.

Ubbelohde viscometer was used for the intrinsic viscosity measurement at 25 °C, from which molecular weight of the copolymers was estimated. The intrinsic viscosity ($[\eta]$) and Huggins equation coefficient (K_H) can be calculated from experimental viscosity data of polymeric solutions over various concentrations using Eq. (1) [13]. Average efflux time for the solvent or the polymer solution was obtained from at least three measurements. Confidence intervals for the measured efflux times were in the range of ± 1 s.

Due to the low concentration of BA in comparison with that of AM in the initial feed and thereby in the copolymer chain, the Mark-Houwink equation proposed for PAM (Eq. (2)) in a 0.1 M solution of NaCl at 25 °C [1,27] was used for molecular weight estimation of the copolymers.

$$\frac{\eta_{sp}}{c} = [\eta] + K_H [\eta]^2 c \quad \text{where} \quad \frac{\eta_{sp}}{c} = \eta_{red} \quad (1)$$

$$[\eta] = 9.33 \times 10^{-3} M_w^{0.75} \quad (2)$$

where η_{sp} is the specific viscosity, η_{red} is the reduced viscosity in ml/g, $[\eta]$ is the intrinsic viscosity in ml/g, c indicates copolymer concentration in g/ml, K_H is the coefficient of Huggins equation in g/ml, and M_w is the viscosity (or almost equivalently weight)- average molecular weight in g/mol.

Under same conditions, aqueous solution viscosity of the HMPAMs is affected by both the molecular weight and intermolecular association, originated from the hydrophobic BA segment's association, of the HMPAMs. To determine extent of the intermolecular association, DLS technique (Model Malvern Zetasizer Nano S90) was used to determine hydrodynamic radius (R_h) of the copolymer chains in the aqueous solution. Then, individual influence of the molecular weight and intermolecular association on the aqueous solution viscosity can be evaluated, which will be discussed later.

Dilute aqueous solutions (with concentrations lower than 0.1 wt%) were prepared and

centrifuged at 14000 rpm to remove any possible impurities. The tests were carried out at 25 °C by a laser light with a wave length of 633 nm, where viscosity of the solution and refractive indexes of the solvent and solution were used as input data in the calculations. DLS technique measures in fact the translational diffusion coefficient (D) of polymer chains, from which hydrodynamic radius of polymer coils can be calculated by considering the Stokes-Einstein equation (Eq. (3)) [28].

$$D = \frac{kT}{6\pi\eta R_h} \quad (3)$$

Here, k is the Boltzmann constant, T is the temperature in Kelvin, η is the solution viscosity in cP and R_h indicates the hydrodynamic radius of the polymer chains in nm.

X-ray diffraction (XRD) patterns were collected on an X-ray diffraction instrument (Philips, Model X'Pert MPD) with a Cobalt tube ($\lambda = 0.179$ nm) as a anode at the room temperature. The system consists of a rotating anode generator operated at 40 kV and 30 mA current. The samples were scanned from $2\theta = 1^\circ$ to 12° at the step scan mode, and the diffraction pattern was recorded using a scintillation counter detector. The distribution of clay layers into the polymer matrix was observed by a TEM (Philips, Model CM-30) operated at an accelerated voltage of 300 kV. Dried product containing a mixture of copolymer and clay was dispersed in the deionized water for 24 h and then one drop of the diluted suspensions was suspended on a carbon-coated copper grid, vacuum dried and subjected to the TEM observation.

Results and discussion

In the previous work [13], heterogeneous (without any additive, Fig. 1a) and micellar (with SDS, Fig. 1b) methods were used for synthesis of the random and multi-block, respectively, AM/BA copolymers. Random distribution of the BA with a microstructure form of the $[(AM)_n\text{-co-(BA)}_m]_p$ with a BA sequence length of about 1 ($m = 1$) was observed in the heterogeneous method while both random and multi-block distributions of the BA with a

microstructure form of the $[(AM)_n\text{-co-(BA)}_m]_x\text{-b-(BA)}_y]_z$ ($m = 1$) was observed for the copolymers formed via micellar method (Fig. 2) [13].

Fig. 1

Fig. 2

Aim of the present work is to investigate effect of the layered nanoclay on the behavior of the aqueous phase copolymerization of the AM and BA. Depending on the hydrophobicity nature of the clay used, it seems that different loci in the aqueous medium can be considered for aggregation of the water-insoluble portion of the BA. When the hydrophilic Cloisite Na⁺ is used, it can rapidly separate to single layers in the water [25,26], therefore, there are no clay galleries for aggregation of the hydrophobic species. Thus, single layers can physically adsorb on the surface of hydrophobic BA droplets, producing a system so called clay-stabilized Pickering emulsion [29,30]. It is expected that reaction in such system proceeds with a pattern similar to the heterogeneous method (Fig. 1c), producing a copolymer with a general formula of $[(AM)_u\text{-co-(BA)}_v]_w$ (Fig. 2). On the other hand, when organically modified clay (Cloisite 30B in the present work) is used in the aqueous medium, interlayer spaces of the clay can provide suitable loci for aggregation of the hydrophobic species (BA in the present case) (Fig. 1d) [22-24]. Therefore, copolymerization of AM and BA in such system is expected to proceed with a pattern similar to the micellar method. However, block length of the BA incorporated into the copolymer chains may be different from that of the micellar method due to the different number of sites available for the BA aggregation. Hence, microstructure of the $[(AM)_p\text{-co-(BA)}_q]_r\text{-b-(BA)}_s]_t$ can be considered for the produced copolymers (Fig. 2).

Microstructural characterization

Structure of the AM/BA copolymers synthesized under various condition (Table 1) were

analyzed from corresponding $^1\text{H-NMR}$ (Fig. 3) and $^{13}\text{C-NMR}$ (Fig. 4) spectra. D_2O was used as a solvent. All peaks appeared in the $^1\text{H-NMR}$ and $^{13}\text{C-NMR}$ spectra were assigned to the corresponding protons and carbons, respectively [13]. Due to their favorable water solubility, copolymer ABC-3 synthesized with Cloisite 30B was used in the $^{13}\text{C-NMR}$ for further characterization of the copolymer structure.

Fig. 3

Fig. 4

Reaction ABC-1 was carried out in the presence of an equal amount of the SDS and Cloisite Na^+ where amount of SDS decreased to half the amount of that in the reaction AB-1. Due to the presence of SDS emulsifier, reaction ABC-1 is still expected to proceed via a micellar mechanism similar to the reaction AB-1 (for more details, see the next paragraph) except that BA block length per micelle (N_{H}) can be different and molecular weight can be affected by the presence of nanoclay, which will be discussed later. This similarity can be observed from signal of the methyl protons of BA at about 0.8 ppm (Fig. 3) where it has been appeared as a relatively broad peak without spin-spin splitting in both reactions. It can be attributed to the high mole fraction of BA incorporated into the chain (case of copolymer AB-1) and/or high value of N_{H} (case of ABC-1) (Table 2), resulting in the microscopic phase separation in the aqueous solution via the hydrophobic intermolecular aggregation (see next sections).

Mole fraction of the BA in the AM/BA copolymer (F_{BA}) can be calculated from corresponding signal intensities of the BA and AM protons in the $^1\text{H-NMR}$ spectra using the following equation:

$$F_{\text{BA}} = \frac{2I_a}{3I_{b,c,e,f} - 4I_a} \quad (4)$$

where I_i indicates the intensity of proton(s) i . Table 2 shows mole fractions of the monomers in the initial feed (f_i) and in the produced copolymer (F_i). F_{BA} values for copolymers AB-

1 and AB-2 produced with the f_{BA} value of 0.07 have been reported to be 0.084 and 0.046, respectively [13]. Results in Table 2 show that F_{BA} value in the copolymer AB-1 is higher than that in the other samples. Moreover, F_{BA} value is higher than f_{BA} value only for reaction AB-1, indicating faster incorporation of BA into the growing chains in the reaction AB-1. It has been observed that solubilization of the hydrophobic comonomer within the micelles not only does not reduce its accessibility to the macroradicals propagated in the aqueous medium, but also leads to an apparent greater reactivity [1,2]. The higher the ratio of hydrophobic BA to SDS emulsifier (or equivalently N_H , see the next section) is, the faster the incorporation of the BA into the growing macroradicals will be [1,2]. On the other hand, minimum value of F_{BA} was observed for reaction ABC-2 where reaction was performed by complete replacement of the SDS with the Cloisite Na^+ . Under such condition, BA droplets can be covered with the individual single layers of the clay [29,30]. These layers as a barrier can slow down diffusion rate of the BA into the copolymerization locus, i.e. water, and/or prevent entrance of propagating macroradicals into the BA droplets.

On the other hand, F_{BA} value of copolymer ABC-1 is expected to be close to that of the copolymer AB-1; however, different results were observed (Table 2). F_{BA} value for copolymer ABC-1 is much lower than that of copolymer AB-1, but still is higher than that of copolymer ABC-2. It may be attributed to the coverage of BA swollen micelles' surface with clay layers, as discussed above, and/ or effect of the layered Cloisite Na^+ on the ionic strength of the aqueous medium and thereby on the CMC value of SDS [31-33]. Due to the repulsion between the anion charges of SDS and Cloisite Na^+ , full coverage of the surface of BA swollen micelles by clay layers may not be occurred; therefore, micellar copolymerization will occurred somewhat [31]. CMC value of the SDS has been observed to decrease significantly in the presence of pristine sodium montmorillonite (i.e. Cloisite Na^+) [32,33].

Without Cloisite Na⁺, the CMC of SDS in the water was 8.32 mM. In the presence of 1 wt% Cloisite Na⁺, this value decreased to 6.4 mM [33]. The decrease of the CMC in the presence of Na-MMT increases the number of micelles for a given emulsifier concentration, resulting in the decreased number of hydrophobic monomers (BA in the present work) per micelles (N_H) (see Eq. (5) in the next section). Therefore, by entrance of propagating macroradical into the micelle, number of the BA consumed in the BA swollen micelle decreases, resulting in the decreased F_{BA} value.

Table 2

For copolymers AB-2, ABC-2 and ABC-3, signal of the BA methyl protons at about 0.8 ppm has been appeared as a triplet peak (Fig. 3), indicating clearly spin-spin splitting of protons in the $-\text{CH}_2-\text{CH}_3$ group. Among three reactions performed in the presence of nanoclay, maximum F_{BA} value was obtained for copolymer ABC-3 to be 0.059 (Table 2), which is higher than that of copolymer AB-2 prepared by heterogeneous method and is lower than that of copolymer AB-1 prepared by micellar method. It means that reaction ABC-3 may proceed simultaneously via two different mechanisms of the heterogeneous and micellar methods. The proposed copolymerization mechanism will further be verified by aqueous solution viscosity and DLS studies on the intermolecular association of BA segments, which will be discussed later. As already mentioned, interlayer spaces of organoclay are desirable loci for aggregation of the hydrophobic species (BA in the present case). By consuming BA in the aqueous medium, BA may exit from organoclay galleries and diffuse to the bulk of aqueous medium. Thus, reaction proceeds via heterogeneous mechanism. However, there is also semi-micellar mechanism for BA to be consumed. Propagating macroradicals can also enter into the interlayer spaces of the BA swollen organoclays and grow by consuming the BA comonomers. Therefore, two different roles in the reaction can be considered for Cloisite 30B organoclay. Consequently, compared to the micellar method with emulsifier, a multi-block

structure with a shorter BA block length ($s < y$) and a higher ratio of random to block distribution of BA ($r/s > x/y$) is expected (Fig. 2). Random copolymer can also be considered as a limiting case of the multi-block structure when s or y value approaches to the unit value. This situation may occur for reactions only performed with a very high concentration of SDS or Cloisite 30B, which is not the case in the present work. For example, a random copolymer may be expected for micellar method when the high ratio of emulsifier to hydrophobic comonomer is used in such a way that each micelle contains only a single hydrophobic comonomer (i.e., $N_H = 1$, see the next section).

Table 3 shows the intrinsic viscosity $[\eta]$, Huggins equation coefficient (K_H) and molecular weight of the copolymers ABC-1, ABC-2 and ABC-3; the corresponding values for (co)polymers PAM, AB-1 and AB-2 have been reported to be 199.0, 0.87 and 5.89×10^5 , 106.5, 1.32 and 2.56×10^5 and 404.3 mLg⁻¹, 0.31 and 1.52×10^6 g mol⁻¹, respectively [13]. It is clear from these data that among the other copolymers, copolymer AB-2 possesses highest molecular weight while a minimum molecular weight of 2.56×10^5 g/mol was observed for copolymer AB-1. Molecular weight of the copolymer decreased for reactions performed with the SDS, Cloisite Na⁺ or Cloisite 30B. It can be attributed to the chain transfer reactions occurred in the presence of clay [32,34] and SDS [1,2]. Impurities such as alcohol in the SDS and functional hydroxyl groups on the surface of clay can act as a chain transfer agent. Moreover, decrease in molecular weight of the copolymer prepared with Cloisite Na⁺ (copolymer ABC-2) is higher than that prepared with Cloisite 30B (copolymer ABC-3). It may be attributed to the higher surface area of the exfoliated structure of the Cloisite Na⁺ relative to the intercalated structure of the Cloisite 30B.

Table 3

It is clear from Table 3 that intrinsic viscosity, K_H value and molecular weights of copolymers ABC-1 and ABC-3 prepared with the SDS/ Cloisite Na^+ mixture and Cloisite 30B, respectively, are close to those of copolymers AB-1 and AB-2, respectively, prepared with and without, respectively, SDS [13]. Again, these results verify structural similarities of the copolymer ABC-1 with copolymer AB-1 as well as the copolymer ABC-3 with copolymer AB-2 originated from similarities in the polymerization mechanism as discussed above (Figs. 1 and 2). It should be mentioned that copolymer ABC-2 with a minimum F_{BA} value showed a K_H value similar to that of the homopolymer PAM (Table 3). Difference in the viscosities can be attributed to the different molecular weights.

Relationship between the microstructure and water solubility of copolymers

The BA block length can be calculated by Eq. (5) in terms of the number of hydrophobic monomers per micelles (N_H) [13-16].

$$N_H = \frac{C_{HM} - C_{HM}^{aq}}{(C_s - CMC) / N_{agg}} \approx \frac{C_{HM} - C_{HM}^{aq}}{C_s} \times N_{agg} \quad (5)$$

where C_{HM} is molar concentration of hydrophobic monomer (BA in the present work), C_{HM}^{aq} is the molar concentration of water soluble portion of the BA, C_s is the molar concentration of surfactant, CMC is the critical micelle concentration of surfactant (9.2 mM at 50 °C for SDS) [1,35] and N_{agg} is the micelle aggregate number, which is equal to 60 for SDS at 50 °C [1,35]. This value of N_{agg} was also used for reaction ABC-1 where SDS has been used in the polymerization recipe. As C_s is very high, the CMC may simply be neglected in comparison to C_s . Eq. (5) shows that hydrophobic block length (N_H) can be determined using N_{agg} and molar ratio of the surfactant to the water insoluble portion of hydrophobic monomer [1-3,13]. To calculate N_H value for a hydrophobic comonomer with a relatively considerable water solubility such as BA (about 0.18 wt% at 50 °C) [36], water soluble portion of the

comonomer, i.e. C_{HM}^{aq} , should be considered. An increase in N_H would result in the water insoluble HMPAM copolymers; therefore, the HMPAM must be optimized in a way that desirable rheological property and solubility could be obtained [2,5,13]. The theoretical N_H value calculated for reaction ABC-1 performed in the presence of SDS as additive has been given in Table 2; the corresponding values for reactions AB-1 and AB-2 have been reported to be 14.9 and 1, respectively [13]. In the calculation for reaction ABC-1, effect of the Cloisite Na^+ on the CMC of SDS [32,33] has not been considered. Thus, as discussed in the previous section, experimental N_H value may be lower than the theoretical one.

Good and excellent water solubility has been observed for copolymers AB-1 and AB-2, respectively [13]. Water solubility of the polymer decreases as the N_H value increases. There would be a microstructure-related interpretation for the water solubility of polymers. In other words, water solubility of the multi-block copolymers decreases as the hydrophobic block length increases. Compared to sample AB-1, although theoretical N_H value has increased two fold in the sample ABC-1, however, F_{BA} value has decreased significantly. It means that copolymer ABC-1 may have a longer but fewer BA blocks than that of copolymer AB-1. Therefore, almost a similar behavior for water solubility of these samples was observed (Table 1). Copolymers AB-1 and ABC-1 were dissolved in the water completely but relatively slowly. It can be attributed to the intermolecular association network of relatively long BA block segments in the aqueous solution.

Copolymers AB-2 and ABC-2 were dissolved quickly in the water probably due to the random distribution of BA in the heterogeneous method. The almost similar result was also observed for sample ABC-3. It should be noted that after reaction, a stable dispersion of Cloisite Na^+ in the aqueous medium was observed for reactions ABC-1 and ABC-2. Via ultracentrifugation at 14000 rpm, copolymer ABC-1 was easily separated from Cloisite Na^+ while separation of the ABC-2 from Cloisite Na^+ was very difficult, indicating that produced

copolymers have different microstructures. It is clear from Table 2 that F_{BA} in copolymer ABC-2 is significantly lower than that in copolymer ABC-1. The higher the mole fraction of BA incorporated into the AM/BA copolymer is, the easier the separation of hydrophobically modified PAM from hydrophilic Cloisite Na^+ via ultracentrifugation will be. BA in the copolymer structure can decrease interactions between the both hydrophilic PAM chains and Cloisite Na^+ layers. As expected in the case of reaction ABC-3, Cloisite 30B organoclay precipitates slowly without centrifugation in the stationary aqueous medium.

Analysis of the hydrophobic intermolecular aggregations

Hydrodynamic radius of the copolymer chains coil (R_h) in dilute solutions can be studied by DLS [13, 28]. Then, one would also be able to analyze the hydrophobic aggregations of the HMPAMs. Number and intensity size distribution curves are illustrated in Fig. 5. Bimodal distribution of size was observed in the intensity distribution curves (Fig. 5b). First distribution in the smaller sizes can be attributed to the copolymer chain coil with a slight and negligible intermolecular aggregation. Average value of the first distribution in the intensity distribution curves was in a good agreement with that in the number distribution curves (Figs. 5a and 5b). Therefore, it was considered to be close to the hydrodynamic radius of the copolymer chains coil (R_h). Number- average R_h values of copolymers ABC-1, ABC-2 and ABC-3 were obtained to be 6.6, 2.7 and 5.9 nm, respectively (Fig. 5a), while those of copolymers AB-1 and AB-2 have been reported to be 13.2 and 5.7 nm, respectively [13]. Second distribution in the larger sizes (Fig. 5b) was attributed to the intermolecular aggregation of the hydrophobic groups from several copolymer chains, forming a large physical network. Intensity-average radius of hydrophobic aggregates of copolymers ABC-1, ABC-2 and ABC-3 were obtained to be 79.5, 46.6 and 73.2 nm, respectively (Fig. 5b), while those of copolymers AB-1 and AB-2 have been reported to be 220 and 100 nm, respectively

[13]. In the case of copolymer AB-2, this second peak was very weak and observed difficulty, indicating that there is no significant BA association.

On the other hand, monomodal distribution of size was observed for all copolymers in the number distribution curves (Fig. 5a), indicating that number of the hydrophobic BA intermolecular aggregations in the dilute solution can be considered to be very small and almost negligible. BA molecules aggregate significantly via multi-block portions [13,21]; hence, the size of BA aggregates in the copolymers AB-1, ABC-1 and ABC-3 was observed to be larger than that in the copolymers AB-2 and ABC-2. In other words, multi-block structure of the copolymer ABC-1 can be concluded from DLS results.

Fig. 5

On the other hand, minimum hydrophobicity and hydrophobic intermolecular aggregation was observed for a copolymer with a minimum F_{BA} value and random copolymer structure, i.e. copolymer ABC-2. Therefore, minimum R_h value is expected for sample ABC-2 (Fig. 5). The higher the hydrophobicity and hydrophobic intermolecular aggregation of the copolymers is, the higher the R_h value will be. Fig. 5 shows almost the same R_h value for copolymers AB-2, ABC-1 and ABC-3; which is lower than that of copolymer AB-1 (micellar method). N_H value of copolymer ABC-1 is theoretically expected to be almost two times higher than that of copolymer AB-1 (Table 2); however, F_{BA} value of copolymer ABC-1 is much lower than that of copolymer AB-1. As already mentioned, CMC value of the SDS decreases significantly in the presence of Cloisite Na^+ [32,33], resulting in the decreased value of the N_H (see Eq. (5)). Therefore, experimental N_H value is lower than theoretical one in the copolymer ABC-1. Moreover, clay layers located on the surface of micelles can prevent entrance of the growing macroradicals into the micelles [31]. Then, decrease in the F_{BA} value of reaction ABC-1 is reasonable [1,2]. By comparing R_h values and intermolecular aggregations obtained for copolymers AB-1 (micellar method), AB-2 (heterogeneous

method) and ABC-3 (with Cloisite 30B), one may conclude that copolymerization of AM and BA can proceed simultaneously via both micellar and heterogeneous methods; however, micellar copolymerization is relatively predominant. It should be mentioned that when R_h values are compared, molecular weight of the copolymers should also be considered. DLS results are consistent with those observed from water solubility test and viscosity measurement.

Morphology of the Polymer/ Clay Nanocomposites

XRD analyses were used to investigate distribution states of the Cloisite Na⁺ or Cloisite 30B in the copolymer matrix. Results obtained from XRD patterns are given in Table 4, indicating basal spacing (d_{001}) of 13.0 and 18.7 Å for pure Cloisite Na⁺ and Cloisite 30B, respectively. Basal spacing of Cloisite 30B is greater than that of Cloisite Na⁺ due to the intercalation of galleries by organic modifier. Value of d_{001} in the copolymerization with Cloisite Na⁺ has increased from 13.0 Å for pure Cloisite Na⁺ to 22.1 and 21.2 Å for nanocomposites ABC-1 and ABC-2, respectively. It means that hydrophilic copolymers produced have been intercalated and located between the interlayer spaces of hydrophilic Cloisite Na⁺ under drying of the reaction mixture. It is reasonable because strong interaction between the polymer chains and clay is expected. On the other hand, as expected, no significant increase in the basal spacing of nanocomposite ABC-3 was observed. Slightly increase in the basal spacing may be attributed to entering macroradicals into the some Cloisite 30B galleries; however, its contribution is not significant. Hence, among two different mechanisms of copolymerization with Cloisite 30B discussed in the previous section, micellar mechanism seems to be relatively dominant.

Table 4

To further investigate its structure, nanocomposite ABC-2 was subjected to the TEM analysis

and the corresponding micrographs are shown in Fig 6. The clay layers appear as dark strips while the polymer matrix appears as a gray/white domain [26]. It is clear from this image and XRD results that silicate layers are dispersed with a thickness of about 2-25 nm in the polymer matrix, indicating that both exfoliated and intercalated morphology may be formed, however, intercalated structure is dominant.

Fig. 6

Aqueous Solution Viscosity of the AM/BA copolymers

Effect of Copolymer Concentration

Copolymers purified and separated from clay as well as those synthesized in the previous work [13] were used in the viscosity measurements by the Ubbelohde viscometer under various conditions. Fig 7 shows aqueous solution reduced viscosity (η_{red}) as a function of the copolymer concentration at the constant temperature of 25 °C. Regardless of the random or block distribution of the BA in the copolymer chains, η_{red} increased for all copolymers by increasing the copolymer concentration. The similar trend has been observed for various hydrophobically associating polymers [2,4]. This behavior can be attributed to the interchain associations by increasing the polymer concentration, forming a polymer chains network with a larger hydrodynamic volume. In the very low concentration, on the other hand, intrachain hydrophobic association is preferred. Maximum and minimum values of η_{red} were observed for copolymers AB-2 and ABC-1, respectively. It can be attributed to the effect of molecular weight on the viscosity (Table 3). It has been found experimentally for PAM homopolymer in the aqueous solution that viscosity (η) varies as almost M^4 for $M > 5 \times 10^5 \text{ gmol}^{-1}$, where M is the molecular weight, and polymer concentration greater than 2 wt% [37], indicating that when the molecular weight is just increased by 20%, the viscosity is doubled. This effect should be enhanced for the HMPAMs.

For copolymers synthesized with clay, maximum η_{red} value was observed for copolymer ABC-3. It may be attributed to the higher molecular weight of copolymer ABC-3 in comparison with the copolymers ABC-1 and ABC-2 as well as to the multiblock microstructure of the copolymer ABC-3 in comparison with the copolymer ABC-2. Therefore, one can conclude that both molecular weight of the copolymer and interchain aggregation of the hydrophobic groups can affect the aqueous solution viscosity of the hydrophobically associating copolymers.

Fig. 7

Effect of NaCl Concentration

η_{red} values as a function of NaCl concentration are given in Fig. 8 where copolymer concentration and temperature were kept constant at 0.2 wt% and 25 °C, respectively. Usually for polymers such as anionic PAMs, aqueous solution viscosity decreases with salt concentration and ionic strength. For all copolymers synthesized by different methods of micellar, heterogeneous and with clay, the almost similar trend of increase in η_{red} with salt concentration can be observed from this figure, however, a significant increase was observed for copolymer AB-1 with a multiblock microstructure having long BA block length. On the other hand, among three copolymers synthesized with clay, slope of increase in η_{red} with salt concentration is higher for a copolymer synthesized with Cloisite 30B, i.e. copolymer ABC-3. These observations can be attributed to the intermolecular aggregation of hydrophobic groups. This behavior is known to the “salting-out” effect [2] arising from change in solubility of hydrophobic units. Solubility of hydrophobic groups decreases by increasing salt concentration in the aqueous solution, resulting in the enhanced hydrophobic groups aggregation and increased viscosity [5-9,12].

Fig. 8

Effect of Temperature

Fig. 9 shows the effect of temperature on the η_{red} value at constant copolymer concentration of 0.1 wt% in the salt-free aqueous solution. It is clear from this figure that η_{red} decreases with temperature for all of the synthesized copolymers. The similar trend has been reported for the hydrophobically associating polymers [4,12,38]. It can be attributed to the weakening of hydrophobicity effect due to the increased mobility of the polymer chains [38]. With temperature, intermolecular interactions and physical networks weaken and thereby solubility of the polymer in the solvent (water in the present case) increases, resulting in the decreased η_{red} . Decrease in the viscosity of copolymer AB-2 was significant. It can be attributed to the random microstructure of copolymer where intermolecular hydrophobic aggregation is easily weakened and broken with temperature. When temperature raised to 80 °C, η_{red} value of random copolymer AB-2 decreased to a value close to that of copolymer ABC-3, indicating that hydrophobically associating polymers with multi-block structures can be used as an efficient rheology modifier at elevated temperatures. By considering all results, one can conclude that copolymerization of BA and AM in the presence of Cloisite 30B may results in a multi-block microstructure with BA block lengths shorter than that of copolymer AB-1 (i.e. $s < y$) (Fig. 2).

Fig. 9

Conclusion

Random and multi-block copolymers of AM and BA were successfully synthesized via free radical aqueous solution copolymerization in the presence of Cloisite Na⁺ and Cloisite 30B, respectively. Microstructural characteristics such as the molecular weight, copolymer composition and hydrophobic intermolecular aggregations were investigated by various techniques and results were compared with those obtained for copolymers prepared by heterogeneous and micellar methods in the previous work [13]. Molecular weight of the

copolymers decreased in the presence of nanoclays, showing that chain transfer reactions occur between the propagating macroradicals and species such as hydroxyl groups on the surface of nanoclays. Maximum and minimum values of F_{BA} (and thereby hydrophobicity values) were deduced from corresponding ^1H NMR spectra for the copolymers AB-1 and ABC-2, respectively, with multi-block and random, respectively, microstructures. Water solubility of the synthesized copolymers showed significant differences between the multi-block and random microstructures. Results obtained by DLS measurements indicated that intermolecular aggregations of the hydrophobic groups can also be found even in the dilute polymeric solutions. It was found from reduced viscosity measurements of the copolymers in the aqueous solution that BA- modified polyacrylamides especially those with a multiblock structure (i.e. copolymers AB-1 and ABC-3) are salt resistant and thermally stable, allowing us to use these copolymers as an efficient thickening agent of the aqueous solutions with a high salinity at elevated temperature. This behavior was attributed to the intermolecular aggregation of the hydrophobic BA units. Results showed that both the molecular weight and intermolecular aggregations of the HMPAMs should be considered to evaluate their rheological properties. XRD and TEM revealed intercalated structure as a dominant structure of the nanocomposites. Intercalation of clay was significant for a reaction performed with Cloisite Na^+ while intercalation of the Cloisite 30B was not remarkable. It was concluded that aqueous solution copolymerization of the AM and BA in the presence of Cloisite Na^+ proceeds similar to the heterogeneous mechanism with additional barrier effects of the clay on the BA diffusion from droplets to the aqueous phase and entrance of the propagating macroradicals into the BA droplets, while that in the presence of Cloisite 30B proceeds simultaneously with both the heterogeneous and micellar mechanisms but with a relatively high tendency toward micellar method. This work revealed that microstructure of the HMPAMs can be controlled using nanoclay, instead of SDS, as an additive. Before addition

of the initiator to the reaction mixture, Cloisite 30B was allowed to intercalate with BA for 1 h. It seems that long time dispersion of the Cloisite 30B with the BA or any other hydrophobic (meth)acrylate in the aqueous solution prior to the polymerization [22-24] may increase contribution of the micellar mechanism in the copolymerization of AM and (meth)acrylates.

Figure 2. Schematic representation of the free radical aqueous solution copolymerization of AM and BA in the presence of various additives and possible microstructures of the produced copolymers

Figure 3. ¹H-NMR spectra of AM/BA copolymers prepared under various conditions (Table 1) in the D₂O solvent along with assigning peaks to the corresponding protons

Figure 4. Proton-decoupled ¹³C-NMR spectra recorded for copolymer ABC-3 in the D₂O solvent along with assigning peaks to the corresponding carbons

Figure 5. Number distribution (a) and intensity distribution (b) of copolymer coils and BA intermolecular aggregates versus size obtained from DLS analysis of the dilute aqueous solution

Figure 6. TEM micrographs with different magnifications of the copolymer/Cloisite Na⁺ nanocomposite prepared by reaction ABC-2

Figure 7. Aqueous solution reduced viscosity (η_{red}) as a function of AM/BA copolymer concentration at constant temperature of 25 °C

Figure 8. Effect of NaCl concentration on the aqueous solution reduced viscosity (η_{red}) of various synthesized copolymers with a constant concentration of 0.2 wt% at 25 °C

Figure 9. Temperature dependence of the aqueous solution reduced viscosity (η_{red}) of various copolymers at the constant copolymer concentration of 0.1 wt%

Table 1. Details of reaction recipes for free radical aqueous solution copolymerization of AM and BA as well as water solubility of the synthesized copolymers^a

Exp. No.	Cloisite		SDS (g)	Conv. (%)	Water Solubility ^b	Method
	Na ⁺ (g)	30B (g)				
ABC-1	0.6	-	0.6	78	+	With SDS and Cloisite Na ⁺
ABC-2	1.2	-	-	71	++	With Cloisite Na ⁺
ABC-3	-	1.2	-	74	++	With Cloisite 30B

a) All reactions were performed with 1.056 g (93 mol%) and 0.144 g (7 mol%) of AM and BA, respectively. KPS amount was kept constant at 0.05 %wt relative to the aqueous phase. Total monomer concentration was selected to be 3 %wt relative to the aqueous phase.

b) Excellent solubility (++) and good solubility (+).

Table 2. Mole fraction of the AM and BA in the initial reaction mixture and produced copolymer along with the theoretical N_H values

Exp. No.	f_{AM}	f_{BA}	F_{AM}	F_{BA}	N_H
ABC-1	0.93	0.07	0.966	0.034	33.8 ^a
ABC-2	0.93	0.07	0.984	0.016	-
ABC-3	0.93	0.07	0.941	0.059	-

a) Theoretical N_H for experiment ABC-1 was calculated according to the previous work [13] by only considering the amount of SDS in the initial reaction mixture. It should be mentioned that interactions between the SDS and Cloisite Na^+ can change ability of SDS molecules to form micelle [31-33].

Table 3. Results of intrinsic viscosity, Huggins equation coefficient and molecular weight obtained for various AM/BA copolymers at 0.1 M NaCl aqueous solution and temperature of 25 °C

Sample	$[\eta]$ (mLg ⁻¹)	K_H	$M_w \times 10^6$ (gmol ⁻¹)
ABC-1	161.1	1.14	0.444
ABC-2	281.8	0.84	0.937
ABC-3	343.0	0.54	1.22

Table 4. Results obtained from XRD patterns for pure Cloisite Na⁺, Cloisite 30B and polymer/ clay nanocomposites synthesized vi free radical aqueous solution copolymerization of AM and BA with Cloisite Na⁺ or Cloisite 30B

Sample	Nanoclay used	Peak angle [2 θ (°)]	Basal spacing (d ₀₀₁)(Å°)
Cloisite Na ⁺	-	7.897	13.0
Cloisite 30B	-	5.499	18.7
ABC-1	Cloisite Na ⁺	4.643	22.1
ABC-2	Cloisite Na ⁺	4.830	21.2
ABC-3	Cloisite 30B	4.999	20.5
