This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Intermolecular carbene S-H insertion catalysed by engineered myoglobin-based catalysts

Vikas Tyagi, Rachel B. Bonn, and Rudi Fasan*

The first example of a biocatalytic strategy for the synthesis of thioethers via an intermolecular carbene S−H insertion reaction is reported. Engineered variants of sperm whale myoglobin were found to efficiently catalyze this C−S bond forming transformation across a diverse set of aryl and alkyl mercaptan substrates and α-diazoester carbene donors, providing high conversions (60-99%) and high numbers of catalytic turnovers (1,100-5,400). Furthermore, the enantioselectivity of these biocatalysts could be tuned through mutation of amino acid residues within the distal pocket of the hemoprotein, leading to myoglobin variants capable of supporting asymmetric S−H insertions with up to 49% ee. Rearrangement experiments support a mechanism involving the formation of a sulfonium ylide generated upon attack of the thiol substrate to a heme-bound carbene intermediate.

Introduction

The development of biocatalysts to execute synthetically valuable transformations not encountered in nature represents a key step toward the implementation of environmentally benign processes for organic synthesis.1 Catalytic methods for the selective formation of carbon-sulphur bonds are of particular interest as these bonds occur in a large number of natural and synthetic molecules with relevant biological activity, including an important fraction (~20%) of marketed pharmaceuticals.2 A most direct approach for the construction of C−S bonds is through the insertion of carbene species, typically generated via the transition metal-catalyzed decomposition of diazo reagents, into the S−H bond of a mercaptan.3 In recent years, a number of transition metal catalysts, including copper 4, rhodium 5, iron 6 and ruthenium 7 complexes, have proven useful in the context of this reaction. Despite this progress, these systems are not devoid of limitations, which include moderate catalytic efficiencies and the requirement for slow addition of the diazo reagent to the reaction mixture in order to minimize undesirable side reactions. In addition, realizing the asymmetric insertion of carbene species into S−H bonds have proven particularly challenging, with low degrees of enantioselectivity (<25% ee) typically being observed in most cases5b,6b,7b, with a few notable exceptions.4c,5a In contrast to the remarkable efforts made in the context of carbene S−H insertions using synthetic catalysts, there are no currently reports of natural or engineered enzymes capable of promoting this synthetically important transformation.

Our group and others have recently begun to explore the potential of cytochrome P450s and other heme-containing proteins as biocatalytic platforms for mediating ‘non-native’ carbene and nitrene transfer reactions.5b,6b,7b,8b In particular, we recently discovered that myoglobin and engineered variants thereof can promote the insertion of α-diazo-ester-derived carbones into C=C double bonds (cyclopropanation) and into N−H bonds with high catalytic efficiency and in the case of the latter, also with excellent levels of diastereo- and enantioselectivity.5b,6b These results prompted us to investigate the reactivity and scope of these myoglobin-based catalysts toward carbene S−H insertion. Here, we report that engineered variants of sperm whale myoglobin can efficiently catalyze this C−S bond forming reaction across a broad range of aryl and aliphatic mercaptans as the substrates and across different α-diazo esters as the carbene donors. Furthermore, our studies show that the activity and enantioselectivity of these hemoprotein-based catalysts can be tuned via active site mutagenesis and provide first insights into the mechanism of this myoglobin-mediated reaction.

Results and Discussion

In initial experiments, we investigated the activity of wild-type sperm whale myoglobin (Mb) toward catalyzing the insertion of ethyl α-diazoacetate (EDA, 2a) into the S−H bond of thiophenol (1) in aqueous buffer (KPi, pH 8.0) and in the presence of dithionite (Na2S2O4) as a reductant (Table 1). Promisingly, this reaction was found to lead to the desired S−H insertion product, ethyl α-(phenylthio)acetate (3), in 68% yield as determined based on GC analysis (Entry 1, Table 1). In the
course of optimization experiments, we established that nearly quantitative conversion of thiophenol to 3 (68 → 98%), and correspondingly higher catalytic turnovers (TON: 170 → 492), could be achieved using a two-fold excess of EDA over the thiol substrate at a catalyst loading of 0.2 mol% (Entry 3, Table 1, Figure S1). Notably, comparable yields in this transformation have been obtained using transition metal complexes at 5- to 25-fold higher catalyst loadings (i.e., 1-5 mol%),4c,5b,5d Further, no formation of the dimerization byproducts, ethyl maleate and fumarate, was observed in these myoglobin-catalyzed reactions in spite of the presence of excess EDA and mixing of the reagents in a single addition (Figure S1). This result is in contrast with the slow addition protocols typically required to avoid this side reaction in the context of transition metal-catalyzed S−H insertion processes.4c,5b,7

a Reaction conditions: 400 μL-scale reactions, 12 hours, room temperature, anaerobic conditions. b Relative to the limiting reagent and as determined based on GC conversion using calibration curves with isolated 3. Error is within 15%.

Time-course experiments showed that the Mb reaction with thiophenol and EDA was close to completion (94%) after 6 hours, with 68% of the S−H insertion product being formed within the first hour (Figure S2). These experiments also indicated that under these conditions the catalytic turnovers of the hemoprotein are limited by the concentration of thiophenol. By lowering the protein concentration, higher TON values were indeed observed (Entries 4-5, Table 1), with Mb supporting a maximum of 985 turnovers at a catalyst loading of 0.05 mol%.

Investigation of the dependence of Mb activity on the reductant showed a decrease in TON as the dithionite concentration was lowered, suggesting that ferrous Mb is the catalytically active form of the protein. Importantly, significant levels of catalytic activity are still maintained in the presence of stoichiometric amounts of dithionite relative to the protein as compared to using an excess of reductant (220 vs. 492 TON; Table 1). Overall, these results are in line with our previous observations in the context of other Mb-catalyzed olefin cyclopropanation.11 In contrast to the latter, however, appreciable Mb-dependent S−H insertion activity was observed also in the absence of reductant (130 TON; Entry 7, Table 1). Even if not very efficiently for aromatic mercaptans, thiols have been shown to be able to reduce metmyoglobin to its ferrous form.9 Accordingly, the activity in the dithionite-free reactions could be explained based on the formation of small amounts of the catalytically active ferrous Mb upon reaction with thiophenol. As observed for cyclopropanation and N−H insertion, molecular oxygen was found to suppress Mb-dependent carbene S−H insertion reactivity, likely due to competition with the diazo reagent for binding to the heme center.

The observed S−H insertion activity supported by Mb is remarkable in light of the fact that thiols can readily coordinate the iron center in heme-containing proteins.9a,9b Efficient catalysis in these reactions is likely facilitated by the considerably lower affinity of these ligands for ferrous Mb as compared to metmyoglobin.9a To examine possible substrate-dependent inhibitory effects, the reactions with Mb, thiophenol, and EDA were repeated using a thiophenol concentration of 40 and 80 mM. Interestingly, the Mb catalyst was found to remain active under these conditions, although a concentration-dependent reduction in catalytic efficiency also became apparent (62% and 42% relative activity, respectively, compared to 10 mM thiophenol), suggesting a certain degree of substrate inhibition at increasing thiol concentrations.

Encouraged by the results obtained with wild-type Mb, we turned our attention to identifying engineered Mb variants with enhanced reactivity toward S−H insertion. In previous studies, we found that mutations at the level of the distal pocket could improve the activity (and selectivity) of this hemoprotein toward carbene transfer reactions.11,16b Accordingly, a panel of Mb variants carrying one and two active site mutations were screened for their improved ability to convert thiophenol into 3 in the presence of EDA as determined based on total turnover numbers (TTN). Gratifyingly, a number of Mb variants were found to exhibit greatly increased (> 2-fold) catalytic efficiency in this transformation (Figure 1). In particular, the single mutant Mb(L29A) and double mutant Mb(L29A,H64V) emerged as the most promising catalysts, yielding 2190 and 2680 TTN, respectively, as compared to the 985 total turnovers supported by wild-type Mb. Interestingly, a similar activity-enhancing effect for the L29A mutation was noted also in the context of Mb-catalyzed carbene N−H insertion.16b As discussed later, the beneficial effect of this substitution may be linked to its role in facilitating attack of the thiol (or amine) nucleophile to the heme-bound carbeneoid intermediate. Noteworthy is also the additive effect of the H64V mutation, whose introduction leads to a comparable increase in TTN (~20%) in both the wild-type Mb and the Mb(L29A) background. As

Figure 1. Total turnover numbers (TTN) supported by the different Mb variants for formation of conversion of thiophenol and EDA to 3. Reaction conditions: 2.5 μM Mb variant, 10 mM PhSH, 20 mM EDA, 10 mM Na₂S₂O₄ in KPi buffer (pH 8.0), 16 h.

This journal is © The Royal Society of Chemistry 2012
judged based on analysis of the available crystal structure of the sperm whale myoglobin,10 (Figure 2), this mutation is likely to enhance the catalytic efficiency of Mb by increasing the accessibility of the heme pocket to the diazo ester and thiol reactants, as noted in the context of other non-native reactions supported by this protein.11,16,20 The initial rate for Mb(L29A,H64V)-catalyzed formation of the S−H insertion product 3 was determined to be 35 turnovers per minute, which is lower than that observed for N−H insertion (740 min−1)3b and cyclopropanation (1000 min−1).11

Having identified Mb(L29A,H64V) as the most promising Mb-based catalyst for S−H insertion, further experiments were carried out to explore its scope across different aryl mercaptans (Scheme 1). To this end, variously substituted thiophenols (4−10) were subjected to Mb(L29A,H64V) catalysis (0.02 mol%) in the presence of EDA (2a). Notably, high to quantitative conversion (67-99%) to the desired S−H insertion products (11−15) were obtained starting from the para-substituted thiophenol derivatives 4−8, showing that electron-donating and electron-withdrawing substituents at this position are equally well tolerated by the protein catalyst. Similar results were obtained with the meta- and ortho-substituted thiophenols 9 and 10, respectively, although a certain influence of the ortho substitution on the efficiency of the reaction was also evident (60% vs. 86-96% conversion for 17 vs 11 and 16).

To further investigate the reactivity scope of Mb(L29A,H64V), the reactions with thiophenol were then performed in the presence of different types of α-diazo ester reagents, namely tert-butyl (2b), cyclohexyl (2c), and benzyl α-diazoacetate (2d). Importantly, formation of the respective S−H insertion products 18, 19, and 20 in 75-95% yields demonstrated the high degree of tolerance of the Mb-derived catalyst toward substitutions at the level of the ester group of the diazo reagent. Albeit in more moderate yield (32%), successful synthesis of 21 indicated that Mb(L29A,H64V) can also accept the α-substituted ethyl α-diazoacetate (2e) as a carbene donor. Altogether, the experiments outlined in Scheme 1 demonstrated the broad scope of the Mb(L29A,H64V) catalyst across different aryl thiol substrates and diazo reagents. Furthermore, repeating these reactions under low catalyst loading conditions (0.025 mol%) showed that Mb(L29A,H64V) support TTN values in excess of 1,300 in each case, yielding over 4,100 and 5,400 TTN in the reactions of thiophenol with 2a and 2c, respectively. These catalytic efficiencies are one to two orders of magnitude higher than those reported for similar S−H insertion reactions with transition metal catalysts.4,16,21

Scheme 1. Yields and total turnover numbers (TTN) for Mb(L29A,H64V)-catalyzed carbene S−H insertion with various aryl mercaptans and α-diazo esters. Reaction conditions: 10 mM thiol, 20 mM EDA, 10 mM Na2S2O4 with (a) 20 μM (0.2 mol%) and (b) 2.5 μM (0.025 mol%) hemoprotein, 16 hours. * Buffer added with 20% (v/v) methanol.

In order to assess the scalability of these Mb-catalyzed transformations, the synthesis of ethyl α-(phenylthio)acetate (3) from 1 and 2a was carried out at a larger scale (~11 mg reaction) in 67% isolated yield thus demonstrated the potential utility of these Mb-mediated reactions for synthetic purposes.

To determine whether the scope of Mb(L29A,H64V)-mediated S−H insertion could be extended to non-aromatic thiols, tests with benzylic and alkyl mercaptans as the substrates were carried out. In the presence of EDA, Mb(L29A,H64V) was found to readily functionalize benzylic mercaptan (22), substituted benzyl mercaptan derivatives (23−25), and alkyl mercaptans such as cyclohexanethiol (26) and octane-1-thiol (27), providing conversions in the range of 30-50% and supporting between 930 and 2,550 total turnover numbers (Entries 1-6, Table 2). Given the clear advantage of using 2c (or 2d) toward improving the TTN in the insertion reactions with thiophenol (Scheme 1), the Mb(L29A,H64V)-catalyzed transformations of benzyl (22) and cyclohexanethiol (26) were carried out also in the presence of 2d. Gratifyingly, higher yields (83-99%) and total turnovers (TON: 3-4,600) were
obtained in both cases (Table 2), further evidencing the good match between the Mb catalyst and these carbene donors.

Further improvements in the enantioselectivity of the Mb(F43V)-catalyzed insertion reaction could be then achieved through optimization of the thiol : diazo ester ratio and other reaction parameters such as pH and temperature (Entries 6-8, Table 3). Under optimal conditions (1 : 2e in 1 : 1 ratio, pH 7.0, 4°C), the S-H insertion product 21 was obtained with an enantiomeric excess of 49% (Figure S3), which corresponds to the highest enantioselectivity ever reported with a single-catalyst system and in the absence of exogenous additives. Taking together, these results support the amenability of the Mb scaffold to promote asymmetric carbene S−H insertions as well as the possibility to tune this property via active site engineering.

Depending on the nature of the transition metal catalyst, the insertion of carbenoids into Y−H bonds (where Y = O, N or S) has been proposed to involve either a concerted11 or stepwise mechanism10,12, the latter proceeding through a oxonium/ammonium/sulfonium ylide formed upon attack of the Y−H nucleophile to a metal carbened intermediate. To shed light into the mechanism of Mb-catalyzed carbene S−H insertion, trapping of the putative sulphur ylide intermediate in the reaction with Mb(L29A,H64V), thiophenol, and EDA, was first attempted via addition of diethyl azodicarboxylate (DEAD), as this approach have proven useful to reveal the occurrence of a stepwise mechanism in other systems.6a,13 However, only the conjugate addition product generated via direct attack of thiophenol to DEAD was observed. As an alternative approach, allyl(phenyl)sulfane 36 was made react with Mb(L29A,H64V) in the presence of EDA (Scheme 2). Interestingly, the only species generated in this reaction was the rearrangement product 38 (TON: 390), whose formation is consistent with the [2,3]-sigmatropic rearrangement of a sulfonium ylide intermediate6a,14 (37, Scheme 2). While this C−C forming transformation has synthetic value on its own right,15 its most relevant implication in the context of this work is that of supporting the occurrence of a step-wise mechanism for Mb-catalyzed carbene S−H insertion.

The development of catalytic systems for asymmetric carbene S−H insertions has proven remarkably difficult, with only low levels of enantioselectivity being observed in most cases (8-23% ee)10,5a,7b. In this regard, significantly better results (70-85% ee) have been more recently achieved by Zhou and coworkers using chiral spiro bis(oxazoline)-copper complexes, although these protocols involve high catalyst loadings (5 mol%) along with additives (6 mol% NaB(ArF)₃).14 Interestingly, the reaction of ethyl α-diazo-propanoate with thiophenol in the presence of wild-type Mb or Mb(L29A,H64V) showed that neither of these proteins was capable of providing chiral induction in the S−H insertion reaction (Entries 1-2, Table 3). In contrast, screening of the panel of Mb active-site variants revealed that both Mb(F43V) and Mb(F43V,V68A) showed appreciable enantioselectivity in this transformation (21-22% ee, Entries 3 and 5 in Table 3). Since Mb(V68A) exhibited only 6% ee, the beneficial effect in terms of enantioselectivity can be mainly attributed to the substitution at the level of Phe43, which is located in close proximity to the heme cofactor (Figure S2).
Based on these results and our previous studies, we propose a mechanism which involves the initial formation of a heme-bound carbene intermediate upon reaction of ferrous myoglobin with the α-diazo ester, followed by nucleophilic attack of the thiol to give a sulphur ylide (Scheme 3). The S–H insertion product would then ensue via a proton transfer to the latter intermediate either prior to (path ‘a’) or after dissociation from the heme (path ‘b’). Indirect evidence that the ylide may undergo protonation at the carbon center while remaining (at least in part) bound to the heme derives from the observed influence of active site substitutions on the enantioselectivity of the reaction in the presence of the α-substituted diazo ester 2e (Table 3). Indeed, complete dissociation of the ylide from the metal center would produce a racemic product. The latter process has been identified as a major factor contributing to the low enantioselectivity exhibited by transition metal catalysts in S–H insertion reactions. Based on these considerations, it is possible that, in addition to affecting the selectivity of the proton transfer step within the distal pocket, the F43V substitution may potentially improve the enantioselectivity of the reaction also by disfavouring dissociation of the sulphur ylide from the heme center. An alternative, albeit not exclusive scenario would entail that the selectivity-determining step is associated with the addition of the thiol nucleophile to the heme-carbene complex. In this case, the role of the protonation step in influencing the enantioselectivity of the reaction would be dependent upon the relative configurational stability of the heme-bound ylide.

While further studies are required to elucidate these steps in more details, the mechanistic model of Scheme 3 can already provide a plausible explanation for the effect of the L29A mutation toward enhancing the catalytic activity of the hemoprotein (Figure 1). Given its location in the active site (Figure 2), this substitution is expected to expand the distal cavity above the heme, thereby better accommodating the aryl/alkyl group of the thiol substrate after attack to the electrophilic carbene moiety group (R2 group, Scheme 3). Consistent with this hypothesis, the catalytic activity of wild-type Mb on the relatively bulky cyclohexanethiol (26) was found to be only ~10% that of the L29A-containing variants. In that regard, it is also instructive to note how the L29A mutation was beneficial for Mb-catalyzed N–H insertion in [2,3]-sigmatropic rearrangement of allyl sulphides (36 → 38) is another notable finding of this work and the scope of this transformation is currently under investigation in our laboratory.

Conclusions

Myoglobin has represented an attractive scaffold for biocatalyst development. This work demonstrates that engineered Mb variants constitute efficient systems for promoting carbene S–H insertion reactions, providing the first example of a biocatalyst capable of supporting this valuable transformation. These Mb-based catalysts were found to offer high catalytic activity (1,000-5,400 TON) across a wide range of aryl and alkyl mercaptan substrates as well as across different α-diazo esters as carbene precursors. Their potential utility for synthetic applications is further highlighted by proof-of-principle demonstrations of their amenability to catalyze asymmetric S–H insertions and of the scalability of these reactions. Initial insights into the mechanism of this reaction were gleaned through the present studies, which can provide a basis for further optimization of the activity and selectivity of these biocatalysts. Finally, the ability of these hemoproteins to catalyze the [2,3]-sigmatropic rearrangement of allyl sulphides is another notable finding of this work and the scope of this transformation is currently under investigation in our laboratory.

16 Consistent with this scenario, the use of a chiral Bronsted acid to intercept the free ylide has proven effective in greatly enhancing the enantioselectivity of carbene S–H insertions.44

17 The present scheme features the thiol nucleophile in its protonated form, which is predominantly populated by the alkyl and benzyl mercaptan substrates (pK<sub>a</sub> > 8.5-9) under the applied conditions (pH = 8.0). Given that the aryl mercaptan substrates are largely deprotonated at this pH (pK<sub>a</sub> < 6.5), the implication of an analogous mechanism in which a thiolate (R<sub>2</sub>S–) acts as the nucleophile in place of the protonated thiol (R<sub>2</sub>S–H) can be also envisioned.

18 Mechanistic similarities between N–H insertion and S–H insertion reactions have been found in the context of other catalytic systems.46
