Low-activated Li-Ion Mobility and Metal to Semiconductor Transition in CdP₂@Li Phases

N. Eckstein^a, I. Krüger^a, F. Bachhuber^b, R. Weihrich^b, J. E. Barquera-Lozada^c, L. van Wüllen^c, Tom Nilges^{*,a}

Solids with high ion mobility are of broad interest for energy storage applications. New systems featuring low-activated ion mobility are important to improve the performance in such systems. Herein we report on a model system dealing with such improved properties. Li_{0.2}CdP₂ was synthesized from the elements, lithium as structure stabilizer and CdI₂ as reaction promoters in sealed silica ampoules at 823 K. It crystallizes tetragonal, in space group $I 4_{1}22$ (a-CdAs₂ structure type), with lattice parameters a = 7.6691(8) Å, c = 4.4467(4) Å and V = 261.53(4) Å³. After 24 h of storage in air lithium ions can be removed in a spontaneous delithiation reaction resulting in Li(OH) · H₂O formation on the surface of the crystals. Formed α '-CdP₂ adopts the a-CdAs₂ structure type. Both compounds consist of isolated cadmium atoms and helical $\frac{1}{20}$ [P⁻]-chains generating empty channels suitable to accommodate Li ions. The heavy atom structure was determined by X-ray diffraction methods while a full model including Lithium was derived from a combined Solid State NMR and Quantum Chemical Calculation approach. An low activation barrier range in the order of 0.1 to 0.2 eV was determined by NMR spectroscopy pointing towards an extraordinary high Li mobility in Li_{0.2}CdP₂. Of course a Cd-based solid will have certain disadvantages like toxicity and mass for storage applications but substitution of Cd by suitable lighter elements can solve this issue.

Introduction

Phosphorus is an element with intriguing structure chemistry¹. In the case of Cd the reactivity is reasonable and binaries like CdP_2^{2-4} , $Cd_3P_2^{5-6}$, CdP_4^{7} , or $Cd_7P_{10}^{8}$ exist. Cd is a prominent element used in photo-semiconductors like $CdTe^9$ or Cd_3Pn_2 (with Pn = P, As)^{10,11} quantum dots for solar cell applications. While solar energy conversion applications are well established features for Cd pnictides and Cd chalcogenides due to their high electron mobility, the knowledge of ion mobility in Cd pnictides is rather small. Mixed ion and electron conducting compounds are potential candidates for batteries while pure ion conductors are also important as solid state electrolytes^{12,13}. Prominent solid ion conductors like garnet-type compounds show conductivities of 10^{-3} S cm⁻¹ at room temperature and activation energies of 0.3 eV¹⁴.

CdP₂ exists in two different modifications. At room temperature, α -CdP₂ crystallizes orthorhombic, in space group *Pna2*₁²⁻⁴ while a high temperature phase β -CdP₂ occurs above 693 K, adopting the space group *P*4₁2₁2³. The prominent structural feature in both cases is a helical ${}_{\infty}^{1}$ [P⁻]-chain coordinated to cadmium ions. A helical arsenic chain was detected in the compound α -CdAs₂, featuring the space group *I*4₁22¹⁵. An examination of the solid solution CdP₂-CdAs_s reveals a continuous series up to CdAs_{2-x}P_x with *x* = 1.8, where all representatives crystallize tetragonal, thus adopting the α -CdAs₂ structure type¹⁶. It has been reported in ¹⁶ that a cadmium polyphosphide in the α -CdAs₂ structure type could not be realized. Unfortunately, this α -CdAs₂ structure offers open channels ready for a coordination of mobile ions whereas such channels are not present in the known polymorphs.

Metal halides are prominent compounds to act as reaction promoters for the synthesis of kinetically stabilized materials and compounds adopting uncommon structure features¹⁷. This feature, called mineralizer principle from now on, can also be used to selectively synthesize element allotropes of phosphorus¹⁸. Recently, fibrous red phosphorus has been prepared by using $CuCl_2^{19}$ and orthorhombic black phosphorus can be realized by a SnI_4/Sn combination²⁰⁻²². This synthesis principle was used to synthesize the present compounds.

Herein we report on the synthesis, reactivity, quantum chemical characterization and ion mobility of $\text{Li}_{0.2}\text{CdP}_2$ and α '-CdP₂, featuring the end member of the solid solution CdAs_{2-x}P_x with x = 2.0. The mineralizer principle has successfully been adopted using CdI₂ as mineralizer agent.

Experimental section

Synthesis

Journal Name

Li_{0.2}CdP₂ was synthesized by reacting Li (Rockwood lithium, 99.9 %), Cd (Chempur, 99.9999 %) and red P (Chempur, 99.999+ %) in a molar ratio of 0.25:0.875:2 in evacuated graphitized silica ampoules. CdI₂ (25 mg), acting as mineralizer, was added to a total amount of 1 g starting materials. The mixture was heated up to 823 K within 12 h, kept for 7 d at this temperature, and slowly cooled down to room temperature within 12 h afterwards. Li_{0.2}CdP₂ was obtained as a black powder. Impurities of cadmium or iodide were never detected the final products.

 $Li_{0.2}CdP_2$ can also be prepared from the elements in ideal ratios (Li:Cd:P = 0.2:1:2) without a mineralizer, resulting in a microcrystalline black powder, but only with sparse crystals. The exchange of the mineralizer from CdI₂ to another mineralizer like CuCl₂ resulted in completely different products. Cd_3P_2 and crystals of LiP₁₅ have been identified after phase analysis. Impurities of copper or chlorine were neither detected in Cd₃P₂ nor in LiP₁₅ fractions.

 α '-CdP₂ can be prepared from Li_{0.2}CdP₂ by a de-lithiation process upon exposing it to moist air. A white powder is formed on top of the needle-shaped Li_{0.2}CdP₂ crystals, after 24 h of exposure. After dissolution of the white powder in water Li₂CO₃ was found as main phase after removal of the solvent, substantiating the Li extraction from Li_{0.2}CdP₂. A full delithiation takes place after four weeks (Results and discussion section).

EDS and ICP Analyses

Semi-quantitative EDS analysis was performed using a SEM 5900LV spectrometer (JEOL) scanning electron microscope equipped with an INCA energy dispersive microanalysis system (Oxford Instruments). An acceleration voltage of 30 kV was used for the measurements. Another system we used was a desktop scanning microscope JCM 6000 NeoScopTM (JEOL) equipped with an energy dispersive X ray unit (JED 2200 JEOL). An acceleration voltage of 15 kV was applied for the measurements. The ICP analysis were performed using an Agilent Technologies (Santa Clara, CA) model 725 Series ICP OES instrument, equipped with an Echelle optics (model Vista/7XX ES), a monochromator (model Variant Liberty) and a CCD sensor (modelVista Pro 720/725_ES, resolution < 0.01 nm). Data analysis was done by the program ICP Expert II for Agilent 725 ES ICP OES.

X ray single crystal diffraction

Li_{0.2}CdP₂ was stored and treated in an argon filled glovebox, while α '-CdP₂ was kept in air for 7 d and subsequently washed with water to remove Li(OH) • H₂O on the surface. Single crystals of Li_{0.2}CdP₂ were sealed in a 0.3 mm glass capillary prior to the measurement. Data were collected on a Bruker APEX II diffractometer equipped with a D8 goniometer (MoK α radiation, $\lambda = 0.71069$ Å, graphite monochromator, rotating anode source) at 123 K. The frames were integrated with the Bruker SAINT software package²³ using a narrow frame algorithm. Numerical absorption correction was done employing the SADABS routine²⁴. A suitable single crystal of The space group $I4_122$ was assigned on the basis of systematic absent reflections and the statistical analysis of the intensity distributions. The structure was solved using the superflip routine ²⁶ implemented in the Jana2006 program suite²⁷.

X-ray powder diffraction

For the X ray powder diffractometer analysis the sample kept under argon (Li_{0.2}CdP₂) and the sample on air (α '-CdP₂) were ground and sealed in glass capillaries. Powder XRD data were collected with a STOE STADI P X-ray powder diffractometer equipped with a DECTRIS Mythen 1K Detector using Cu K α_1 radiation ($\lambda = 1.54051$ Å, curved Ge (111) monochromator). An external calibration was performed with Si (a = 5.43088 Å). Data were collected from 10.03° to 119.755° 20. The XRD pattern was fitted using the Rietveld routine implemented in the program Jana 2006²⁷.

Electronic structure calculations

The first-principles calculations were carried out within the framework of DFT with exchange-correlation functionals in the generalized gradient approximation (GGA)^{28,29} according to Perdew Burke Enzerhof (PBE)³⁰ and in the local density approximation according to Perdew and Zunger (LDA)³¹. Full geometry optimizations were executed with the Vienna Ab initio Simulation Package (VASP)32,33. All atomic site parameters and cell constants were allowed to fully relax with the conjugant gradient algorithm. The interactions between the ions and the electrons are described by the projectoraugmented-wave (PAW) method³⁴ with a cut-off energy of 500 eV. All calculations were performed in several subsequent steps with increasing k-grid meshes (depending on the size of the unit cell) between 2 x 2 x 2 and 12 x 12 x 12 to reach sufficient accuracy. A structure optimization was considered to be converged with a difference in total energy of less than $1 \ge 10^{-6}$ eV and a maximum Hellmann-Feynmann force of 1 x 10⁻⁴ eV/Å. The final values of the total energies of the investigated systems were obtained with energy differences (between last and second to last step) of less than 1×10^{-3} eV per formula unit.

Solid State NMR

Experiments were performed on a Bruker Advance III spectrometer operating at 7 T with resonance frequencies of 116.6 MHz, 121.5 MHz and 300.13 MHz for ⁷Li, ³¹P and ¹H, respectively. A Bruker 4 mm WVT MAS probe was used for the experiments. The $Li_{0.2}CdP_2$ sample was handled in a glovebox and dry N₂ was employed for spinning and cooling the sample. Static ⁷Li NMR spectra were recorded in the temperature range 117 K < T < 561 K employing single pulse excitation and the solid echo pulse sequence for data

Journal Name

acquisition. For the ⁷Li T₁-NMR measurements, the inversion recovery sequence was used. The temperature was calibrated employing the chemical shift of Pb(NO₃)₂ as a chemical shift thermometer.^{35,36 31}P MAS NMR and ⁷Li MAS NMR spectra were recorded employing spinning speeds of 8-12 kHz using the Bruker system. Additional spectra at higher spinning speeds (up to 35000 Hz) for ¹H and ³¹P were acquired on a Varian DMR2 NMR spectrometer operating at 11,7 T using a Varian T3 MAS 1.6 mm NMR probe. Spectra are referenced as usual employing TMS for ¹H, 1 M LiCl for ⁷Li and 85 % H₃PO₄ for ³¹P.

Differential scanning calorimetry (DSC)

Finely ground samples of phase pure $Li_{0.2}CdP_2$ (8.8 mg) and α '-CdP₂ (9.0 mg) were transferred to aluminum crucibles and were measured with a rate of 10 K/min using a Netzsch DSC 200 F3 Maja machine. H₂O, In and Zn were used as standards for temperature calibration. All measurements were performed under N₂ atmosphere. No thermal effect was found in the temperature range from 123 K to 373 K for $Li_{0.2}CdP_2$. α '-CdP₂ cannot be transferred to α -CdP₂ or β -CdP₂ up to 673 K.

DC Conductivity measurements

Total electric conductivities of $Li_{0.2}CdP_2$ and $\alpha'-CdP_2$ have been measured using a homemade tool, which is capable to measure pressurized powdered samples (200 MPa, up to 2 mm height and 6 mm diameter) with a scale for measuring the height of the compressed powder. With a potentiostat (VMP-3, Biologic), a voltage of up to 10 V is applied to the compressed powder and the resulting current is measured. This unconventional procedure was necessary because a stable and dense pellet for impedance measurements could not be made from powdered samples in both cases. Temperature dependent conductivity measurements on single crystals are currently underway.

Results and discussion

CdP₂ shows polymorphism with two known polymorphs, a low temperature α -CdP₂ adopting the space group $Pna2_1^{2-4}$ and a high temperature β -phase stable above 693 K, crystallizing in space group $P4_12_12^{-3}$. A brief overview of the two CdP₂ structures is given in Figure 1a and 1b.

The main difference is the arrangement of ${}_{\infty}^{\infty}[P^-]$ -chains parallel and perpendicular towards each other featuring alternating P-P bond lengths. α -CdAs₂ contains a ${}_{\infty}^{1}[As^-]$ -chain (see Figure 1c) with no bond length alteration and a slightly different arrangement of the Cd substructure than observed in α -CdP₂. Surprisingly, a α -CdAs₂-type CdP₂ polymorph does not exist till now - a solid solution α -CdAs_{2-x}P_x has only been realized up to x = 1.8 ¹⁶. We therefore started systematic investigations to close this gap to x = 0.2 and call this new phase α '-CdP₂ from now on.

All our attempts to prepare α '-CdP₂, either from the elements directly or by the mineralizer principle using CdI₂ or CuCl₂, failed. CdP₄, Cd₃P₂ and β -CdP₂ were found instead. If lithium was added in small portions as starting material, $Li_{0.2}CdP_2$, adopting the α -CdAs₂ structure type, was found.

Figure 1. Crystal structures of a) α -CdP₂ in the space group *Pna*2₁ (No. 33), b) β -CdP₂ in the space group *P*4₁2₁2 (No. 92), c) \mathbb{D} -CdAs₂ in the space group *I*4₁22 (No. 98) and d) Li_{0.2}CdP₂ in space group *I*4₁22 with displacement parameters at 90 %. Li could not be detected during the structure refinement and was therefore determined from quantum chemical calculations. All structures possess helical pnictide chains. Cadmium atoms are drawn as cyan, phosphorus atoms as purple, and arsenic atoms as white spheres. Li channels are marked with arrows.

Structural characterization and elemental analysis of Li_{0.2}CdP₂

Single crystals of Li_{0.2}CdP₂, separated from a batch with the nominal composition x = 0.125, have been used to perform a single crystal X-ray structure determination. An executed neutron scattering experiment of microcrystalline Li_{0.2}CdP₂ has also been performed, but due to the large neutron absorption cross section of $\sigma_a = 2520$ b, it was not possible to derive any structural parameters from that data.

Li_{0.2}CdP₂ crystallizes tetragonal, isostructural to α -CdAs₂, in space group *I*4₁22, with *Z* = 4. The lattice parameters (*a* = 7.6691(8) Å, *c* = 4.4467(4) Å and *V* = 261.53(4) Å³; [*c/a* = 0.5798]) are taken from the powder analysis. Displacement parameters of Cd are slightly anisotropic, pointing towards a possible symmetry reduction. We found no evidences for a loss of the 4₁ symmetry which would directly lead to a bond length variation within the P substructure. Also a loss of centering was checked but could not be confirmed. The selected symmetry was crosschecked by X-ray powder phase analysis including Rietveld refinements (see Supplement).

The cadmium atoms are located on 4*a* position (0, 0, 0) while phosphorus occupies 8*f* (0.42546(9), 0.25, 0.125). Li could not be localized in this case. Even at 123 K we were not able to locate Li in the structure (see Supplement). This arrangement of heavy atoms leads to four channels per unit cell along the *c*-direction, of which two of them are filled with a helical ${}_{\infty}^{1}[P^{-}]$ -chain (Figure 1d). The bond length observed within the helical ${}_{\infty}^{1}[P^{-}]$ chain is d(P-P) = 2.2040(6) Å, lying within the expected range for covalently bonded phosphorus (2.14 – 2.30 Å)¹. The Cd-P bond length of 2.6043(4) Å represents a The composition and exact Li-content was determined from Ii single crystals by ICP-OES resulting in $\text{Li}_{0.20(3)}\text{Cd}_{0.90(5)}\text{P}_{2.00(3)}$ A (or Li:Cd:P = 6.43:28.93:64.64 in at-%). This finding is close to d the expected composition but features a slightly reduced Cd q content. An EDX analysis substantiated the 1:2 ratio of the F heavy atoms. As shown later on by quantum chemical calculations, NMR spectroscopy, and phase analysis the $\text{Li}_{0.2}\text{Cd}_{1.0}\text{P}_2$ composition was substantiated. In the following, we use the idealized composition $\text{Li}_{0.2}\text{CdP}_2$ for further discussions. **Lithium mobility in Li_{0.2}CdP_2** Due to the high Li mobility (see later on) we tried to localize Li a but other methods, then contrained to be a substantiated of the substantiated is a substant

well suited value reported for many cadmium polyphosphides. Examples are α -CdP₂ (d(Cd-P) = 2.495(15) to 2.627(15) Å)⁴ or

 Cd_7P_{10} (d(Cd-P) = 2.49 to 2.85 Å)⁸. The distances between

neighbored cadmium atoms are close to 4 Å. A section of the

crystal structure of Li_{0.2}CdP₂ is given in Figure 1d.

by other methods than scattering techniques. We therefore decided to do quantum chemical model calculations and temperature dependent Solid State NMR spectroscopy to evaluate the most probable position within the structure and to check for Li mobility in the present system.

A first hint for a high Li ion mobility is the reasonable reactivity of $Li_{0.2}CdP_2$ against humid air. If $Li_{0.2}CdP_2$ is stored in air for 24 h, a white powder can be observed on the surface being identified as $Li(OH) \cdot H_2O$. Details are given in the supplement. Assuming simple exchange reactions the formation of $Li(OH) \cdot H_2O$ is explainable.

On the crystal surface:

 $\begin{array}{cccc} 10 \text{ x } 0.2 \text{ Li}^{+}(\text{Li}_{0.2}\text{CdP}_2) + \text{H}_2\text{O}(\text{air}) \xrightarrow{\rightarrow} 2 \text{ LiOH} + 2 \text{ H}^{+} \\ \text{LiOH} + \text{H}_2\text{O} & \xrightarrow{\leftarrow} & \text{Li}(\text{OH}) \cdot \text{H}_2\text{O} \\ \text{LiOH} + \text{H}^{+} & \xrightarrow{\rightarrow} & \text{Li}_2\text{O} + \text{H}_2\text{O} \end{array}$

After dissolution and removal of water on air:

 $2 \operatorname{Li}^{+} + 2 \operatorname{OH}^{-} + \operatorname{CO}_2 (\text{from air}) \rightarrow \operatorname{Li}_2 \operatorname{CO}_3 \checkmark + \operatorname{H}_2 \operatorname{O}$

Driving force for this de-lithiation reaction is the formation of a Lithium compounds on the surface of the crystals. A possible proton exchange has been addressed by NMR spectroscopy. The proton content was determined as $H_{0.050(5)}CdP_2$ (see Supporting Information).

Structural characterization and elemental analysis of *a*'-CdP₂

Carefully washed α '-CdP₂ crystals were subject of a single crystal structure determination. The α -CdAs₂ structure type has been confirmed (see Supplement) but slightly larger lattice parameters have been observed as for Li_{0.2}CdP₂. Lattice parameters of a = 7.6829(2) Å, c = 4.46036(11) Å and V = 263.279(12) Å³ [c/a = 0.581] have been derived from the scattering data, being 0.3 % larger than for the lithiated compound. The effect is not drastic but outside the 3σ criteria for all lattice parameters. Bond length of d(P-P) of 2.2104(10) Å (d(P-P) = 2.2040(6) Å in Li_{0.2}CdP₂) and d(Cd-P) of 2.6102(3) Å (d(Cd-P) = 2.6043(4) Å in Li_{0.2}CdP₂) resulted.

 α '-CdP₂ can be regarded as an electron precise compound with Cd²⁺ ions and two-bonded (2b)P⁻, resulting in Cd²⁺(P⁻)₂

An ICP analysis of the carefully washed black crystals after full de-lithiation resulted in $Cd_{0.89(3)}P_{2.00(3)}$. Li can be extracted quantitatively from $Li_{0.2}CdP_2$ by storage on air to form CdP_2 . Following the notation we called the new phase α '-CdP₂ to illustrate the close relationship but also significant difference to α -CdP₂.

Quantum chemical calculations

Band structure calculations and DOS representations were performed for $\text{Li}_{0.2}\text{CdP}_2$ and its de-lithiated form α '-CdP₂. Li positions in $\text{Li}_{0.2}\text{CdP}_2$ were determined by a supercell approach and localized within the empty channels along the crystallographic *c*-axis. While α '-CdP₂ is destabilized in relation to known α -CdP₂ and β -CdP₂, a substantial stabilization is found for a Li incorporation into the empty channels (see Figure 3 and supplement). Substitution of Cd by Li does not lead to a significant stabilization effect and can be ruled out.

Figure 2. Cell volumes of the solid solution $CdAs_{2,x}P_x$ derived from literature [16] for 0 < x < 1.8 and from single-crystal X-ray experiments for x = 2. A Vegard-like³⁸ decrease of the cell volume is observed up to the maximum P content of x = 2.

Li_{0.2}CdP₂ is metallic featuring a pseudo band gap 0.9 eV below the Fermi level (see Figure 3). In contrast, α '-CdP₂ is a semiconductor with a calculated band gap of 0.77 eV (LDA) and 0.71 eV (GGA). Total conductivity measurements of microcrystalline $Li_{0.2}CdP_2$ (10⁻⁵ S/cm) and α '-CdP₂ (10⁻⁹ S/cm) exhibit a difference of four orders of magnitude at room temperature, nicely reflecting the different electronic structures. The present conductivity values from powdered samples cannot be more than a first hint due to the extreme sensitivity of the samples against mechanical stress. This feature causes disintegration of the structure upon grinding prior to the measurements. Temperature dependent conductivity measurements on single crystals are currently underway.

Journal Name

Obviously, the intercalation of Lithium ions into the host structure leads to the closure of the band gap and the occurrence of a metal to semiconductor transition. Upon intercalation of Li into α '-CdP₂, 0.2 electrons are located in the conduction band and the band gap vanishes. The integrated DOS (i-DOS) between the Fermi level and the pseudo gap of Li_{0.2}CdP₂ corresponds to 0.2 electrons, in good accordance with the expected value from the formula sum (black area in Figure 3).

Figure 3. 0 K energies calculated by LDA and GGA for existing α - and β -CdP₂, α' -CdP₂ and Li_{0.2}CdP₂ (top). Band structure representation and total Density of States (DOS) for Li_{0.2}CdP₂ and α' -CdP₂. The integrated DOS within the black area represents 0.2 electrons, in good accordance with the Li content in Li_{0.2}CdP₂.

Solid state NMR spectroscopy

The ³¹P-MAS-NMR spectra for α '-CdP₂ and Li_{0.2}CdP₂ are compiled in Figure 4. In accordance with the crystal structure, we find a single phosphorous site in α '-CdP₂ with an isotropic chemic shift of $\delta_{iso} = -172.6$ ppm. From a simulation employing

the DMFIT software³⁹, the chemical shift anisotropy (CSA) parameters were determined as $\delta_{CS} = 189.5$ ppm and $\eta_{CS} = 0.5$. We note that the spinning sidebands on the high field side of the spectrum experience some broadening, especially at higher spinning speeds.

We ascribe this to the combined action of the chemical shift anisotropy and extremely strong homo-nuclear dipolar coupling. The experimental data is found to be in good agreement with the results of quantum chemical calculations of the CSA parameters employing the WIEN2k software package⁴⁰, which produces $\delta_{iso} = -171$ ppm, $\delta_{CS} = 210$ ppm and $\eta_{CS} = 0.46$.

For Li_{0.2}CdP₂, on the other hand, clearly two different P sites with isotropic chemical shifts of -157.4 ppm and -167.4 ppm with relative ratio of 1:1 can be identified. The CSA parameters for both sites are $\delta_{CS} = 182$ ppm and $\eta_{CS} = 0.6$. The virtual identical CSA parameters for P in Li_{0.2}CdP₂ and the de-lithiated α '-CdP₂ sample confirm that the local ³¹P environment in both compounds is rather similar, as suggested by the XRD results. In addition the presence of two distinct P sites in Li_{0.2}CdP₂ indirectly confirms the presence of Li within the structure.

The static ⁷Li NMR spectra as a function of temperature in the temperature range 140 K $\leq T \leq$ 295 K, acquired employing either a single pulse excitation or a solid echo pulse sequence, are collected in Figure 5.

For a I = 3/2 nucleus, the overall static line width represents the magnitude of the quadrupole coupling constant $C_Q = eV_{ZZ}Q/h$, with Q denoting the quadrupolar moment, elementary charge and V_{ZZ} the principal component of the electric field gradient. The narrow line in the middle of the spectrum (central transition) is only affected by the homo- and hetero-nuclear dipolar interactions. Since both, the (first order) quadrupolar coupling and the dipole interaction scale with the second Legendrian $3\cos^2\beta$ -1 with β denoting the angle between the direction of the magnetic field B_0 and the principal axis of the respective interactions and hence a motional narrowing of the NMR line if the inverse of the corresponding correlation time exceeds the magnitude of the interaction.

In the absence of any motional process on the other hand, the line width adopts a constant line width, which is usually referred to as the rigid lattice value. From the evolution of the line shape of the static ⁷Li NMR spectra with temperature we can clearly conclude considerable Li ion mobility in Li_{0.2}CdP₂. At T < 180 K, the spectrum is characterized by a broad signal $(m = \pm 1/2 - m = \pm 3/2$ transitions) from which a quadrupolar coupling constant of $C_0 = 95$ kHz can be deduced. The width of the central transition at T = 140 K (4 kHz) indicates the presence of sizeable dipole coupling. Upon increasing the temperature, the overall width of the spectrum decreases to a value of 11 kHz at ambient temperature. Thus, the quadrupolar interaction is partially averaged out due to Li dynamics. For an isotropic diffusive motion, a vanishing EFG and hence zero quadrupolar coupling would be expected. The presence of a residual average quadrupolar coupling as observed here indicates a hopping process in which the Li ion traces well defined positions within the crystal structure, as observed e.g. in crystalline Li ion conductors.⁴¹⁻⁴³ In this situation, which is often termed anisotropic diffusion, the effective EFG, averaged over these positions, does not average to zero, but to a small residual value.

The evolution of the width of the central line with temperature is plotted in Figure 5b. At ambient temperature, a line width of 800 Hz is observed. The line width does not suffer from any broadening down to temperatures of 200 K, then a broadening sets in, resulting in a line width of 3300 Hz at T = 117 K. Surprisingly, the rigid lattice regime is not reached even at these low temperatures. Employing the empirical Waugh-Fedin relation, $E_A = 0.156 \times T_{onset}$, which relates the activation energy E_A of the motional process to the onset temperature T_{onset} , at which the motional narrowing sets in, we can give an upper limit for the activation energy of approx.. 20 kJ mol⁻¹.

Figure 5. a) Static ⁷Li NMR spectra as a function of temperature in the temperature range 140 K \leq 7 \leq 295 K for Li_{0.2}CdP₂. b) Evolution of the central signal line-width with temperature. c) Measurement and fit for the 293 K signal of Li_{0.2}CdP₂.

A more precise evaluation of the activation energy is possible from an analysis of the temperature dependence of the spin lattice relaxation time T_1 , which was measured using a standard inversion recovery pulse sequence. The T_1 values were determined from measuring the magnetization built-up which was found to be exponential over the complete investigated temperature range. The data (cf. Fig. 6) exhibits a clear T1minimum at approx. 310 K. The activation energy and the correlation time of the dynamic process were then obtained from a simulation of the data employing the relaxation model of Bloembergen, Purcell and Pound (BPP)⁴⁷, resulting in $E_A = 15$ kJmol⁻¹, $\tau_c^{0} = 3.1 \times 10^{-12} \text{s}^{-1}$.

Figure 6. Evolution of 1/T1 plotted as a function of the inverse temperature for $\text{Li}_{0.2}\text{CdP}_2.$

Since the low temperature side of the BPP curve is – especially in the case of disordered solids – often biased to lower values,^{48,49} the low temperature T_1 data was not taken into account during the simulation. We emphasize that this value is among the lowest observed activation energies for crystalline Li ion conductors. A selection of Li ion conductors is shown in Table 1. Such a low value is in line with the best known Li ion conductors. With respect to the proposed structures for Li_{0.2}CdP₂, the ⁷Li NMR results clearly rule out the substitution model and favor the intercalation model.

Conclusions

Metallic $Li_{0,2}CdP_2$ was prepared by a mineralizer assisted reaction from the elements and CdI₂ as reaction promoter. Semiconducting α '-CdP₂ with a band gap of ~0.7 eV can be synthesized via a de-lithiation process upon a simple storage process on humid air. Li(OH) \cdot H₂O is formed on the surface of $Li_{0,2}CdP_2$ after 24 h and a complete de-lithiation to α '-CdP₂ takes place within weeks. A combined approach using diffraction techniques, spectroscopy and quantum chemistry was necessary to determine the crystal structures. Li_{0.2}CdP₂ shows a reasonable Li-ion mobility which was examined and confirmed by solid state NMR spectroscopy. An activation barrier range of 0.15 eV has been derived from spin lattice relaxation time (T1) experiments, being at the low end of the activation energy spectrum known for the best solid Li-ion conducting materials. During the de-lithiation process, a metal to semiconductor transition occurs which has been examined and substantiated by quantum chemical calculations.

compound	EA /eV (kJmol ⁻¹)	Determination method	T/K	Lit.
LiFePO ₄	0.6 (57.9)	IS	RT	[44]
Li ₇ PS ₆	0.16 (Li/LiClO4) (15.4)	IS	313	[45]
