Nanoflower-like metallic conductive MoO$_2$ as a high-performance non-precious metal electrocatalyst for hydrogen evolution reaction

Yanshuo Jin,$^a$ and Pei Kang Shen*,$^a$

Searching for hydrogen evolution reaction (HER) non-precious metal electrocatalysts with high activity and stability has attracted considerable attention. Herein, we report the synthesis of nanoflower-like MoO$_2$ on nickel foam (NFL MoO$_2$/NF). Remarkably, as HER electrocatalyst operating in alkaline electrolyte, NFL MoO$_2$/NF exhibits high stability and activity. The onset potential of NFL MoO$_2$/NF is almost 0 V versus the reversible hydrogen electrode (RHE) and bubbles can be produced on the surface of NFL MoO$_2$/NF under static overpotential of only 10 mV, comparable to commercial Pt/C. NFL MoO$_2$/NF needs overpotentials of only about 55 and 80 mV to achieve current densities of 10 and 20 mA cm$^{-2}$, respectively. NFL MoO$_2$/NF has superior stability in the long-term electrochemical process and keeps 94.3 percent of its initial current density after 25 hours.

Introduction

Hydrogen has been proposed as an alternative to the diminishing fossil fuel.$^1$ Electrolysis of water into hydrogen and oxygen in an electrolyzer is the simplest way to produce high-purity hydrogen.$^2$ Nickel (Ni) is typically used in industry for water electrolysis in alkaline solution but with high overpotential and large Tafel slope.$^3$ The platinum (Pt) and its alloys are the best HER catalysts, but the cost and scarcity of Pt are serious impediments to its large-scale industrial application for electrolysis.$^4,5$ These disadvantages have motivated many research efforts and some active and stable non-precious metal-based HER catalysts have been pursued in the past few years.$^6,7$ Molybdenum based non-precious-metal compounds have been intensively studied for HER catalysts, including MoS$_2$,$^8-12$ MoSe$_2$,$^8,13$ MoB$_2$,$^14$ MoC$_2$,$^{14-18}$ MoP,$^{19,20}$ and so on. According to the literature data, molybdenum based metallic transition metal oxide MoO$_2$ crystallizes in a monoclinic cell and has a distorted rutile structure.$^{21}$ The banding is a complex and involves delocalization of some of the Mo electrons in a conductance band accounting for the metallic conductivity.$^{21}$ Tungsten based metallic transition metal oxide WO$_2$ has the same distorted rutile crystal structure with MoO$_2$ and exhibits excellent performance for H$_2$ generation: the onset overpotential is only 35 mV.$^{22}$ Thus, metallic transition metal oxide is a potential candidate of electrocatalyst for hydrogen evolution reaction.

Polymer binder (Nafion or PTFE) is usually used to immobilize the catalysts on electrode surface for electrochemical measurements and practical applications.$^{23}$ However, the whole process is time-consuming and the polymer binder may reduce effective catalytic activity because it blocks active sites and reduces gas permeability and increases mass transfer overpotential.$^{24}$ Thus, the problem can be solved by synthesizing electrocatalytic nanomaterials on substrates without binder.$^{25}$

Herein, we report on our recent efforts in developing a novel nanoflower-like MoO$_2$ on nickel foam (NF). The nanoflower-like MoO$_2$·2H$_2$O precursor was directly grown on commercial nickel foam (NFL MoO$_2$·2H$_2$O/NF) by a wet-chemical route first. With an annealing treatment at 500 °C in N$_2$ atmosphere and a subsequent annealing treatment at 400 °C in H$_2$ atmosphere were used to synthesize NFL MoO$_2$/NF. As an integrated non-precious metal high-performance cathode for generating hydrogen from alkaline solution, the NFL MoO$_2$/NF maintains its activity for at least 50 hours and shows an onset potential of almost 0V, a Tafel slope of 66 mV dec$^{-1}$. NFL MoO$_2$/NF needs overpotential of only about 55 and 80 mV to achieve current densities of 10 and 20 mA cm$^{-2}$, respectively. The large exchange current density (~1.8 mA cm$^{-2}$) of NFL MoO$_2$/NF can be associated with its high surface area, corresponding many more active sites exposed for HER.

Experimental

Materials

Ammonium molybdate tetrahydrate ((NH$_4$)$_3$MoO$_4$·4H$_2$O), hydrochloric acid (HCl), potassium hydroxide (KOH) and Ni...
foam were purchased from Dongzheng Ltd. All chemical reagents used in this experiment were of analytical grade. The water used throughout all experiments was purified through a Millipore system.

**Synthesis of NFL MoO$_2$-2H$_2$O/NF**

Two Ni foams (40.0 mm×20.0 mm×1.0 mm) were cleaned by diluted hydrochloric acid, ethanol and deionized water for several times. Then, 20 mmol L$^{-1}$ (NH$_4$)$_6$Mo$_7$O$_{24}$·4H$_2$O were dissolved in 35 mL deionized water at room temperature to form a uniform solution. The solution was subsequently transferred into a 50 mL Teflon-lined stainless steel autoclave, and the pre-treated Ni foams were placed upright in the autoclave. The autoclave was heated to 100 °C in an electric oven and maintained for 18 h, after that the Ni foams with precursor were cleaned with deionized water for several times before being fully dried in air at 60 °C.

**Synthesis of NFL MoO$_2$/NF**

NFL MoO$_2$-2H$_2$O/NF was annealed in N$_2$ at 500 °C for 1 h and subsequently in H$_2$ at 400 °C for 1 h.

**Synthesis of NFL MoO$_3$ (MoO$_7$)/NF**

NFL MoO$_2$-2H$_2$O/NF was annealed in N$_2$ at 500 °C for 1 h.

**Calculated MoO$_2$ loading**

NFL MoO$_2$/NF was immersed in a 35 % HCl solution for one day, then was filtered, dried and weighed.

**Characterizations**

Powder XRD data were acquired on a D-MAX 2200 VPC diffractometer with Cu Ka radiation (λ=1.54056Å). The Raman spectrum was performed on a micro-Raman system (Renishaw, in via). IR spectrum was performed on a Nicolet6700/Thermo/America Fourier transform infrared spectrometer. DSC of the products was carried out on a DSC-204/Netzsch/Bruke differential scanning calorimetry. SEM measurements were carried out on a Quanta 400/INCA/HKL scanning electron microscope at an accelerating voltage of 30 kV. TEM measurements were performed on a Tecnai G2 F30 transmission electron microscope at 300 kV. XPS measurements were performed on an ESCALAB 250 system.

**Electrochemical measurements**

The electrochemical measurements were conducted in a typical three-electrode setup with a reversible hydrogen electrode (RHE) as the reference electrode and a graphite rod as the counter electrode. Steady-state potential polarization curves were measured in 1M KOH solution under different temperatures. Accelerated degradation measurement was conducted for 3000 cyclic voltammetry (CV) cycles in 1M KOH solution at a scan rate of 50 mV s$^{-1}$ and linear sweep voltammetry (LSV) measurements were conducted at a scan rate of 1 mV s$^{-1}$. Electrochemical impedance spectra (EIS) experiments were performed with the three-electrode cell system in 1M KOH at 25 °C. The potentiostat has a frequency range of 1 kHz-100 mHz in a 10.0 mV AC voltage.

**Results and discussion**

After hydrothermal treatment, nanoflower-like precursor is grown on the Ni foam which changes in color from silver-grey to reddish brown and then the color changes to black after annealing treatments (Figure S1, Supporting Information). Figure 1a shows the X-ray diffraction (XRD) pattern of the NFL MoO$_2$/NF, the peaks which assigned to monoclinic MoO$_2$ (PDF#65-5787) were detected. The strong peaks at 44.5°, 51.8°, and 76.4° originate from to the Ni foam substrate (PDF#65-2865). Figure 1b shows the Raman spectrum, the monoclinic MoO$_2$ was detected with Raman bands at 200, 226, 345, 351, 456, 492, 569 and 739 cm$^{-1}$.26

![Fig. 1. a) XRD pattern and b) Raman spectrum of NFL MoO$_2$/NF.](image-url)

Figure S2, Supporting Information shows the scanning electron microscopy (SEM) images of nanoflower-like precursor/Ni foam, indicating that the entire surface of the Ni foam is uniformly covered by nanoflower-like/calyx-type precursor. IR spectrum of the precursor is consistent with the standard spectrum of the molybdenum dioxide. As shown in Figure S3a, Supporting Information, the intense band at 950 cm$^{-1}$ is assigned to ν(Mo=O), while the prominent bands in the range of 500-850 cm$^{-1}$ are attributed to ν(Mo-O-Mo). In addition, the broad band at 3210 cm$^{-1}$ and 1610 cm$^{-1}$ correspond to the absorbed water.27 Figure S3b shows the XRD pattern of the precursor, but it is still hard to judge what the precursor is. The TG and DTA curves of the precursor in N$_2$ atmosphere are shown in Figure S4, Supporting Information. It shows two major events. The endothermic peak and exothermic peak at 121 °C and 485 °C on the DTA curve give two thermal behaviors. The broad endothermic peak on the DTA curve at about 121 °C corresponds to the release of the adsorbed water.27 The sharp exothermic peak at 485 °C is associated with the formation of crystalline MoO$_2$ in N$_2$ atmosphere (Figure S5, Supporting Information), it is the same as the data reported in literature.27 The mass loss of 21 % is corresponding to the loss of almost two molecular absorbed water (theoretical value 22 %) and we can deduce that the anion is MoO$_2·2$H$_2$O. So we can conclude that the reaction mechanism is expressed by Equation (1) and Equation (2) in the hydrothermal synthesis reactor and the tube furnace, respectively.

$$20 \text{(NH}_4\text{)}_2\text{MoO}_7\text{O}_4 + 7 \text{Ni} + 4 \text{H}_2\text{O} \rightarrow 20 \text{NH}_4\text{H}_5\text{O}^+ + 7 \text{MoO}_2\text{·2H}_2\text{O} + 7 \text{Ni}^{2+} \quad \text{(1)}$$

$$\text{MoO}_2\text{·2H}_2\text{O} \rightarrow \text{MoO}_2^+ + 2\text{H}_2\text{O} \quad \text{(2)}$$
TEM (Figure 3b) images show that the nanoflower-like MoO$_2$ electron microscopy (TEM, Figure 3a) and high-resolution (HR) maintained completely, thus enabling its direct use as an ratio of Mo to O. The skeletal structure of the Ni foam was (Figure S6, Supporting Information) verifies the 1:2 atomic contributed the majority of the active sites exposed for HER. The corresponding energy dispersive X-ray (EDX) spectrum (Figure 3c) showed that the nanoflower-like morphology is consisted of many nanosheets and the bulk MoO$_2$ plays a role in linking nanoflower-like MoO$_2$ and nickel foam. The nanoflower-like structure could lead to much higher surface area than bulk materials, so nanoflower-like structure contributed the majority of the active sites exposed for HER. Scanning electron microscopy (SEM, Figure 2a,b) images of NFL MoO$_2$/NF show that the nanoflower-like morphology is preserved and the entire surface of the nickel foam is uniformly covered by nanoflower-like MoO$_2$. A close view of nanoflower-like MoO$_2$ (Figure 2c) reveals that nanoflower-like morphology is consist of many nanosheets and the bulk MoO$_2$ plays a role in linking nanoflower-like MoO$_2$ and nickel foam. The nanoflower-like structure could lead to much higher surface area than bulk materials, so nanoflower-like structure contributed the majority of the active sites exposed for HER.

The corresponding energy dispersive X-ray (EDX) spectrum (Figure 3c) showed that the nanoflower-like morphology is consisted of many nanoparticles, forming lamellar superstructures at the micrometer scale. The HRTEM image shows well-resolved lattice fringes with an interplanar distance of 0.48 nm, which corresponds to the (100) plane of the MoO$_2$. A high-angle annular dark-field scanning transmission electron microscopy (HAADF–STEM) image and the corresponding energy-dispersive X-ray (EDX) mapping (Figure 3c) showed that the Mo and O atoms were distributed homogeneously.

Figure 4a shows the steady-state potential polarization curves of Ni foam, commercial 46.7% Pt/C (TTK, Japan, loading: 0.2 mg cm$^{-2}$) and NFL MoO$_2$/NF (MoO$_2$ loading: ~4.5 mg cm$^{-2}$) in N$_2$-saturated 1M KOH solution at 25 °C. In sharp contrast, NFL MoO$_2$/NF is significantly active for the HER with onset overpotential of almost 0V, and additional negative potential leads to rapid increase in the cathodic current. This value is superior to most of reported values for non-precious-metal HER electrocatalysts (Table S1, Supporting Information). In addition, NFL MoO$_2$/NF needs overpotentials of only about 55 and 80 mV to achieve current densities of 10 and 20 mA cm$^{-2}$, respectively. The inset picture in Figure 4a shows the bubbles on NFL MoO$_2$/NF after steady-state overpotential of only 10 mV for several minutes and Movie S1 shows a HER movie on NFL MoO$_2$/NF under steady-state overpotential of only 10 mV and 50 mV. Both of them show bubbles produced on the surface of NFL MoO$_2$/NF under steady-static overpotentials, indicating the onset potential is smaller than 10 mV. The Tafel slopes were 29 mV/dec, 66 mV/dec and 117 mV/dec for commercial 46.7% Pt/C, NFL MoO$_2$/NF and Ni foam, respectively (Figure 4b). The Tafel slope for NFL MoO$_2$/NF indicated that the HER proceeds by a Volmer–Heyrovsky mechanism. By using the extrapolation method on the Tafel plots, the exchange current density ($j_0$) of NFL MoO$_2$/NF was calculated to be 1.8 mA cm$^{-2}$.
that the equivalent circuit for the HER is characterized by one time constant.\textsuperscript{29} Thus, as shown in the inset of Figure S7a, the HER can be described by a simple equivalent electrical circuit, the solution resistance $R_s$ is approximately 1.1 $\Omega$ for both electrodes. With respect to $R_{ct}$, there is a very large difference between the two electrodes. For instance, at $\eta=100$ mV, $R_{ct}$ is only 2.4 $\Omega$ for the NFL MoO$_2$/NF electrode remarkably smaller than that for Ni foam (~80 $\Omega$). The $R_{ct}$ value is strongly related to the kinetics of the HER. The lower the $R_{ct}$ value, the more active the associated electrode for the catalytic reaction.\textsuperscript{30} Therefore, it is clear that the NFL MoO$_2$/NF electrode is more active for the catalysis of HER than that of Ni foam electrode. Figure S8, Supporting Information shows the polarization curve of NFL MoO$_2$/NF in 1M KOH at different temperatures. The HER activation energy on NFL MoO$_2$/NF is about 20.0 kJ mol$^{-1}$, according to the Arrhenius Equation and Arrhenius plots.\textsuperscript{31} The activation energy of NFL MoO$_2$/NF is lower than other none-precious metal catalysts.\textsuperscript{32-34}

![Figure 5a](image1.png)

**Fig. 5.** a) Polarization curves of the NFL MoO$_2$/NF in 1M KOH initially and after 15,000 CV scanning between +0.05 and -0.15 V vs. RHE. b) time-dependent current density curve for NFL MoO$_2$/NF under steady-state overpotential of 100 mV for 50 h.

The durability of NFL MoO$_2$/NF was examined. As shown in Figure 5a, the NFL MoO$_2$/NF exhibited a fairly stable performance within the accelerated degradation measurement for 15,000 cyclic voltammetry (CV) cycles between +0.05 and -0.15 V vs. RHE in N$_2$-saturated 1M KOH at a scan rate of 50 mV s$^{-1}$. The Figure 5b shows the time dependent current density and percentage curves for NFL MoO$_2$/NF under steady-state overpotential of 100 mV, NFL MoO$_2$/NF kept 94.3 and 83.6 percent of its initial current density after 25 and 50 hours, respectively. After a long period of time, the current density only slightly degraded, indicating that the NFL MoO$_2$/NF has superior stability in the long-term electrochemical process.

The superior HER electrocatalytic performance and stability of the NFL MoO$_2$/NF could be attributed to the following reasons: 1) MoO$_2$ possesses good electrical conductivity because it has a distorted rutile structure and its banding involves delocalization of some of the Mo electrons in a conductance band, 2) the nanoflower-like structure of NFL MoO$_2$/NF could lead to high surface area, there are correspondingly many active sites exposed for HER, 3) NFL MoO$_2$/NF avoids the use of polymer binder which would block active sites, inhibiting diffusion and increases the time of exposure to air and 4) the porous configuration of Ni foam allows easy diffusion of the electrolyte.

**Fig. 6.** XPS spectra of Mo 3d for (a) NFL MoO$_2$/NF and (b) NFL MoO$_2$(MoO$_3$)/NF. c) The polarization curves of NFL MoO$_2$/NF and NFL MoO$_2$(MoO$_3$)/NF in 1M KOH.

t is important to note that the annealing treatment at 400 $^\circ$C in H$_2$ atmosphere is indispensable. With an annealing treatment at 500 $^\circ$C in N$_2$ atmosphere, the MoO$_2$-$\text{H}_2\text{O}$ precursor became MoO$_3$ (Figure S5) and the surface of MoO$_2$ was further oxidized into MoO$_3$ (Figure 6b) due to the remains of oxygen in the tube furnace (NFL MoO$_2$(MoO$_3$)/NF). A subsequent annealing treatment at 400 $^\circ$C in H$_2$ atmosphere was used to reduce the MoO$_3$ surface of NFL MoO$_2$(MoO$_3$)/NF to MoO$_2$ (NFL MoO$_2$/NF). Figure 6a,b show the X-ray photoelectron spectroscopy (XPS) spectra of Mo 3d for NFL MoO$_2$(MoO$_3$)/NF and NFL MoO$_2$/NF, the Mo 3d$_{5/2}$ peak of Mo$^{6+}$ was almost coincident with the Mo 3d$_{3/2}$ peak of Mo$^{5+}$, thus leading to the characteristic three-peak shape of Mo$^{5+}$ and Mo$^{4+}$. Treatment at 400 $^\circ$C in H$_2$ atmosphere decreased the amount of Mo$^{6+}$ at the surface of MoO$_2$ and the ratio of O/Mo from 2.215 for NFL MoO$_2$(MoO$_3$)/NF to 2.077 for NFL MoO$_2$/NF.

Figure 6c shows the steady-state polarization curves of NFL MoO$_2$/NF and NFL MoO$_2$(MoO$_3$)/NF in N$_2$-saturated 1M KOH solution at 25 $^\circ$C. In sharp contrast, NFL MoO$_2$(MoO$_3$)/NF is less active for the HER with onset overpotential of about
150 mV. In addition, NFL MoO$_2$/NF needs overpotentials of only about 55 mV to achieve current densities of 10 mA cm$^{-2}$, however, NFL MoO$_2$(MoO$_3$)/NF needs overpotentials of about 265 mV to achieve current densities of 10 mA cm$^{-2}$. The bad HER performance of NFL MoO$_2$(MoO$_3$)/NF could be attributed to the MoO$_3$ surface, which blocked MoO$_2$ from contacting with electrolyte. MoO$_2$ dissolves in alkaline solution and MoO$_3$ does not dissolve in alkaline solution. Thus, MoO$_2$ can be stored in alkaline solution and the MoO$_3$ surface would dissolve and the MoO$_2$ would reveal again. Figure 6a and Figure S5, Supporting Information show the X-ray photoelectron spectroscopy (XPS) data in the Mo 3d and O 1s regions for NFL MoO$_2$/NF, respectively. It is known that peaks at ~ 530 eV are due to oxides and the one at ~ 532 eV is attributed to adsorbed oxygen. Two peaks at 232.4 and 229.2 eV in the Mo 3d region and peaks at ~530.0 eV in the O 1s region are close to the binding energies for Mo and O in MoO$_2$. The Mo 3d$_{3/2}$ binding energy of 232.4 eV is positively shifted from that of metallic Mo 3d$_{3/2}$ (231.0 eV) and the Mo 3d$_{5/2}$ binding energy of 229.2 eV is positively shifted from that of metallic Mo 3d$_{5/2}$ (228.0 eV).$^{35,36}$ While the O 1s has a lower binding energy (~530.0 eV) than oxygen (~532 eV). It suggests that the Mo has a partial positive charge ($\delta^+$) while the O has a partial negative charge ($\delta^-$), thus implying the transfer of electrons from Mo to O.$^{37,39}$ A metal complex HER catalyst incorporates proton relays from pendant acid or basic groups, positioned close to the metal center where hydrogen production occurs.$^{40,41}$ Recent work showed that MoP, CoP and FeP as highly active HER catalysts consist of the metal center ($\delta^+$) and the pendant base P ($\delta^-$) close to it.$^{37,39}$ Given that MoO$_2$ is also rich with metal centers (Mo; $\delta^+$) and pendant bases (O; $\delta^-$) positioned close to it, it is believed that it adopts a catalytic mechanism similar to that of metal complex, like MoP, CoP and FeP catalysts for the HER. The Mo and basic O act as the hydride-acceptor and proton-acceptor center, respectively, thus facilitating the HER.$^{32}$ To probe the morphology and composition of the NFL MoO$_2$/NF after HER electrocatalysis, the SEM, XRD and XPS results of a post-HER NFL MoO$_2$/NF were collected. As shown in Figure S10-S11, nanoflower-like morphology is preserved and the composition is still MoO$_2$. Figure S12 shows the X-ray photoelectron spectroscopy (XPS) spectrum of Mo 3d for NFL MoO$_2$/NF after HER electrocatalysis, the amount of Mo$^{6+}$ was decreased due to MoO$_2$ dissolves in alkaline solution.

Conclusions

In conclusion, nanoflower-like MoO$_2$ has been synthesized successfully for the first time according to our self-developed method. NFL MoO$_2$/NF showed excellent HER electrocatalytic performance and durability in alkaline electrolytes. The onset potential of NFL MoO$_2$/NF is almost 0 V versus RHE and bubbles can be seen on the surface under steady-state overpotential of only 10 mV. NFL MoO$_2$/NF needs overpotentials of about 55 and 80 mV to achieve current densities of 10 and 20 mA cm$^{-2}$, respectively.
