Crystalline poly(triazine imide) as an efficient electrocatalyst for counter electrodes of dye-sensitized solar cells using a triiodide/iodide redox electrolyte
Crystalline poly(triazine imide) as an efficient electrocatalyst for counter electrodes of dye-sensitized solar cells using a triiodide/iodide redox electrolyte

Woo-ram Lee, Young-Si Jun, Jihee Park, and Galen D. Stucky*

We report utilization of graphitic carbon nitride (g-CN) as an electrocatalyst for dye-sensitized solar cells (DSSCs). Crystalline poly(triazine imide) based g-CN was synthesized via a modified ionothermal method, and deposited onto the counter electrodes along with a conductive additive and a sacrificial polymer binder. The resulting DSSCs exhibited a power conversion efficiency (7.8%) comparable to that of conventional Pt catalyst (7.9%), confirming the excellent catalytic activity of poly(triazine imide) g-CN as a non-precious metal electrocatalyst.

Dye-sensitized solar cells (DSSCs) have been considered a promising alternative to conventional silicon solar cells due to their low cost, easy fabrication, and high performance. The counter electrode (CE, cathode), which is used to collect the electrons from the external circuit and to catalyze the reduction of the redox couple in electrolytes in DSSCs, usually consists of a fluorine-doped tin oxide (FTO) glass coated with a catalyst. Platinum is the most widely used CE catalyst owing to its superior electrical conductivity and catalytic activity, but the high cost of this metal hinders its use for the industrial mass production of DSSCs. Several types of new materials such as inorganic materials, polymers, carbon materials, multiple compounds, and composites have been proposed as alternative electrocatalysts.

Carbon-based materials, including carbon nanotubes, graphenes, and mesoporous graphitic carbons, are of particular interest as metal-free CE catalysts. They are inexpensive, abundant, non-toxic, and conductive, meeting most of requirements for commercial electrode materials. Furthermore, they are easily processable into a shape and composition favorable for target applications. For example, incorporation of heteroatoms, especially O, N, and halogens, creates more redox-active sites and increases surface hydrophilicity, thereby improving the electrocatalytic activity of pristine carbon materials in the triiodide reduction of DSSCs. Changes in the sp² hybridized carbon structure, resulting from the introduction of heteroatoms, significantly alters the DSSC physicochemical and electronic properties. A fundamental understanding of the structure/composition/function relationships is, therefore, crucial for the discovery and design of more efficient CE electrocatalysts based on carbon materials. For this purpose, novel synthetic approaches are needed for the design of efficient heteroatom configured carbon-based electrocatalysts.

Graphitic carbon nitride (g-CN) is an organic compound that consists of alternating sp² hybridized carbon and nitrogen atoms. Analogous to graphitic carbon materials, this organic polymer features controllable surface termination, i.e. curvatures, edges and heteroatom dopants favorable for substrate adsorption/desorption and electron relocalization/transfer, as well as controllable electronic band structure. Its intrinsic semiconducting property coupled with its electron-rich nitrogen surface functionality imparts excellent electro-, organo- and photo-catalytic activities in a number of catalytic applications, such as Friedel-Crafts, CO₂ activation, oxygen reduction/evolution and hydrogen evolution reactions, thereby rendering g-CN a promising candidate for enabling more efficient conversion chemistries. For example, optimally structured g-CN showed 90% conversion efficiency in the Friedel-Crafts acylation of benzene while the efficiency of graphite was only 1%. In spite of such desirable properties, to the best of our knowledge, g-CN has not been employed as a CE catalyst in DSSCs, possibly due to its low electrical conductivity. In order to resolve this issue, two additive materials are used in this research, along with g-CN, in the synthesis and processing of the CE film used in this study. For the formation of g-CN, crystalline poly(triazine imide) (cPTI) is chosen because of its (electro-)chemical stability and well-defined structure and composition. Ionothermal syntheses using inert molten salt and heteroatom containing precursors lead to the bulk formation of a cPTI that is homogeneously intercalated by alkali metal halides; and, also incorporated with other types of heteroatoms by the replacement of trigonal N atoms. In addition this synthesis strategy facilitates charge transfer and adsorbate adsorption/desorption. Furthermore, this ‘born-in-halogen’ nature is expected to endow the cPTI with compatibility for I/I₃ electrolyte chemistry, in contrast to the catalyst corrosion by the electrolyte that occurs when the traditional Pt is used. The resulting DSSCs with the cPTI CE show high power conversion efficiency (PCE), comparable to that of DSSCs with a conventional Pt CE.

cPTI was prepared via a modified ionothermal synthesis method. A melamine-cyanuric acid (MCA) complex was used as a pre-organized, nitrogen-rich and oxygen-containing molecular precursor. The goal is to homogeneously incorporate O into the cPTI framework, in order to create additional redox active sites for triiodide reduction (Scheme 1). Thermal polycondensation of MCA in an eutectic mixture of LiCl:KCl (45:55 wt%) at 550 °C under nitrogen in an open glass container yields a pale yellow powder after removal of the excess salt. It is referred to as cPTI-MCA-LiKCl-550 since nitrogen-rich molecular precursors including melamine or dicyandiamide (DCDA) generate cPTI intercalated with Li, K and Cl at 550~600 °C.

Powder X-ray diffraction (PXRD) patterns of cPTI-MCA-LiKCl-550 show well-resolved and intense peaks of a crystalline phase, while PTI prepared from DCDA exhibits no crystallinity at 550 °C, nor do samples prepared in the presence of heteroatom containing molecular precursors such as 4-amino-2,6-dihydroxypryimidine (4-AP) or 2,4,6-triaminopyrimidine (TAPI) (Figure 1a). The diffraction pattern of cPTI-MCA-LiKCl-550 is in good agreement with that of cPTI-DCDA-LiKCl-600 with a P63cm space group for a sample prepared at 600 °C in a sealed glass ampoule using DCDA. The strongest peak at ~26.8°, corresponding to a d spacing of ~3.3 Å, is assigned to the (002) reflection of 2D cPTI nanosheets stacked in a graphitic fashion. This is further supported by transmission electron microscopy (TEM) images which show the graphite-like stacking (Figure 1b). The partial exfoliation of the graphite-like structure during washing with hot water gives rise to another strong peak at 28.4° (marked with an asterisk in Figure 1a), indicating a weak interplanar interaction between 2D cPTI layers. Furthermore, the in-plane diffraction at 12.1°, corresponding to a d spacing of 7.3 Å, results from the trigonal voids spanned by triazine units, the intact ordering and stacking of which again confirm the successful thermal polycondensation of MCA into cPTI under the synthesis condition. We note a slight shift of the (002) peak to higher scattering angle. Replacement of N with O is probably responsible for such an interlayer contraction.

Formation of oxygen containing cPTI is further supported by FT-IR spectroscopy. The FT-IR spectrum of PTI-MCA-LiKCl-550 shows the characteristic out-of-plane breathing mode of triazine at 803 cm⁻¹ and the stretching mode of CN heterocyclic ring around 1100~1700 cm⁻¹ (Figure 2a). We attribute a small band at 1760 cm⁻¹ and strong band at 1240 cm⁻¹ to oxygen containing groups such as C=O or C-O. A small band at 2170 cm⁻¹ can be assigned to the surface nitrile group. A broad band around 3300 cm⁻¹ indicates the presence of surface uncondensed amine (-NH- or -NH₂) or hydroxyl functional groups (-OH).
Further insights into the chemical composition of cPTI-MCA-LiKCI-550 were given by elemental analysis (EA), X-ray photoelectron (XPS) and energy dispersive X-ray (EDX) spectroscopy studies. The H content that resulted from the surface uncondensed functional groups was estimated by EA to be 2.1 wt%. Although a similar degree of polycondensation (or C/N ratio calculated by EA) was expected from the H content, replacement of N with O resulted in a C/N ratio (0.76) for cPTI-MCA-LiKCI-550, which is much higher than that (0.64) of cPTI-DCDA-LiKCI-600. \(^{30}\) Cyanuric acid seems to be incorporated into the cPTI framework in a manner similar to that found in 4-AP or TAPI during ionothermal synthesis,\(^{21,28}\) while the hydroxyl groups of cyanuric acid are known to easily decompose and thereby facilitate the polycondensation procedure in the absence of the eutectic mixtures.\(^{30}\) A XPS survey scan indeed reveals the high O content in cPTI-MCA-LiKCI-550 compared to that in MCA-550 (Figure 2b). High resolution C 1s shows a new peak at 288.12 eV corresponding to C-O species in the cPTI framework, confirming that O is chemically bonded to a carbon atom of the triazine ring (Figure S1 in the Supporting Information).\(^{31}\) The K and Cl contents were estimated from XPS to be about 2.3 and 1.3 wt%, respectively. The presence and homogeneous distribution of these, as well as C, N and O were also evidenced by EDX and elemental mapping analyses (Figure S2).

Scanning electron microscopy (SEM) images of cPTI-MCA-LiKCI-550 show a uniform rod-like morphology with a lateral size of ~300 nm and height of ~30 nm (Figure S3a). Nitrogen sorption analysis indicates a BET surface area of 58 m\(^2\)/g and a pore volume of 0.25 cm\(^3\)/g (Figure S3b). cPTI-MCA-LiKCI-550, with small particle size and high surface area compared to the bulk cPTI-DCDA-LiKCI-600, features textural properties appropriate for electrocatalytic applications in DSSCs as a CE catalyst.

Since the photovoltaic performance of DSSCs was poor when cPTI-MCA-LiKCI-550 was used alone as a CE catalyst (data not shown), two more additives that could be coated on the CE substrate were added to the catalyst solution. A conductive material, Super P® carbon black, was added to improve conductivity of the CE film according to a recent strategy.\(^{32,33}\) In addition, poly(ethylene oxide) (PEO) of \(M_\text{w}=5,000,000\) was added as a sacrificial binder to make a homogeneously dispersed solution and the resultant uniform CE film of cPTI-DCDA-LiKCI-600/Super P. A drop-cast thin layer of this catalyst solution was dried at room temperature and annealed at 450 °C for 3 h under nitrogen to make ~25 μm thick CE films (Figure S4), which was also verified with a profilometer. Figure S5 shows the photovoltaic characteristics in case any of the three components is absent. In the absence of cPTI-MCA-LiKCI-550, the PCE is only 0.7% confirming that catalytic performance of the CE film mainly stems from cPTI-MCA-LiKCI-550. When Super P is not present, the fill factor (FF) is very low (0.28) due to high internal series resistance. Although the solution contains both cPTI-MCA-LiKCI-550 and Super P, it still has low FF (0.45) and poor PCE (3.9%) if PEO is absent. This shows that the role of PEO to microscopically blend g-CN and Super P is crucial in achieving high performance. The heating temperature during formation of CE films has significant influence on the PCE as well (Figure S6). By annealing the CE at higher temperatures, a higher PCE was obtained (5.2% for 300 °C, 6.4% for 400 °C, 7.8% for 450 °C).

Electrochemical impedance spectroscopy (EIS) measurements, which are the most convincing supporting analyses on the charge transfer process and catalytic activity,\(^{34,35}\) were performed using a symmetric cell configuration to investigate the effect of the ratio change of the components. The dummy cells were prepared from four cPTI-MCA-LiKCI-550 catalyst solutions (designated as CC1, CC2, CC3, and CC4) with different content ratios of cPTI-MCA-LiKCI-550 and Super P (15:15, 20:10, 25:5, and 28:2, respectively) (Table 1). Each Nyquist plot consisted of two semicircles as shown in Figure 3, and they were fitted to the Randles circuit in the inset of Figure 3b. The left semicircle in the high frequency range represents the charge transfer resistance \(R_{\text{ct}}\) at the electrolyte/electrode interface and the corresponding capacitance \(C_{\text{ct}}\), and the right semicircle at low frequency can be assigned to the Nernst diffusion impedance \(Z_{\text{d}}\) of the redox species in the electrolyte.\(^{34,35}\) The left semicircle becomes smaller with a higher ratio of cPTI-MCA-LiKCI-550 to Super P (CC1 to CC4), indicating that a lower \(R_{\text{ct}}\) can be obtained with a greater amount of cPTI-MCA-LiKCI-550 by the creation of more catalytic active sites. From a quantitative viewpoint, \(R_{\text{ct}}\) is calculated as half the value of the real component of impedance multiplied by the active area of each of the symmetric cells. The calculated \(R_{\text{ct}}\) values were 1.8, 1.5, and 0.5 Ω cm\(^2\) for CC1, CC2, and CC3, respectively (Table 1). The Nyquist plot for CC4 did not provide an adequate fit to the equivalent Randles circuit, probably because the excess amount of cPTI-MCA-LiKCI-550 relative to the Super P concentration resulted in a less uniform CE film. It is noteworthy that the \(R_{\text{ct}}\) of CC3 was even lower than that of conventional Pt (1.1 Ω cm\(^2\)), in accordance with the normally reported values\(^{34,35}\), which implies that CC3 CEs can be more catalytically active than thermally platinized CEs. The right circle, however, became larger with higher content of cPTI-MCA-LiKCI-550 (CC1 to CC4). All the \(Z_{\text{d}}\) values in Table 1 were larger than that of Pt due to the thick CE films.

In summary, oxygen-containing crystalline poly(triazine imide), cPTI-MCA-LiKCl-550, was prepared via a simple ionothermal method by using a MCA complex as a pre-organized, nitrogen-rich, and oxygen-containing precursor. When it was employed as a CE electrocatalyst in DSSCs, cPTI-MCA-LiKCl-550 gives a high FF of 0.68, Vₜh of 0.749 V, and PCE of 7.8%. This high performance may be attributed to the low Rₑₒ of cPTI-MCA-LiKCl-550 CEs and could be further improved by optimizing coating method, doping level, and surface area.
