This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the author guidelines.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the ethical guidelines, outlined in our author and reviewer resource centre, still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Exploring the potential of a hybrid device combining solar water heating and molecular solar thermal energy storage

Ambra Dreos, Karl Börjesson, Zhihang Wang, Anna Roffey, Zack Norwood, Duncan Kushnir, and Kasper Moth-Poulsen†

A hybrid solar energy system consisting of a molecular solar thermal energy storage system (MOST) combined with a solar water heating system (SWH) is presented. The MOST chemical energy storage system is based on norbornadiene-quadricyclane derivatives allowing for conversion of solar energy into stored chemical energy at up to 103 kJ/mol (396 kJ/kg). It is demonstrated that 1.1% of incoming solar energy can be stored in the chemical system without significantly compromising the efficiency of the solar water heating system, leading to efficiencies of combined solar water heating and solar energy storage of up to 80%. Moreover, prospects for future improvement and possible applications are discussed.

Solutions for efficient solar energy conversion and solar energy storage are crucial for the development of a sustainable society. Technologies for conversion of solar energy into heat and electricity is seeing an impressive evolution leading to rapid integration into the energy system in several countries. The most common concepts for solar energy conversion are photovoltaics (solar-electric) and solar-thermal (solar-heat). The most common photovoltaic technology is based on single junction silicon solar cells. The maximal efficiency of a single junction solar photovoltaic cell is estimated to be 32% (solar to electricity) due to spectrum losses, whereas typical efficiencies for modules today are upwards of 20%. Comparatively, solar water heating systems (SWH) typically have an efficiency (solar to heat) of 20-80% depending on the application, required temperature, etc. Such systems have found widespread use in e.g. water heating, district heating, industrial heating and in concentrating solar power (CSP) using heat engines for electric power production. SWH systems make use of the full solar spectrum whereas photovoltaics are limited to harvesting of photons with energies higher than the bandgap. This has led to the consideration and development of hybrid systems, as for example combined solar thermal and photovoltaic devices.

As photovoltaics is finding more and more widespread use, technologies for mitigating challenges with intermittency and load-leveling are becoming increasingly important. In addition to electrochemical (battery) technologies, methods for storage of solar energy in chemical bonds is an attractive option since

---

Fig. 1 Schematic representation of the norbornadiene-quadricyclane molecular solar thermal energy storage system. The energy levels are drawn to scale using values for NBD 2 where the difference between the relaxed and excited molecule corresponds to 262 kJ/mol, $\Delta H$ to 92 kJ/mol, and $\Delta H_{storage}$ to 103 kJ/mol.
the chemical energy can be stored in a very compact way.\textsuperscript{9} In this context, an approach is to store solar energy as latent chemical energy in photo-induced isomerization in chemical bonds, so-called molecular solar thermal (MOST).\textsuperscript{10} In a MOST system a parent molecule is exposed to solar photons and by that converted to a high energy photoisomer; this is kinetically stable but it can isomerize back to the parent molecule and doing so it releases heat (see figure 1). An important parameter to consider here is the quantum yield of the photoisomerization (\(\phi_{\text{iso}}\)), which is defined as in equation 1:

\[
\phi_{\text{iso}} = \frac{\text{number of isomerization events}}{\text{number of photons absorbed}}
\]  

(1)

Several systems have been explored in this context, including norbornadienes,\textsuperscript{11-13} ruthenium compounds,\textsuperscript{14-17} azobenzenes\textsuperscript{18-25} and other systems;\textsuperscript{26,27} the field has recently been reviewed.\textsuperscript{10,28}

The focus point here is on the norbornadiene-quadricyclane system, that has shown energy storage densities up to 966 kJ/kg\textsuperscript{29} and storage time exceeding several months.\textsuperscript{13} The energy release can be carried out either by thermal activation\textsuperscript{30} or by the use of catalysts.\textsuperscript{13,31} The requirements of an efficient MOST system has been discussed several times in the literature\textsuperscript{10,11,13,32} and can be summarized as: i) the parent compound must absorb a significant part of the solar spectrum, ii) the photoisomer must not compete for the absorption of sunlight, iii) the quantum yield of the photoisomer should be 100\%, iv) the stored energy density should exceed 300 kJ/kg,\textsuperscript{33} v) the photoisomer must be stable over extended periods of time and vi) all reactions must proceed quantitatively, e.g. allows for multiple solar energy storage-release cycles. Although several systems have been greatly improved towards these requirements, no single system has fulfilled them all and thus the norbornadiene-quadricyclane system still needs optimisation to meet requirements for future applications.\textsuperscript{34-36}

A part of the photon energy in MOST systems is needed to supply energy for the barrier preventing back conversion, at least 1.14-1.24 eV, as previously calculated by us\textsuperscript{34} (the energy barrier is indicated as \(\Delta H^\ddagger\) in Figure 1). We have therefore evaluated in a previous work how these systems are expected to operate at up to 10-12\% solar energy storage efficiencies (\(\eta_{\text{MOST}}\)), when able to absorb relatively high photon energies (1.8-1.9 eV).\textsuperscript{34} There are two processes of energy loss in the MOST system, both resulting in heat: relaxation from the electronically excited parent molecule to the photoisomer, and \(\phi_{\text{iso}}\) less than unity. Heating of the MOST system is in this work regarded as a pure loss.

The currently available MOST systems that are most promising in aspect of the requirements listed above operate at bandgaps in the region of 2.48-3 eV.\textsuperscript{13,37} As a consequence, it is relevant to try to combine MOST systems with concepts for utilization of long wavelength photons. Photon upconversion has been explored as a way to improve the performance of MOST systems,\textsuperscript{38,39} this is a very promising strategy but many challenges are still to be addressed in the development of efficient upconverting materials.\textsuperscript{40-42}

Here we investigate for the first time a hybrid technology combining SWH and MOST, making it possible to exploit the sub-bandgap photons which the MOST systems cannot utilize. Combining SWH and MOST allows for efficient usage of low energy photons for SWH, combined with storage of the high energy photons in the form of chemical energy in the MOST system. Storage of a part of the solar energy by using the NBD-QC system can add the valuable feature of long term energy storage and on demand energy delivery to existing low or medium temperature SWH systems.

![Fig. 2 Sketch of the hybrid solar energy conversion device. The upper collector is used for the conversion of the MOST system; the lower collector is used for solar water heating. Measured efficiencies are reported (NBD 2 as MOST, 0.1 M in toluene, \(n_i=2.7 \times 10^8 \text{ mol s}^{-1}\), \(m=1.6 \times 10^4 \text{ kg s}^{-1}\).](image)

To demonstrate the effect of adding MOST based energy storage to SWH, a microfluidic hybrid device was designed (Figure 2). The hybrid device contains two layers, with SWH in the bottom layer (dark grey) and MOST in the top layer (light grey). The upper MOST part is constituted of a fused silica microfluidic chip; it allows the high energy photons from the solar spectrum to photochemically convert norbornadiene (NBD) to quadricyclane (QC). As shown in Figure 3a, photons with lower energy than the absorption onset of NBD, are efficiently transmitted through the upper layer of the device, and used to heat water in the lower collector, constituted of a 3D printed flow cell covered by a quartz glass slide. The front face dimensions of the device are \(\approx 2\) by 2 cm.

The solar energy storage efficiency of the MOST system (\(\eta_{\text{MOST}}\)) is calculated according to equation 2:

\[
\eta_{\text{MOST}} = \frac{\eta_{\text{NBD}} \cdot \eta_{\text{QC}} \cdot \Delta H_{\text{storage}}}{\Delta E_{\text{AM1.5}}}
\]  

(2)

Where \(\eta_{\text{QC}}\) is the measured conversion of QC after irradiation, \(\Delta H_{\text{storage}}\) is the stored energy of QC (in J/mol), \(A\) is the flow speed (in mol s\(^{-1}\)), \(A\) the irradiated area (in m\(^2\)), and \(E_{\text{AM1.5}}\) is the energy of incoming solar radiation (in W m\(^{-2}\)). To calculate the efficiency of the SWH system (\(\eta_{\text{SWH}}\)) equation 3 was used:

\[
\eta_{\text{SWH}} = \frac{n_i \cdot C_P \cdot m \cdot \Delta T}{A \cdot k \cdot E_{\text{AM1.5}}}
\]  

(3)
Where \( \dot{m} \) is the water flow rate (in Kg s^{-1}), \( C_P \) is the heat capacity of water (J Kg^{-1}K^{-1}), and \( \Delta T \) is the measured temperature rise (in K). The combined efficiency of the device \( \eta_{comb} \) is defined as:

\[
\eta_{comb} = \eta_{MOST} + \eta_{SWH}
\]

(4)

Two norbornadienes (2,3-diphenylnorbornadiene and 2-Cyano-3-((4-dimethylamino)phenyl)ethynyl)norbomadiene, indicated as NBD 1 and NBD 2 respectively in Figure 3b) were selected to be tested in the hybrid device. These two compounds have previously been synthesized by us, and their properties thoroughly assessed, by means of both theoretical calculations and experimental characterization.\(^{30,35,37,43}\) They both show promising features considering the requirements stated above, including complete photoswitching (see Figure 4a), good kinetic stability of quadricyclane, high solubility (see SI for details) and high energy storage density, making them interesting systems for testing in a device.

NBD 1 features a photoisomerization quantum yield (\( \Phi_{iso} \)) of 60%, and a half-life of the backconversion from high energy isomer to the parent compound (\( t_{1/2} \)) of 42.9 days at room temperature.\(^{30}\) NBD 2, features \( \Phi_{iso} \) of 28%, and \( t_{1/2} \) of 5 hours at room temperature\(^{37}\) (summarised in Table 1, moreover, rate constants for QC to NBD conversion of 1 and 2 at different temperatures are reported in SI, section I). The absorption onset (\( \lambda_{onset} \)) of 1 and 2 is 389 nm and 456 nm respectively, resulting in 2 absorbing up to 12% of the solar spectrum, compared to 1, capable of absorbing up to 3.8%, (MOST transmittance and solar spectrum overlap are shown in figure 3).

The energy release associated with the thermal isomerisation of QC 1 to NBD 1 was measured using differential scanning calorimetry (DSC, Figure 4b; see SI for details), while the value for 2 was recently reported.\(^{37,1}\) In solutions of 5% store 86.5 kJ/mol (354 kJ/kg) and 2 can store 103 kJ/mol (396 kJ/kg). Assuming that the density of unsubstituted norbornadiene (906.4 g/L), it is possible to calculate the volumetric energy density of 1 and 2, which correspond to 321 kJ/L and 359 kJ/L respectively. This energy storage density of 1 and 2 can be translated to a potential temperature rise of 213 and 238 °C, respectively under adiabatic conditions. In this work 1 and 2 are dissolved in toluene (at concentrations of 70 and 100 mM respectively), in order to create a fluid system, reducing the volumetric energy density accordingly.

Photosomerization of norbornadienes 1 and 2 in solution was carried out using a solar simulator and the \( \eta_{QC} \) determined by \(^1\)H NMR. Using eqn (2), \( \eta_{MOST} \) of 1 and 2 was calculated to 0.1% and 1.1%, respectively. These values are up to 2 orders of magnitude higher than our previously reported efficiencies of MOST systems in a device.\(^4\) The improvement in the measured MOST solar energy storage efficiencies can be attributed largely

| Table 1 Properties of the two MOST systems 1 and 2. |
|---|---|---|---|---|---|
| MOST System | \( \lambda_{max} \) | \( \lambda_{max} \) | \( \Phi_{iso} \) | \( \Delta H_{merge} \) | \( \eta_{MOST} \) |
| 1 | 308° | 389° | 42.9 d° | 60° | 86.5 | 0.1° |
| 2 | 398° | 456° | 5.0 h° | 28° | 103° | 1.1° |

a) ref. 29 b) ref. 31 1) \( \eta_{MOST} \) calculated according to eqn. 2, where 1 was dissolved in toluene (70 mM) and circulated in the device at 2ml/h. The reported value is an average of 2 independent measurements. 2) 2 was dissolved in toluene (100 mM) and circulated in the device at 10 ml/h. The reported value is an average of 6 independent measurements.
to higher quantum yield of norbornadienes 1 and 2 used in this study (60% and 28% respectively) with respect to the quantum yield of the ruthenium compounds previously used (0.2%)\textsuperscript{14,45}. The fact that a part of the absorbed light is not stored is related to 1) that $\phi_{iso}$ is not equivalent to unity, and 2) the intrinsic property of the MOST system, which looses energy in the photoisomerization process, from the excited norbornadiene to the relaxed quadricyclane (\textit{vide supra}).

We can calculate the energy loss depending on $\phi_{iso}$ as $E_{iso}$ (point 1 above):

$$E_{iso} = J_0^{\lambda_{onset}} n_f \cdot E_f \cdot (1 - \phi_{iso}) d\lambda$$

where $n_f$ is the number of photons in the solar spectrum (s$^{-1}$ m$^{-2}$ nm$^{-1}$), and $E_f$ is the energy of each photon (J nm$^{-1}$). The energy loss depending on the relaxation from the electronically excited norbornadiene to the quadricyclane (point 2 above) is calculated:

$$E_{relax} = J_0^{\lambda_{onset}} n_f \cdot (E_f - \Delta H_{relax} / N_A) \cdot \phi_{iso} d\lambda$$

where $N_A$ is Avogadro’s number. In the same way we can calculate the theoretical energy stored by a MOST system, $E_{stored}$, as:

$$E_{stored} = J_0^{\lambda_{onset}} n_f \cdot \Delta H_{relax} / N_A \cdot \phi_{iso} d\lambda$$

In the case of NBD 2 it is calculate that $E_{iso}$=84 W m$^{-2}$, $E_{relax}$=21 W m$^{-2}$, and $E_{stored}$=11 W m$^{-2}$. Where the latter corresponds to 1.1% of the AM1.5 solar spectrum, in accordance with $\eta_{MOST}$, the experimentally determined value. The sum of all the three contributions is equal to 117 W m$^{-2}$, which corresponds to the incoming solar power below 456 nm, confirming that eqn (4) and eqn (5) are describing the main losses affecting $\eta_{MOST}$. As a consequence, increasing $\phi_{iso}$ to reduce $E_{iso}$ is becoming a key parameter to improve in future works in order to reach a higher $\eta_{MOST}$.

To further evaluate the performance of the norbornadienes, the most promising compound (2) was subjected to a cycling test in solution (photoisomerization and subsequent thermal back-conversion) at 60°C. As shown in Figure 5, Compound 2 undergoes 127 cycles with negligible degradation, demonstrating excellent robustness. Additionally, the cycling test was carried out under ambient conditions (no degassing), leading to 0.2% degradation per conversion cycle (figure S2) highlighting the need for an oxygen free environment to obtain negligible degradation.

The performance of the SWH collector was assessed in four different working conditions. Water was circulated at different flow-rates (m$^3$ h$^{-1}$) in the lower collector, while in the upper collector circulated air, toluene or solutions of 1 or 2 in toluene. The water temperature increase ($\Delta T$) in the SWH collector was measured by monitoring the temperature before ($T_1$) and after ($T_2$) exposure to simulated sunlight and $\eta_{SWH}$ was calculated according to eqn (3). The concentration of 1 or 2 were chosen in order to maintain transmission through the upper collector near zero below $\lambda_{onset}$. In this way the MOST layer is acting as a cut-off filter below the onset of absorption. However, a significant part of the solar photons, those with lower energy than $\lambda_{onset}$, is still available for water heating after being transmitted through the upper collector (as can be seen in Figure 2).

Figure 6 show measured temperature rises over the SWH collector ($\Delta T$), recorded at different water flow-rates. The observed $\Delta T$ is between 8°C and 17°C, with calculated $\eta_{SWH}$ between 47% and 82%. In the presented device, adding toluene or a solution of MOST in the upper layer of the collector does not significantly affect the measured $\Delta T$ of the water and thus $\eta_{SWH}$ of the SWH device. While using MOST 1 or 2 to store the energy it is still possible to reach values of $\eta_{SWH}$ up to 80%.

An energy balance equation for the full system can be therefore defined as:

$$E_{stored} = \frac{\Delta H_{relax}}{N_A} \cdot \phi_{iso} \cdot \int_{0}^{\lambda_{onset}} n_f \cdot E_f \cdot (1 - \phi_{iso}) d\lambda$$

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure5}
\caption{Cycling tests, photoconversion followed by thermal back reaction at 60°C for 127 cycles. The normalized absorption (a.u.) of the solution of 2 after each half cycle of thermal back-conversion and photoisomerization is reported. The insert shows a detail of the normalized absorption (a.u.) of cycles 81 to 86.}
\end{figure}
\[ E_{\text{AM1.5}} = (\eta_{\text{SWH}} + \eta_{\text{MOST}}) \cdot E_{\text{AM1.5}} + E_{\text{iso}} + E_{\text{relax}} + E_{\text{th}} \]  

(7)

Where \( E_{\text{th}} \) are the thermal energy losses, which correspond to 8% of the incoming solar radiation at a flow speed of \( n = 1.6 \cdot 10^{-5} \text{ Kg s}^{-1} \).

The above described experiments demonstrate that it is possible to capture and store part of the high energy photons in a MOST system without severely compromising the SWH efficiency. To validate and extrapolate these results, the thermal behaviour of the hybrid device was simulated. The basis of the simulation was a parametric analysis of a coupled MOST and SWH system (see SI for details), in analogue to the coupled PV/SWH simulations by Norwood et al.,65 Otanicar et al.,67 and Zondag et al.,48 A Matlab script was developed to solve the coupled mass and heat transfer equations using the Newton-Raphson method (See SI for details). The solid lines in Figure 6 show simulated values of temperature rises and \( \eta_{\text{SWH}} \) of a SWH device having an incorporated MOST system (Fig. S4). The results from the simulation follows the experimental trends, although with a general decrease in \( \Delta T \) and \( \eta_{\text{SWH}} \). Using existing MOST systems, which have relatively low onset of absorption (389 nm and 456 nm respectively, corresponding to 3.4 eV and 2.8 eV), only minor decreases in the generated heat of the SWH system is experienced. This is rationalized by the relatively low amount of solar flux in the UV/blue part of the solar spectra which is absorbed by the MOST (12% in the case of NBD 2). If instead an optimized MOST system, having a bandgap of 2.1 eV (as defined in previous work by us34), was used, a 13% decrease in \( \eta_{\text{SWH}} \) is expected based on the simulation. However, a MOST system with a bandgap of 2.1 is expected to be able to harvest and store 9.9% of the solar energy in chemical bonds for on demand delivery.34 The performed simulations validate the experimental results, and leads to a high combined efficiency \( \eta_{\text{comb}} \) of a hybrid device that uses an optimal bandgap MOST system. Figure 7 show how \( \eta_{\text{MOST}} \) and \( \eta_{\text{SWH}} \) varies with the bandgap of the MOST system. With lowering bandgap, the solar energy storage efficiency of the MOST system increases until a maximum point at around 2 eV. At the same time the SWH efficiency decreases. However, in combination the decreased SWH efficiency is balanced by an increase in the MOST solar energy storage efficiency. It should noted that at high MOST bandgaps, \( \eta_{\text{comb}} \) is decreasing. This because the MOST system is absorbing the majority of photon energy but at the same time \( \Delta H_{\text{storage}} \) decrease towards zero, resulting in heating of the MOST system, which we here regard as an energy loss. As is the case with any new technology, initial applications will be in niches where MOST offers unique technical properties and where cost-per-joule is of lesser importance. Because a portion of energy in the MOST system is stored in chemical bonds, the potential exists for very stable long-term storage limited by the volume of the storage capacity. This energy can be transported and delivered in very precise amounts with high reliability. An interesting contribution in this context is the review by Kucharski et al.,10 where MOST technologies are thoroughly analysed and put into context by comparing them with other heat batteries. They as well discuss how MOST solar thermal batteries could be useful in some niches applications as discussed in our work (e.g. off grids stations, extreme environments like deserts, heating of water for disinfection and cooking).

Another example of a possible application could be satellite thermal control systems. Here the system might run best without the SWH system for instance, collecting solar energy exclusively in the chemical bonds of the MOST system for use as a thermal buffer that can be renewably regenerated. Design drivers for satellite thermal storage systems heavily emphasize precision controllability, reliability and, to a lesser degree, energy storage density.49 The MOST system described here has reached a performance level where it has some technical advantages over common solutions such as fluid cooling and phase change materials (PCMs), namely that it works over a range of temperatures and has the ability to produce a controlled temperature rise as well as actively transport heat. The demonstrated technical performance of the system (397 kJ/kg = 110 Wh/kg (present compounds), with a potential of 966 kJ/kg = 268 Wh/kg (unsubstituted norbornadiene)) is very competitive with modern lithium ion battery chemistries for energy density, indicating that it may be a viable technique in any application that uses battery energy for resistive heating. It also exceeds the enthalpy of fusion for most common PCMs (e.g. paraffin waxes 200-270 kJ/kg). The MOST system can thus also be competitive from a gravimetric energy density standpoint. The system as described thus represents an advance to the point where MOST is a technically interesting solution in some applications. Future work along these lines should produce prototypes that can empirically demonstrate real world performance and reliability and begin to shed light on system costs. The strong cyclability performance of the system as demonstrated is one essential prerequisite for applications demanding reliability in harsh or remote environments, as well as for systems that are energy efficient in a full lifecycle sense.

If such prerequisites are met, the potential to release heat at up to 238°C indicates that applications may extend beyond what is possible with water based heat storage. Such applications include pre-warming of stand-alone systems that require heat on startup below certain temperatures (e.g. pumps or engines), but which might be located in remote locations or harsh environments without access to full-time power (or steady...
sunlight) and where high logistics cost of delivered fuel enhances the competitiveness of renewable approaches. Of course, the additional need for SWH under the sunlight hours would greatly enhance the applicability of the MOST technology.

Any future large-scale application of MOST technology faces two primary challenges, which together can form a roadmap for long-term research and development. The first challenge is to overcome for further development of such thermochemical storage technologies is likely the toxicity of the solvent; reduction in the toxicity, or elimination of the solvent as demonstrated for azobenzenes by Kimizuka and co-workers would open up many more potential applications such as portable cooking devices that can be recharged with sunlight and can cook when the sun is down.

Lastly, reduction of cost through mass production of the constituent chemicals is certainly needed before such systems could compete with other solar renewable technologies in bulk energy applications. Space heating, with storage from day to night, for instance would be a very challenging application area given the maturity of other technologies in that field. The old analysis of Philippopoulous et al. is still largely correct in that it may be impossible for the MOST system by itself to reach cost competitive generation of bulk steam, although the current system does represent a significant advance towards the optimal end of the parameter space they used. Their economic analysis explicitly did not include MOST as a marginal source in combination with other solar approaches, however the hybrid system is mentioned in their outlook section. We have demonstrated here that such a hybridized approach is achievable technically while maintaining high efficiency of the device, which is one critical step towards being able to re-evaluate the technology. Complete economic analysis of such a system is well beyond the remit of this paper. Breaking through the barrier for commercialization in a very competitive solar landscape would be a significant and difficult challenge, but breakthroughs are likely happening, given the relative youth of solar technologies and the current worldwide trend to phase out fossil fuels.

Conclusions

A new concept in the form of a hybrid technology, combining solar water heating and molecular solar thermal energy storage has been presented, and a device fabricated. Two nortbornadienes (1 and 2 in Fig. 3) have been selected to be tested in the device, and their robustness tested through cyclability experiments, which showed negligible degradation over more than 100 cycles. The energy storage efficiency of the molecular solar thermal system, \( \eta_{MOST} \), is up to 1.1%, representing a major step forward compared to previously reported MOST efficiencies in devices \(^{14}\). The efficiency of the solar water heating part, \( \eta_{SWH} \), is measured to be up to 80%. Main areas areas where to focus future efforts to improve the hybrid technology and generically a MOST technology, are identified as: improved quantum yield of photoisomerization \( \phi_{iso}, \) half life of quinacrylance, \( t_1/2 \), and developing a solvent free, liquid MOST system.

Broader Context

Development of technologies for solar energy storage is a key challenge for a future society independent of fossil fuels. Hybrid solar technologies is an appealing way to overcome the limitations in current technology, and by that achieve better performing systems able to harvest and store solar energy. We present an efficient hybrid solar thermal energy storage system that combines energy storage in covalent bonds in molecular solar thermal systems with thermal energy storage in heated water. It is demonstrated that the molecular system can convert up to 1% of the incoming sunlight to storable chemical energy and at the same time, up to 80% of the incoming sunlight is transformed to heat in the water heating system. Moreover, it is shown that the chemical system can operate through more than 100 energy storage and release cycles with negligible degradation. The combined system mitigates challenges associated with both chemical and thermal energy storage and enables both long and short term energy storage.
