Binary Mixtures of Charged Colloids: A Potential Route to Synthesize Disordered Hyperuniform Materials

Duyu Chen, Enrique Lomba, and Salvatore Torquato

Disordered hyperuniform materials are new, exotic class of amorphous matter that exhibit crystal-like behavior, in the sense that volume-fraction fluctuations are suppressed at large length scales, and yet they are isotropic and do not display diffraction Bragg peaks. These materials are endowed with novel photonic, phononic, transport and mechanical properties, which are useful for a wide range of applications. Motivated by the need to fabricate large samples of disordered hyperuniform systems at the nanoscale, we study the small-wavenumber behavior of the spectral density of binary mixtures of charged colloids in suspension. The interaction between the colloids is approximated by a repulsive hard-core Yukawa potential. We find that at dimensionless temperatures below 0.05 and dimensionless inverse screening lengths below 1.0, which are experimentally accessible, the disordered systems become effectively hyperuniform. Moreover, as temperature and inverse screening length decrease, the level of hyperuniformity increases, as quantified by the “hyperuniformity index”. Our results suggest an alternative approach to synthesize large samples of effectively disordered hyperuniform materials at the nano scale under standard laboratory conditions. In contrast with the usual route to synthesize disordered hyperuniform materials by jamming particles, this approach is free from the burden of applying high pressure to compress the systems.

The concept of disordered hyperuniformity was first introduced in the context of many-particle systems over a decade ago, and was subsequently generalized to two-phase heterogeneous materials. Disordered hyperuniform systems and materials belong to a new, exotic class of amorphous matter that lies between crystal and fluid states: they behave like crystals in the way that they suppress density or volume-fraction fluctuations at large length scales, and yet they are statistically isotropic with no Bragg diffraction peaks, as in the case of liquids or glasses. Specifically, for disordered hyperuniform materials, the local volume-fraction variance \( \sigma^2_V(R) \) within a \( d \)-dimensional spherical observation window of radius \( R \) goes to zero for large \( R \) asymptotically more rapidly than the inverse of the window volume, i.e., faster than \( R^{-d} \). This is different from typical disordered two-phase materials, which possess \( \sigma^2_V(R) \) that vanishes like \( R^{-d} \) for large \( R \). Equivalently, the spectral density \( \tilde{\chi}_V(k) \), which is proportional to the scattering intensity, goes to zero as the wavenumber \( k \) vanishes, i.e.,

\[
\lim_{k \to 0} \tilde{\chi}_V(k) = 0.
\]

Note that the widely-used structure factor \( S(k) \) can be thought as the counterpart of \( \tilde{\chi}_V(k) \) for point patterns. Methods to design realizations of two-phase disordered hyperuniform systems have been devised.

Disordered hyperuniform systems have been shown to be endowed with novel physical properties; see the recent overview by Torquato. In particular, disordered hyperuniform dielectric networks were found to possess large complete photonic band gaps comparable in size to photonic crystals, but superior to photonic crystals because of their perfect isotropy and robustness to defects. As a result, these networks are suitable for a wide range of applications such as lasers, sensors, waveguides, and optical microcircuits. Similarly, disordered hyperuniform materials possess desirable phononic, electronic, transport, and mechanical properties, and wave-propagation characteristics, and their full potential in technological applications has yet to be explored.

Despite the desirable physical properties and technological potential of disordered hyperuniform materials, their synthesis and fabrication remain challenging, especially for large samples at the nano scale. While 3D printing and lithographic technologies can now be applied to the rational design of materials with tunable disorder at the micro-scale, in this particular instance, the spatial resolution of these techniques limits their application at the nanoscale. Novel avenues need

to be explored to optimize fabrication in the nanometer range.

The self-assembly and self-structuring of nanoparticles with designed interactions into target structures represents a promising route,21,22 and its application to the synthesis of disordered hyperuniform materials is still in its infancy. While disordered hyperuniformity was shown to arise in hard-particle systems as they approach jammed (mechanically stable) states,23–25 the experimental realization of such systems requires applying high pressure to compress the systems, which is challenging. It is also known that systems with pure Coulombic interactions in a neutralizing background can be disordered and hyperuniform at positive temperatures.26–28 However, these systems by themselves cannot be experimentally realized. Any real charged colloidal systems will have a finite non-zero inverse screening length for finite non-zero counterion concentration, by which \( \bar{\chi}_v (k = 0) \) will also be non-zero.

In this work, as an alternative, we computationally explore the use of the self-structuring (self-assembly) process of binary mixtures of charged colloids in suspension in order to guide experimentalists to fabricate large samples of effectively disordered hyperuniform materials in two dimensions. Specifically, it is desired that these designed materials be realized in the laboratory at the nanoscale without resorting to compression techniques. Following the coarse-graining approach of Derjaguin, Landau, Verwey and Overbeek29,30 (DLVO), we model the colloidal particles using repulsive hard-core Yukawa interactions31,32. The system is studied by means of canonical Monte Carlo simulations, using a sample size, \( N, \) of 10000 particles and periodic boundary conditions. We note that this system size is already large enough to determine small-\( k \) behavior of the systems given the range of our potential, and it is reasonable to assume that the effective disordered hyperuniformity will also hold for large sample sizes and thus could be realized in experiments. We have considered different systems with varying inverse screening lengths (i.e., effective counterion concentrations in the DLVO model) and temperatures, up to a total of 50 different systems and conditions. Particle size disparity is introduced to frustrate crystallization.33 Our two-dimensional study applies to particles at interfaces and thin films (monolayers). Additionally, for a periodic finite sample, in two dimensions we can access smaller wavenumbers with a scaling of \( 2\pi/\sqrt{N} \), compared to the scaling of \( 2\pi/N^{1/3} \) in three dimensions. We study the small-\( k \) behavior of the volume-fraction fluctuations of the resulting structures, as measured by the spectral density. To that aim we employ the “hyperuniformity index”, \( H \), defined as:

\[
H = \bar{\chi}_v (0)/\bar{\chi}_v (k = k_{\text{max}}),
\]

where \( \bar{\chi}_v (0) \) is the extrapolated value of the spectral density as \( k \) goes to zero and \( \bar{\chi}_v (k = k_{\text{max}}) \) is the value of the largest peak (often the first peak) of the spectral density. Clearly, the lower is the value of \( H \), the larger the degree of hyperuniformity displayed by the system. In this work, we deem the systems to be effectively hyperuniform whenever \( H \leq 10^{-2} \), consistent with previous experience concerning hyperuniformity in binary maximally-randomly-jammed packings of hard disks.25 However, as detailed below, we note that \( H \) here is different from its counterpart \( H_L \) based on the structure factor that is used in previous works.25,33,34

We find that at experimentally accessible temperatures and inverse screening lengths, the disordered structures indeed become effectively hyperuniform. Moreover, the degree of hyperuniformity, as measured by \( H \), increases as temperature and inverse screening lengths decrease. On the other hand, the spatial distribution associated with each individual component is not hyperuniform, i.e., the system is not “multihyperuniform” (the patterns of both the total population and the individual types are simultaneously hyperuniform),35 which is contradiction to some systems with bare Coulomb interactions.28

Specifically, the hard repulsive Yukawa potential between particles \( i \) and \( j \) is given by31,32

\[
v(r_{ij}) = \begin{cases} \infty, & r_{ij} \leq D_{ij} \\ \epsilon_{ij} \left[ \exp[-\kappa (r_{ij} - D_{ij})] - \exp[-\kappa (r_{ij} - D_{ij})/r_C D_{ij}] \right], & D_{ij} < r_{ij} < r_C \\ 0, & r_{ij} > r_C \end{cases}
\]

where \( r_{ij} \) is the distance between particles \( i \) and \( j \), \( D_{ij} = R_i + R_j \) (\( R_i \) and \( R_j \) are the hard-core radii of particles \( i \) and \( j \)), \( \kappa \) is the inverse screening length, and \( r_C \) is the cutoff of the soft repulsions [chosen to be sufficiently large compared to the screening length, which increases as the screening length increases such that the cutoff does not affect \( \bar{\chi}_v (0) \)]. The energy of the system \( E \) is the sum of these effective pairwise repulsions, i.e.,

\[
E = \sum_{i<j} v(r_{ij}).
\]

Here we consider an equimolar binary mixture of small and large colloids with a small to large colloid diameter ratio \( \alpha \equiv D_S/D_L = 2/3 \) and a small-colloid mole fraction \( x \equiv N_S/(N_S + N_L) = 0.5 \). The packing fraction (the fraction of space covered by the colloids) is set to \( \theta = 0.21 \). Here \( D_S \) and \( D_L \) are the hard-core diameters of the small and large colloids, and \( N_S \) and \( N_L \) are the number of small and large colloids in the system, respectively. We set the ratios of the energy scales \( \epsilon_{SS} : \epsilon_{SL} : \epsilon_{LL} = 1 : 2 : 4 \), where \( \epsilon_{SS}, \epsilon_{SL}, \) and \( \epsilon_{LL} \) are energy scales of the interactions between two small colloids, between a small colloid and a large colloid, and between two large colloids, respectively. In addition, we note that the behavior of our systems at small wavenumbers is not sensitive to the specific choice of the values of \( D_S/D_L, N_S/N_L, \) and \( \epsilon_{SS} : \epsilon_{SL} : \epsilon_{LL} \).

We then systematically study the effect of temperature \( T \) and inverse screening length \( \kappa \) on the small-\( k \) behavior of the spectral density of our system. For each \( T \) and \( \kappa \), we employ
a standard canonical Monte Carlo simulation technique. After a thermalization run consisting of 5000 translation trials per particle, we collect 50 uncorrelated sample configurations from each system and temperature under consideration. The pair structure is first analyzed in terms of the total pair correlation function, \( g_2(r) \), and the corresponding spectral density, \( \tilde{\chi}_c(k) \). Specific contributions for each mixture component are also studied. Thus, for a binary mixture of small and large colloidal particles, \( g_2(r) \) can be decomposed into three components:

\[
g_2(r) = x^2g_{2,S}(r) + (1-x)^2g_{2,L}(r) + 2x(1-x)g_{2,C}(r),
\]

where \( x \) is the small colloid relative concentration, \( g_{2,S}(r) \) and \( g_{2,L}(r) \) are the pair distribution functions of the small and large colloids, respectively, and \( g_{2,C}(r) \) is a cross correlation term.

In parallel, the spectral density \( \tilde{\chi}_c(k) \) can be decomposed into three contributions:

\[
\tilde{\chi}_c(k) = \tilde{\chi}_{c,S}(k) + \tilde{\chi}_{c,L}(k) + \tilde{\chi}_{c,C}(k),
\]

where \( \tilde{\chi}_{c,S}(k) \), \( \tilde{\chi}_{c,L}(k) \), and \( \tilde{\chi}_{c,C}(k) \) are given by

\[
\tilde{\chi}_{c,S}(k) = \frac{|\tilde{m}(k;R_S)\sum_{j=1}^{N_S}\exp(-ik \cdot r_j^{(S)})|^2}{V},
\]

\[
\tilde{\chi}_{c,L}(k) = \frac{|\tilde{m}(k;R_L)\sum_{j=1}^{N_L}\exp(-ik \cdot r_j^{(L)})|^2}{V},
\]

and

\[
\tilde{\chi}_{c,C}(k) = 2\text{Re}\left[ \tilde{m}(k;R_S)\tilde{m}(k;R_L)\sum_{j=1}^{N_S}\exp(-ik \cdot r_j^{(S)})\sum_{n=1}^{N_L}\exp(ik \cdot r_n^{(L)}) \right].
\]

Here \( \tilde{\chi}_{c,S}(k) \), \( \tilde{\chi}_{c,L}(k) \) are the spectral densities of the small and large colloids, respectively, \( \tilde{\chi}_{c,C}(k) \) is the cross term (that already includes a factor two stemmed from identical small-large and large-small contributions), \( \{r_j^{(S)}\} \) and \( \{r_j^{(L)}\} \) denote the positions of the small and large colloids, respectively, and \( \tilde{m}(k;R) \) is the Fourier transform of the indicator function of a disk with radius \( R \) given by

\[
\tilde{m}(k;R) = \frac{2\pi R}{k}J_1(kR).
\]

where \( J_1(x) \) is a Bessel function of the first kind. This quantity, which reflects the finite size of the particles, would correspond in a real scattering experiment to the form factor function, which accounts for the interaction of the probe particles (photons, electrons, ...) with the individual sample particles.

As an example, Fig. 1 shows a representative configuration of the equilibrated system with \( \kappa D_S = 0.2 \) at \( k_BT/\varepsilon_S = 0.1 \), where \( k_B \) is the Boltzmann’s constant. The lower graph corresponds to a 10-fold enlargement illustrating the size difference of our colloidal particles. Both figures correspond, at first sight, to a simple disordered fluid.

A more quantitative description at the pair-statistics level
can be obtained from the computed total pair correlation function \( g_2(r) \), and its three partial contributions, \( g_{2,S}(r) \), \( g_{2,L}(r) \), and \( g_{2,C}(r) \). These are shown in Fig. 2, and are consistent with the apparent lack of long-range correlations, as can be appreciated by their decay to unity at pair distances \( r \approx 5D_L \) and beyond in all instances.

Fig. 2 Total pair correlation \( g_2(r) \) and its partial counterparts for the small and large charged colloids and the cross term \( g_{2,S}(r) \), \( g_{2,L}(r) \), and \( g_{2,C}(r) \) of the equilibrated equimolar mixture of large and small charged colloidal particles, with a small to large colloid diameter ratio \( \alpha = 2/3 \), dimensionless inverse screening length \( \kappa D_S = 0.2 \), a packing fraction \( \phi \) of 0.21, and at dimensionless temperature \( k_BT/\varepsilon_{SS} = 0.1 \). Note that all of these four pair correlation functions decay rapidly to unity as \( r \) increases, implying the lack of long-range order at the two-particle level for the overall system as well as the individual components.

The computed total spectral density \( \tilde{\chi}_V(k) \) and its three components \( \tilde{\chi}_{V,S}(k) \), \( \tilde{\chi}_{V,L}(k) \), and \( \tilde{\chi}_{V,C}(k) \) are shown in Fig. 3. We fit \( \tilde{\chi}_V(k) \) with a third-order polynomial \( f(k; a_0, a_1, a_2, a_3) = \sum_{j=0}^{3} a_j k^j \) for all wavenumbers within \( 0.0130 \leq kD_S/(2\pi) \leq 0.157 \). Interestingly, the resulting intercept \( a_0 \) has a value of \( 2.26 \times 10^{-3} \), indicating that \( \tilde{\chi}_V(k) \) is effectively going to zero as \( k \) goes to zero.

We have determined \( H \) to be \( 1.0 \times 10^{-2} \) from the spectral density shown in Fig. 3, showing that the corresponding system is effectively hyperuniform. However, \( \tilde{\chi}_{V,S}(k) \) and \( \tilde{\chi}_{V,L}(k) \) do not go to zero as \( k \) goes to zero, an indication that the spatial distribution of the small or large colloids alone is not “multi-hyperuniform”.\(^{35}\)

The value of \( H \) based on the spectral density \( \tilde{\chi}_V(k) \) here in general significantly higher than that of \( H_S \) based on the structure factor \( S(k) \) of the corresponding point configura-

Fig. 3 Total spectral density \( \tilde{\chi}_V(k) \) and its partial counterparts for the small and large colloids and the cross term \( \tilde{\chi}_{V,S}(k) \), \( \tilde{\chi}_{V,L}(k) \), and \( \tilde{\chi}_{V,C}(k) \) of the equilibrated equimolar mixture of large and small charged colloidal particles, with a small to large colloid diameter ratio \( \alpha = 2/3 \), dimensionless inverse screening length \( \kappa D_S = 0.2 \), a packing fraction \( \phi \) of 0.21, and at dimensionless temperature \( k_BT/\varepsilon_{SS} = 0.1 \). Note that the spectral densities are all scaled by \( D_L^2 \) so that they are dimensionless, where \( D_L \) is the diameter of the small colloid. The total \( \tilde{\chi}_V(k) \) practically vanishes as \( k \) goes to zero, implying the effective hyperuniformity of the overall system. However, this is not the case for the partial counterparts \( \tilde{\chi}_{V,S}(k) \) and \( \tilde{\chi}_{V,L}(k) \). This means that the spatial distributions of the small or large colloids alone are not hyperuniform, i.e., the system is not “multihyperuniform”.

Next, we carry out a similar analysis for 50 different combinations of \( T \) and \( \kappa \) in the range of \( k_BT/\varepsilon_{SS} \in [0.01, 0.2] \) and \( \kappa D_S \in [0.2, 2.0] \). We then can construct a structural “phase diagram” of \( H \) in terms of \( T \) and \( \kappa \), as shown in Fig. 4. Interes-
ingly, $H$ is on the order of $10^{-2} \sim 10^{-3}$ when $k_BT/\varepsilon_{SS} \leq 0.05$ and $\kappa D_S \approx 1.0$, implying that the corresponding systems are effectively hyperuniform. Moreover, as $T$ and $\kappa$ decrease, $H$ decreases, implying the increasing level of hyperuniformity for the corresponding system. For example, when we decrease $k_BT/\varepsilon_{SS}$ to 0.01, the value of $H$ falls below $10^{-3}$. This is consistent with the fact that as $\kappa$ decreases, the “screening” effect becomes weaker and the potential becomes longer-ranged. As a result, the suspension of charged colloids behaves more like the pure-Coulombic system in a neutralizing background, which is known to be perfectly hyperuniform. 26–28 Also, as $T$ decreases, the system is increasingly accessing lower energy states, in parallel with hard-core systems evolving towards lower enthalpy jammed states. As mentioned above, as hard-particle systems are driven towards jammed states, they tend to become hyperuniform. 23–25

Last, we note that the configurations generated in our computer simulations could potentially be realized in experiments by depositing colloids onto solid substrates or at fluid interfaces 39-41 and allowing them to self-organize. Promising candidate colloids include polystyrene particles, proteins, and other macromolecules 42-45. Note also that the hard-core component of our interactions can be experimentally modeled by grafting polymer chains to the surface of colloidal particles, minimizing the effect of attractive interactions 46. In this connection, the set of parameters $\kappa$ and $\varepsilon_{ij}$ defining our interaction model can be approximately transformed into experimentally accessible/measurable quantities using the DLVO theory. 43,47 For instance, a binary mixture of colloids with $Z_S = 150$, $Z_L = 367$, $D_S = 300nm$, and $D_L = 450nm$ ($Z_S$, $Z_L$, $D_S$, and $D_L$ are charges and diameters of the small and large colloids, respectively) in an aqueous solution at 300K, with its corresponding counter-ions and no other electrolytes present, roughly leads to $k_BT/\varepsilon_{SS} \approx 0.04$ and $\kappa D_S \approx 0.96$, and this system is predicted to be effectively hyperuniform. Once an experimental realization of the colloidal system on solid substrates or at fluid interfaces is obtained, snapshots of the configurations can then be taken by means of video optical microscopy, which can be further analyzed to check for hyperuniformity. Interested readers are referred to the work by Dreyfus and coworkers 48 for more detailed information on these issues. In addition, although in this work we focused on generating disordered hyperuniform materials in two dimensions through the self-structuring of binary mixture of colloids in suspension, we expect that similar procedures can be applied to their three-dimensional counterparts, which might even have greater practical relevance.

Conclusions and Discussion

In this work we proposed an approach to synthesize in silico two-dimensional disordered hyperuniform materials through the self-structuring (self-assembly) process of binary mixtures of charged colloids. Specifically, we systematically studied the small-wavenumber volume-fraction fluctuation behavior of a relatively large number of samples, probing the $\kappa-T$ parameter space in search for effective hyperuniformity. In this way we have constructed a structural “phase diagram” of the “hyperuniformity index”, $H$, in terms of $T$ and $\kappa$. We have found that $H$ reaches the order of $10^{-2} \sim 10^{-3}$ when $k_BT/\varepsilon_{SS} \leq 0.05$ and $\kappa D_S \leq 1.0$, implying that the corresponding systems are effectively hyperuniform. Moreover, as $T$ and $\kappa$ decrease, $H$ decreases, implying the increasing level of hyperuniformity for the corresponding system.
In addition, we note that in the limit $\kappa \to 0$ and $r_C \to \infty$, the interaction in (3) becomes a bare Coulomb. From the findings of Lomba, Weis, and Torquato, $^2$ we know that in the limit our system will not reach strict multihyperuniformity, since it does not fulfill the required condition $\epsilon_{ij} \neq \sqrt{\epsilon_{ii} \epsilon_{jj}}$, $\forall i \neq j$. In this work, we have shown that the system is also not multihyperuniform for non-zero $\kappa$. Finally, we note that while the present work focused on binary mixtures of charged colloids, it is straightforward to extend the analysis to charged mixtures with arbitrary size distributions and compositions.
