Enhanced photostability of cuprous oxide by lignin films on glassy carbon electrodes in the transformation of carbon dioxide

E. Landaeta\textsuperscript{a}, Zachary D Schultz\textsuperscript{b,c}, Ana Burgos\textsuperscript{d}, Ricardo Schrebler\textsuperscript{e} and M. Isaacs\textsuperscript{a,*}\textsuperscript{d,e}\textsuperscript{f}

Photoelectrochemical reduction of CO\textsubscript{2} was investigated on carbon electrodes modified with lignin and cuprous oxide. The electrodes were modified by electropolymerization of lignin and subsequent pulse electrodeposition of CuO\textsubscript{2}. Characterization of the electrodes was performed by SEM microscopy; Raman; IR-ATR; and UV-visible spectroscopies, as well as electrochemical methods. Lignin films provide a micro-environment where CuO\textsubscript{2} is stabilized and also its reactivity is modified toward C-H-O containing compounds. The main products obtained from the reduction of CO\textsubscript{2} are formaldehyde, methyl formate and ethyl acetate, as detected and quantified by nuclear magnetic resonance and UV-Vis spectroscopy. Our results demonstrate that lignin is a good material for the formation and support of the electrodeposited CuO\textsubscript{2}, where the CuO\textsubscript{2} enables the potential use of solar energy for the photoelectrochemical reduction of CO\textsubscript{2} at low overpotentials.

Introduction

In the last two decades, the different entities responsible for the study and mitigation of climate change have focused on the rapid and constant increase of atmospheric carbon dioxide associated with global warming\textsuperscript{1}. The earth’s climate has warmed by about 0.6 \degree C in the last 100 years,\textsuperscript{2} which coincides with atmospheric CO\textsubscript{2} increasing by more than 60 ppm since it was first recorded in 1958\textsuperscript{3}. The direct relationship between the increase in global temperature and the concentration of CO\textsubscript{2} has affected, is affecting and irreproachably is affecting ecological systems and biota that are highly sensitive to ecological variables like temperature and precipitation\textsuperscript{4–6}.

At present, the atmospheric CO\textsubscript{2} concentration has exceeded the 400 ppm barrier, a value that had never before been recorded\textsuperscript{7}. To mitigate the CO\textsubscript{2} increase, efforts are focused on enhancing energy efficiency and improving technologies for capture, storage and transformation of CO\textsubscript{2}. Differents methods have been used for CO\textsubscript{2} transformation, among them, electrochemical and photoelectrochemical reduction are versatile methods that can be done under ambient conditions. In this context several metallic electrodes like, Pt, Ni, Cr and Mo, among others,\textsuperscript{8,9} have been used to reduce CO\textsubscript{2} electrochemically, producing mainly C\textsubscript{2} compounds like CO or HCOO\textsubscript{2}\textsuperscript{10–12}. The main problem is the high electrochemical overpotential required to reduce CO\textsubscript{2}. Because CO\textsubscript{2} is stable and chemically inert, the single-electron reduction of CO\textsubscript{2} to an anion radical CO\textsubscript{2}\textsuperscript{-}\textsuperscript{13} requires a significant negative electrochemical potential of -1.9 V vs NHE\textsuperscript{13}. On the other hand, photoelectrochemical studies show decreased overpotential for CO\textsubscript{2} reduction.

Electrodes modified with a metal oxide semiconductor allow one to take advantage of semiconductor properties and to create the charge carriers using the eletrons from the conduction band to reduce the CO\textsubscript{2}. A disadvantage of semiconductor materials is that oxidation of the electrode or recombination of the photogenerated carriers, that may occur and decrease system efficiency\textsuperscript{14}. Metal oxide semiconductors have been used for CO\textsubscript{2} reduction, such as TiO\textsubscript{2}\textsuperscript{15,16}, WO\textsubscript{3}\textsuperscript{17,18}, ZnO\textsuperscript{19,20}, CdS\textsuperscript{21,22}, CdTe\textsuperscript{23}, and CuO\textsubscript{2}\textsuperscript{24,25}. TiO\textsubscript{2} is the most widely used, but an important limitation of this semiconductor is the requirement of UV photons with wavelengths shorter than 380 nm to create electron-hole pairs\textsuperscript{26}. This wavelength range impedes the use of the solar spectrum in more applied devices.

Cuprous oxide, CuO\textsubscript{2}, is another semiconductor that has attracted great interest. In contrast to TiO\textsubscript{2}, CuO\textsubscript{2} has a high absorption coefficient\textsuperscript{27} across the solar spectrum that allows it to photogenerate electron-hole pairs. Furthermore, CuO\textsubscript{2} has a conduction band edge positions that lies at a very negative potential, translating into high reducing power for the
photogenerated electrons. Cu$_2$O is a semiconductor that is easy to prepare and is composed of two very abundant and non-toxic elements. It has been reported with a direct band gap near to 2.2 eV, and depending on doping level may have a n-type or p-type character. In recent works, Cu$_2$O has been used as a photocathode for photoelectrochemical reduction of CO$_2$.

Using a hybrid CuO/Cu$_2$O semiconductor, K. Rajeshwar et al. reported the photoelectroreduction of CO$_2$ to methanol in aqueous solution by applying -0.2V vs NHE under simulated AM 1.5 solar irradiation. Also, using the Cu/Cu$_2$O system and applying high overpotential the reaction yields CH$_4$ and C$_2$H$_6$ as the main products. However, the main drawback in the use of this semiconductor as a photocathode is its instability in aqueous solution resulting from the redox potentials of cuprous oxide lying within its own bandgap.

Then, to protect the electrode in aqueous solution A. Paracchino et al. covered Cu$_2$O with ZnO:Al, TiO$_2$ and Ag nanoparticles. Their results showed that the electrodes produced photocurrents of up to ~7.6 mA cm$^{-2}$ at a potential of 0V vs RHE and remained active after 1 hour of testing.

On the other hand, lignin is a biopolymer present in plants, which constitutes the cell wall along with cellulose and hemicellulose. In the paper industry, lignin is a byproduct from the treatment of lignocellulosic material. Lignin is a very abundant biopolymer in nature, which is environmentally benign, sustainable, biodegradable and low cost.

The typical structure of lignin consists of three basic monomer units: coumaryl alcohol, coniferyl alcohol and sinapyl alcohol. It has a random organization, with C-O and C-C linkages. The common functional groups in lignin include methoxyl, phenolic hydroxyl, aliphatic hydroxyl and carbonyl groups. In recent works, lignin has been used in different applications, such as lithium ion batteries for photoelectrochemical reduction of CO$_2$.

Electrochemical experiments were carried out using a three-electrode system with a glassy carbon electrode as working electrode, a platinum wire counter electrode and an Ag/AgCl (saturated KCl) reference electrode.

Glassy carbon activation and electrochemical deposition of lignin

Prior to electrode modification, 3mm diameter glassy carbon electrodes (model CHI104, CH Instruments) for cyclic voltammetry and glassy carbon plate (SPI-Glas 11 grade, SPI supplies) of 1.18 cm$^2$ for electrolysis or characterization were polished with alumina powders decreasing in size from 1.0 μm to 0.3 μm and 0.1 μm, then rinsed with milli-Q water (18 MΩ cm$^{-1}$), sonicated for 5 minutes in acetone and rinsed again with milli-Q water. Activation of the glassy carbon electrode was done by cyclic voltammetry in a phosphate buffer (pH = 7.4), performing 15 continuous cycles at a scan rate of 100 mV s$^{-1}$ in a potential window from -0.2 to 1.7V vs Ag/AgCl (sat. KCl) (Figure S1, ESI†). For the polymerization process the activated electrode was placed vertically and 50 μL of a 0.5 mg/mL solution of sodium lignosulfonate and 0.5 M H$_2$SO$_4$ was added and left standing for 20 minutes, then the electrode was carefully rinsed with water and immersed in a solution consisting of 0.25 mg/mL lignin and 0.5M H$_2$SO$_4$. The lignin was electropolymerized by cycling the potential between -0.6 V and 1.0 V vs Ag/AgCl at a scan rate of 100 mV s$^{-1}$ for 20 continuous cycles.

Electrodeposition of Cu$_2$O

Cu$_2$O particles were pulse deposited at 50% duty cycle at 5 Hz with a pulse-on time of 100 ms and a total reaction time of 30 minutes. The pulse potential varied between -0.4V and -0.35V vs Ag/AgCl. The pulse electrodeposition method was done in a copper-citrate solution with 0.05M CuSO$_4$, 5H$_2$O and 0.1M sodium citrate. The pH was adjusted to pH = 12.50 by additions of 4M NaOH aliquots.

CO$_2$ reduction

The photoelectrochemical experiments and controlled potential electrolysis were carried out in a 0.1M Na$_2$SO$_4$ and CO$_2$ saturated solution in a homemade three compartments electrochemical cell with a window quartz, where the catholyte is separate from anolyte by a glass frit. Irradiation was carried out using a 500 W Xe–Hg Lamp (Oriel Corporation) light source. The reaction products were detected by nuclear magnetic resonance and gas chromatography and UV-Vis spectroscopy.

To the best of our knowledge, the use of lignin as a supporting material for the modification of electrodes with Cu$_2$O has not been reported. This work investigates glassy carbon electrodes modified with lignin and cuprous oxide (GC-LS-Cu$_2$O) and glassy carbon electrodes modified with Cu$_2$O (GC-Cu$_2$O). We report the characterization and use of these modified electrodes for the photoelectroreduction of CO$_2$. Our results indicate that GC-LS-Cu$_2$O electrodes show better photo-stability than GC-Cu$_2$O in aqueous solution obtaining formaldehyde, methyl formate and ethyl acetate as reduction products at low overpotentials.

**Experimental**

**Electrochemical experiments**
In several experiments, the same sample was used for Raman, AFM and SEM characterization. Using the 532 nm laser source, a specific area was marked. Afterward this mark was easily identified in the SEM or AFM microscope allowing correlation between the SEM image and other measurements.

Results and discussion

Lignin was electropolymerized on glassy carbon electrode between -0.6 and 1.0 V vs Ag/AgCl in a 0.05 M lignosulfonic acid and 0.1M sulfuric acid solutions at a scan rate of 100 mV/s for 20 continuous cycles. The cyclic voltammogram in Figure 1 shows the electropolymerization process. An irreversible oxidation peak is observed initially at 0.72V, but in subsequent scans a reversible redox pair at ca. 0.5V appears. These processes are assigned to the irreversible oxidation of the methoxy groups and the quinone-hydroquinone redox couple, respectively.

The quinone-hydroquinone redox couple does not disappear when the electrode is transferred to a Lignin-free solution, showing the efficient electrode modification (Figure S2, ESI†). The maximum surface coverage of lignin was calculated using the following relationship (1):

\[ \Gamma = \frac{Q}{nFA} \]  

Where \( Q \) is the charge consumed during the cyclic voltammetry, \( n \) is the numbers of electrons transferred in the redox process, \( F \) is Faraday’s constant and \( A \) is electrode area (cm\(^2\)). From Eq. 1, a surface coverage of 1*10\(^{9}\) molcm\(^{-2}\) is determined, which corresponds to multilayers of lignin films over the glassy carbon electrode.

The presence of sulfonate groups in the lignin can be observed by FT-IR ATR spectroscopy. Figure 2(b) displays peaks characteristic of the lignin on the GC electrode with a wide band at 1210 cm\(^{-1}\) and another band at 1028 cm\(^{-1}\) that can be assigned to the stretching of O=S=O and SO\(_3\)H stretching in SO\(_3\)H groups, respectively. Other characteristic vibrations of lignin are observed, such as the C=C stretching (1593 cm\(^{-1}\) and 1507 cm\(^{-1}\)) from benzene structures and aromatic and aliphatic hydroxyl groups (ca. 3550 cm\(^{-1}\)). Cu\(_2\)O was formed on the lignin-modified electrode by pulse electrodeposition, generating the final modified electrode. As a control measurement a bare glassy carbon electrode was modified in the same way and then used to compare the observed
characterization and electrochemical properties. X-ray diffraction spectroscopy was used to determine the crystal structure of the semiconductor. Figure 3 shows the diffraction patterns observed from GC-Cu$_2$O and GC-LS-Cu$_2$O. The observed peaks correspond to the Miller indices (111), (200), and (220) for a face centered cubic structure, which are consistent with the presence of cuprite as the main species on the electrodes $^{58}$. 

Figure 4: Raman spectra, 2D Raman map and SEM images of GC-LS-Cu$_2$O (blue line in spectra (a), (b) and (c) images respectively) and GC-Cu$_2$O electrodes (red line in spectra (a), (d) and (e) images respectively). The Marc in the vibrational mode 2E$_u$ correspond to filter to maximum intensity of 2D map of GC-LS-Cu$_2$O and GC-Cu$_2$O.
Raman spectroscopy was performed to further investigate the chemical nature of modified electrodes. Raman spectra from the GC-LS-Cu$_2$O and GC-Cu$_2$O were obtained with 532 nm laser irradiation. The Raman spectrum of the electrodes (Figure 4(a)) show characteristic vibrational modes of Cu$_2$O with A, E, and T symmetry in the region between 100 and 700 cm$^{-1}$. The observed Raman shifts are assigned as follows: 105 cm$^{-1}$ (T2u), 156 cm$^{-1}$ (T1u), 227 cm$^{-1}$ (2Eu), 322 cm$^{-1}$ (A2u), 430 cm$^{-1}$ (T2g), 517 cm$^{-1}$ (T1u(TO)) and 639 cm$^{-1}$ (T1u(LO)). Also, in both electrodes, Cu$_2$O shows a broad peak near 3000 cm$^{-1}$ (not shown) which has been previously assigned to photoluminescence that arises when the semiconductor is irradiated with a 532 nm laser$^{60-62}$. On the GC-LS-Cu$_2$O electrode, areas associated with lignin exhibited a large fluorescence signal and Raman scattering was not detectable, using either 532nm or 785nm laser excitation. Thus, the lignin structure was not possible to identify because of the fluorescence. Additionally, extended exposure to the laser can burn the lignin. Other work has used a 1064 nm laser to reduce the fluorescence on this polymer and thus identify the characteristic signals$^{63}$. Cu$_2$O has a larger Raman cross-section than the substrate or lignin, which allows one to discriminate the semiconductor from the substrate (glassy carbon) and the lignin in a 2D Raman map. The 2D images of the Figure 4(b) and 4(d) correspond to a 20 μm x 20 μm region, mapped by the intensity in gray band that corresponds to the 2Eu vibrational mode of Cu$_2$O$^{64}$ and is indicative of Cu defects$^{59}$. The features arising from GC-Cu$_2$O and LS-Cu$_2$O in the Raman map, correlate well with the AFM (Figure 5) and SEM images (Figure 4(c)) and 4(e). The Raman spectrum of Cu$_2$O reveals p-type character. The observed Raman bands are associated with copper vacancies interactions that lead to p-type conductivity,$^{59}$ and are consistent with previous reports$^{59}$. n-type semiconductors arise from oxygen vacancies that are not pronounced in our spectra.

The surface morphology of electrodes also was characterized by AFM and FE-SEM microscopy. The AFM images in Figures 5 show the 2D, 3D and cross-sectional surface of GC-LS-Cu$_2$O (5(a), 5(b) and 5(c), respectively) and GC-Cu$_2$O (5(d), 5(e) and 5(f), respectively) electrodes. Both electrodes show well-dispersed cuprous oxide particles on the surface; however, the particles grew to at least twice the size on electrodes modified with lignin than on GC-Cu$_2$O, as is evident in the cross-sectional profile analysis of the electrodes. The increased size of the GC-LS-Cu$_2$O may occur due to the more hydrophilic microenvironment. The lignosulfonate used presents various hydrophobic phenylpropanoid residues, but also presents hydrophilic groups like aromatic and aliphatic hydroxyl groups and sulfonates groups that can provide hydrophilic zones with a propitious environment for the Cu$_2$O to grow. In related work, Li et al synthesized ZnO with the assistance of sodium lignosulfonate and proposed a mechanism for ZnO growth where a synergistic effect between the lignosulfonate aggregation shape and polar ZnO crystals$^{66}$. SEM images verified that the morphology of GC-LS-Cu$_2$O and GC-Cu$_2$O electrodes correspond to well disperse cuprous oxide cubic particles on the surface of electrodes. The SEM images in the Figure 4(c) and 4(e) show the particles measured in the same area that AFM images were recorded. EDX analysis reports the presence of copper, oxygen, sulfur and carbon on GC-LS-Cu$_2$O electrodes and copper and oxygen in GC-Cu$_2$O electrodes (Not shown). SEM image of GC-LS showed well disperse lignin on the surface of electrodes (Figure S6, ESI†).
semiconductor is expressed according to the Mott Schottky equation (3):

\[
\frac{1}{C^2} = \left( \frac{2 \varepsilon e_N}{\varepsilon_0} \right) \cdot \left( V - V_F - \frac{kT}{e} \right)
\]

Where \( \varepsilon \) is the dielectric constant of Cu₂O (\( \varepsilon = 6.3 \)) \(^{44} \), \( \varepsilon_0 \) is the permittivity of vacuum (8.854 \( \times \) 10\(^{-12} \) F m\(^{-1} \)), \( N_D \) is the donor density, which is calculated from the slope of the curve, \( e \) is the electronic charge (1.603 \( \times \) 10\(^{-19} \) C), \( T \) is the operation temperature (298 K), and \( k \) is the Boltzmann constant (1.38 \( \times \) 10\(^{-23} \) J K\(^{-1} \)). \( V \) is the electrode potential, \( V_F \) is the flat band potential, and \( C \) is the depletion-layer capacitance. The Mott-Schottky plot of the Cu₂O film are shown in Figure 6(b). There is a positive slope in the linear region of the plot, indicating a p-type characteristic according to Equation 3. The carrier donor concentration \( (N_D) \) calculated from the Mott-Schottky analysis was 8.1 \( \times \) 10\(^{21} \) cm\(^{-3} \) and the flat band potential extrapolation of the straight line corresponds to 1.15 V vs Ag/AgCl. The apparent donor carrier concentration is higher than expected; however, polycrystalline Cu₂O can contain grain boundaries and surface sites that can increase the number of defects in its structure\(^ {50} \). The p-type character obtained from Mott-Schottky equation is consistent with photocurrent transient for CO₂ reduction shown in the Figure 7 and the Raman results.

The photoelectrochemical response of GC-LS-Cu₂O (red) and GC-CuO (black) modified electrodes in a 0.1M sodium sulfate solution saturated with CO₂ under visible light irradiation (100 mW cm\(^{-2} \)) agrees well with those reported in the literature for the Cu₂O phase\(^ {59} \).

Thus, when $I_{\text{ph-off}}$ decreases, the transient ratio between steady-state and the maximum of photocurrent increases to 1, where recombination processes disappear. The pulse photocurrent transient in Figure 7 results from a square wave chopped light excitation, and compares the transient between a GC-LS-Cu$_2$O electrode and a GC-Cu$_2$O electrode in a 0.1M sodium sulfate saturate with CO$_2$ applying -0.4V vs. Ag/AgCl. A larger current density is observed in the GC-Cu$_2$O electrode compared to GC-LS-Cu$_2$O according to linear sweep voltammetry experiments (Figure 8). This difference in photocurrent may arise from the lignin support material hampering the charge transfer at the electrode; however, the most important feature is less recombination is observed when lignin is used as support material. According to equation 4, While GC-Cu$_2$O shows a maximum of photocurrent (R) of 0.81, GC-LS-Cu$_2$O shows a maximum of 0.92 that exhibits the best R value close to 1. This indicates that when we use a GC-LS-Cu$_2$O the electron-hole recombination decreases compared to GC-Cu$_2$O. This result suggest that, in the presence of lignin, the sulfonate and hydroxyl groups may act like commonly used electron-hole scavengers, impeding the recombination process of the charge carriers.\(^{(22,24)}\)

The CO$_2$ photoelectrochemical reduction was performed by controlled potential electrolysis applying -0.4V vs Ag/AgCl over 4 hours. The applied overpotential was selected according to the stability of Cu$_2$O. At potentials greater than -0.4V it is possible to find Cu (0) that interferes with electrocatalysis. The reaction products were detected and quantified by nuclear magnetic resonance, UV-Vis spectroscopy, and gas chromatography, where gaseous products were not detected.

Table 1 summarizes and assigns the signals of $^1$H NMR for observed CO$_2$ reduction products and internal standards, such as phenol and DMSO. The reaction products identified were ethyl acetate and methyl formate (Figure S3, ESI†), which was corroborated by comparisons with a database of standards. Also, using UV-Vis spectroscopy with chromotropic acid method\(^{(22)}\), formaldehyde was detected (Figure S8, ESI†). The amounts of product detected, analytical methodology used and faradaic efficiency are summarized in Table 2.

It is worth mentioning that the electrochemical reaction in the absence of light at the overpotential studied did not generate reaction products using either the GC, GC-LS or GC-Cu$_2$O electrodes.

**Stability test**

After electrolysis, SEM images and Raman spectra were recorded to identify significant changes in the structure and chemical nature of both electrodes.

The SEM image in Figure 9(a) for GC-LS-Cu$_2$O shows the morphology of the cubic Cu$_2$O is maintained, with little grains in the surface of electrodes from the sodium sulfate solution. In contrast, Figure 9(b) shows the GC/Cu$_2$O electrode is deformed from the initial structure, probably due to photocorrosion processes\(^{(36)}\). A Raman spectrum of different zones of GC-Cu$_2$O shows mainly the presence of CuO, in agreement with previous reports for an unprotected electrode.\(^{(36)}\) Raman spectra of GC-Cu$_2$O, Figure 9(c), shows three characteristic vibrational modes with Raman shifts of 282 cm$^{-1}$ ($A_1$), 324 cm$^{-1}$ ($B_2$) and 617 cm$^{-1}$ ($B_3$) consistent with CuO.\(^{(36)}\) On the other hand, the post-electrolysis Raman analysis of GC-LS-Cu$_2$O electrode continues to show features of Cu$_2$O particles quite similar to those presented in Figure 4(c). This indicates the chemical nature of the semiconductor remains constant and does not photodegrade, which is consistent with the morphology observed in Figure 9. These results, together with the photocurrent studies, show that the system where lignin is used as a support material is better compared to a system devoid of the biopolymer. We believe that this is due to the mechanism described above regarding the generation of a microenvironment that, in addition to allowing a greater growth of the semiconductor in specific zones, reduces the recombination processes, where the hydrophilic groups on lignin act as scavengers of the photogenerated holes that can oxidize Cu (I) to Cu (0).

**Conclusions**

In this work, it was demonstrated the synthesis of Cu$_2$O semiconductor particles using lignin as a support material. GC-LS-Cu$_2$O were synthetized by pulse electrodeposition and fully characterized. This electrode was capable of reducing carbon dioxide to formaldehyde, methyl formate and ethyl acetate applying a very low overpotential (-0.4 V vs Ag/AgCl). While Cu$_2$O has appeared as a good candidate for photo-electrochemical applications, due to its semiconductor properties, low stability has been a challenge for the extensive use of this material. Our results indicate a lignin film provides a specific microenvironment that is able to photostabilize Cu$_2$O. This result offers new uses for this biopolymer, which is underrated and is mainly used for thermal energy generation in cellulose mills. The as designed electrode further demonstrates a new concept in the use of biomass and an abundant, low toxicity transition metal for photo-electrocatalysis in CO$_2$ transformation.
