ABSTRACT

It is known that the addition of salts to symmetric block copolymers leads to stabilization of ordered phases and an increase in domain spacing; both trends are consistent with an increase in the effective Flory-Huggins interaction parameter between the blocks, \( \chi \). In this work, we show that the addition of salt to a disordered asymmetric block copolymer first leads to the formation of coexisting ordered phases which give way to a reentrant disordered phase at a higher salt concentration. The coexisting phases are both body centered cubic (BCC) with different domain spacings, stabilized by partitioning of the salt. Further increase in salt concentration results in yet another disorder-to-order transition; hexagonally packed cylinders are obtained in the high salt concentration limit. The coexisting phases formed at intermediate salt concentration, elucidated by electron tomography, showed the absence of macroscopic regions with distinct BCC lattices. A different asymmetric block copolymer with composition in the vicinity of the sample described above only showed only a single disorder-to-order transition. However, the dependence of domain spacing on salt concentration was distinctly non-monotonic, and similar to that of the sample with the reentrant phase behavior. This dependence appears to be an announcement of reentrant phase transitions in asymmetric block copolymer electrolytes. These results cannot be mapped on to the traditional theory of block copolymer electrolyte self-assembly based on an effective \( \chi \).

INTRODUCTION

There is continuing experimental\(^1\)\(^-\)\(^8\) and theoretical\(^9\)\(^-\)\(^12\) interest in the thermodynamic properties of block copolymer electrolytes. A commonly studied system is polystyrene-\textit{block}-poly(ethylene oxide) (SEO) mixed with lithium bis(trifluoromethanesulfonyl) imide salt, SEO/LiTFSI. The thermodynamic interactions in these systems are often expressed in terms of an effective Flory-Huggins interaction parameter between the blocks, \( \chi \). Current work suggests that \( \chi \) increases with increasing salt concentration.\(^2\)\(^-\)\(^5\),\(^13\),\(^14\) It is, perhaps, surprising that the addition of salt to disordered block copolymers generally results in the formation of ordered phases.\(^15\)\(^-\)\(^17\) Experimental work thus far focuses on symmetric (or nearly symmetric) block copolymers.\(^2\),\(^18\),\(^19\) The purpose of
this paper is to describe the thermodynamic properties of a series of asymmetric block copolymer electrolytes. Our work builds on previous studies on neat asymmetric block copolymers. Particularly relevant to the present study is the limited long-range order observed in some asymmetric systems. We report on disorder-order and order-order phase transitions that are very different from those reported in previous studies. In particular, we show that reentrant phase transitions are possible in these systems. The addition of salt to a disordered block copolymer first leads to the formation of ordered phases which give way to a reentrant disordered phase upon further salt addition. In the ordered state, we find two coexisting phases with the same geometry but different lattice constants.

EXPERIMENTAL SECTION

Synthesis and preparation of the block copolymer electrolytes

The SEO copolymers were synthesized using methods described in ref. 26 and purified using methods described in ref. 4. The electrolytes were prepared according to methods described in ref. 27 using argon gloveboxes. SAXS samples were prepared by pressing/melting the polymer into a 1/8 in. diameter spacer made of 1/32 in. thick Aflas rubber and annealing them at 120 °C overnight followed by a 24 hour period of controlled cooling under vacuum to room temperature. The samples were sealed with Kapton windows.

Small Angle X-ray Scattering (SAXS)

SAXS measurements were performed at beamline 7.3.3. at the Advanced Light Source (ALS) at Lawrence Berkeley National Laboratory and beamline 1-5 at the Stanford Synchrotron Radiation Lightsource (SSRL) at SLAC National Accelerator Laboratory. Silver behenate was used to determine the beam center and sample-to-detector distance. The scattered intensity was corrected for beam transmission and empty cell scattering. Two-dimensional scattering patterns were integrated azimuthally using the Nika program for IGOR Pro to produce one-dimensional scattering profiles and are reported as scattering intensity, I, as a function of the scattering vector, q. Measurements were taken in a custom-built 8-sample heating stage, starting at 132 °C and cooling in steps of about 10 °C to 75 °C. Samples were annealed for about 30 min at each temperature before taking
measurements. A typical temperature scan takes about six hours (including time required to cool the sample stage). To a good approximation, the SAXS profiles of all our samples were independent of temperature in the range studied. We thus only discuss data obtained at the highest temperature in the main text. The temperature range of our SAXS experiments is well above the melting temperature of the crystallizable poly(ethylene oxide) (PEO) block. Data obtained at the lowest temperature, 75 °C, is shown in the Supplemental Information.

**Electron Tomography**

A bulk sample, annealed using the same protocol used to prepare the SAXS samples, was sectioned at -120 °C using cryo-microtome (Leica Ultracut 6) to obtain an ultrathin film (~100nm). The ultrathin film was transferred to C-flat grid with ultrathin continuous carbon supporting film and stored in a glove box immediately after cryo-microtoming to minimize the effect of humidity. PEO domains were stained to increase contrast and stability under electron beam by exposing the ultrathin film to RuO$_4$ vapor for 10 minutes at room temperature. 5 nm gold colloid nanoparticles were deposited on the backside of the grid as fiducial markers. Dual-axis tomography was performed using Philips CM200 transmission electron microscope at 200 KV at the Donner Lab Electron Microscopy Facility at Lawrence Berkeley National Lab. The tilt series were collected with 1.5 degrees step from -65 to 65 degrees. Tomograms were reconstructed and filtered (nonlinear anisotropic diffusion filter) in IMOD. The tomogram of a small area was binarized for segmentation by adjusting threshold.$^{30-32}$

Parameters $f_{EO}$, $N_{PS}$, $N_{EO}$ were evaluated at 140 °C
RESULTS AND DISCUSSION

The properties of the polymers used in this study are given in Table 1. We refer to each copolymer by its molecular weight, for example, in SEO(9.4-4.0) the molecular weights of the polystyrene (PS) and PEO blocks are 9.4 kg mol\(^{-1}\) and 4.0 kg mol\(^{-1}\). Figure 1 shows the scattering profiles of the block copolymer electrolytes at 132 °C at selected salt concentrations. LiTFSI concentrations are reported as the molar ratio of lithium ions to ethylene oxide moieties: \( r = \frac{[Li]}{[EO]} \). For SEO(9.4-4.0), Figure 1a, we see that the addition of salt drives microphase separation, as previously reported.\(^4\,5\,7\) The broad scattering peak obtained in the neat sample becomes sharper at \( r = 0.005 \). The scattering profiles obtained in this salt concentration regime (0 ≤ \( r \) ≤ 0.005) are consistent with a disordered state. Further increase of salt concentration to \( r = 0.01 \) results in dramatic sharpening of the primary scattering peak and the emergence of higher order scattering reflections at \( \frac{q}{q^*} = \sqrt{3} \) and \( \sqrt{4} \) where \( q^* \) is the location of the primary scattering peak, consistent with a hexagonally packed cylindrical phase (HEX). These reflections persist at all remaining salt concentrations, and at higher salt concentrations, \( r \geq 0.025 \), higher order reflections at \( \frac{q}{q^*} = \sqrt{7} \) and \( \sqrt{9} \) appear. For SEO(17.4-3.9), Figure 1b, the neat sample is also disordered, and the
addition of salt induces microphase separation at all measured salt concentrations (0.005 ≤ r ≤ 0.075). The higher order scattering reflections in this sample are located at $q^{*} = \sqrt{2}, \sqrt{3},$ and $\sqrt{6}$ indicative of a body center cubic spherical phase (BCC). The $q^{*} = \sqrt{2}$ peak is not detected for $r = 0.01, 0.05,$ and 0.075 due to the broadening of the primary $q^{*}$ peak.

More complex phase transformations are seen with SEO(9.4-2.4), Figure 1c. The neat polymer is disordered as is the mixture with $r = 0.005$. However, we see the emergence of two coexisting BCC phases at $r = 0.01$. The scattering signatures of the larger BCC lattice are indicated by open symbols while those of the smaller BCC lattice are indicated by filled symbols in Figure 1c. Reflections at $q^{*} = \sqrt{2}$ and $\sqrt{3}$ corresponding to both lattices are seen in Figure 1c. To our knowledge, two coexisting lattices with the same symmetry have been neither observed nor predicted in block copolymer systems. The domain spacing, given by $d = \frac{2\pi}{q^{*}}$, of the two coexisting BCC lattices are 12.8 and 14.8 nm. It is apparent that the two BCC phases must have different salt concentrations; if this were not the case, it is impossible to rationalize the presence of two coexisting morphologies. Further increase in overall salt concentration to $r = 0.025$ results in the formation of a reentrant disordered phase. Finally, at $r = 0.05$ and $r = 0.075$, a single HEX phase is obtained with higher order scattering reflections at $q^{*} = \sqrt{3}, \sqrt{4}, \sqrt{7}$ and $\sqrt{9}$. SEO(9.4-2.4) exhibits phase behavior that appears to be a combination of behaviors observed in SEO(9.4-4.0) and SEO(17.4-3.9). While SEO(9.4-4.0) and SEO(17.4-3.9) electrolytes exhibit HEX and BCC phases in the ordered state, SEO(9.4-2.4) electrolytes exhibit both ordered phases. For all three block copolymers, the addition of salt results in broadening of SAXS peaks associated with the ordered phase, suggesting a decrease in long-range order. In previous studies, we have used TEM to establish this effect, which arises due to the formation of temporary crosslinks created by the coordination of PEO chains and $\text{Li}^{+}$ ions that impede chain motion.
The disordered and ordered morphologies of the block copolymer electrolytes are shown in Figure 2a on a plot of salt concentration in the PEO domains, $r$, versus volume fraction of the PEO-rich domains, $f_{EO,salt}$. We
calculate $f_{\text{EO,salt}}$ based on the assumption that LiTFSI preferentially segregates into the PEO domains and from reported densities of LiTFSI/PEO mixtures in ref 35.\textsuperscript{36,37} The phase diagram contains three sets of data points representing the three polymers; as salt is added to the copolymer, $f_{\text{EO,salt}}$ increases linearly with $r$ for each polymer. SEO(9.4-4.0) and SEO(17.4-3.9) exhibit one salt-induced phase transformation from DIS to HEX and DIS to BCC respectively. SEO(9.4-2.4) exhibits three phase transformations: DIS to coexisting BCC lattices to DIS to HEX. The Gibbs phase rule requires coexistence at all phase boundaries. We conclude that the widths of all of the coexistence windows in the samples are smaller than our coarse steps in salt concentration; for example, the Gibbs phase rule necessitates coexistence of DIS and BCC phases at the disorder-order boundary.\textsuperscript{16} The origin of the two coexisting BCC lattices, which were observed throughout the entire temperature window in two independently prepared samples, is thus not clear. Figure 2a thus applies to the entire temperature window. The fact that the morphologies of the copolymers listed in Table 1 can be represented on a simple $r$ versus $f_{\text{EO,salt}}$ diagram (Figure 2a) is non-trivial.

The effect of added salt on block copolymer thermodynamics is due to two competing factors: (1) the addition of salt generally increases the effective $\chi$ between the blocks and induces ordering, (2) the salt molecules partition into and swell the PEO domains, thereby increasing $f_{\text{EO}}$. The $f_{\text{EO}}$ of neat SEO(9.4-2.4) is 0.20, which is at the border between BCC and HEX phases. (Floudas et al. studied the phase behavior of poly(ethylene oxide)-block-polyisoprene block copolymers, where the BCC/HEX border was identified at $f_{\text{EO}} = 0.21$.\textsuperscript{22}) Adding salt to SEO(9.4-2.4) at $r = 0.01$ results in the formation of coexisting BCC lattices consistent with (1). The salt concentration at this composition does not result in sufficient swelling of the PEO domain to obtain hexagonally packed PEO cylinders. This phase is only formed at $r \geq 0.05$. The disordered phase at an intermediate salt concentration, $r = 0.025$, is due to the interplay between the two competing factors.

The dependence of domain spacing, $d$, on salt concentration, $r$, is shown in Figure 2b. The colors in the figure depict the morphology of the electrolytes. The simplest behavior is seen in SEO(9.4-4.0) wherein $d$ increases monotonically with increasing $r$ with no discontinuity at the DIS to HEX transition.\textsuperscript{2–4} The domain spacing of neat SEO(9.4-2.4) is identical to that of neat SEO(9.4-4.0), but it decreases with increasing salt concentration before
increasing at \( r = 0.01 \) where two coexisting BCC lattices are obtained. It is unusual that a salt-containing sample would have a lower \( d \) compared to its neat counterpart. Further increase of salt concentration results in a decrease in \( d \) as the sample disorders. At \( r \geq 0.025 \), \( d \) increases monotonically with increasing \( r \) with no discontinuity at the DIS to HEX transition. The dependence of \( d \) on \( r \) of SEO(17.4-3.9) is most interesting. This sample exhibits a simple DIS to BCC transition, but the dependence of \( d \) on \( r \) is non-monotonic, similar to that of SEO(9.4-2.4). These two copolymers have similar compositions but their chains lengths differ by a factor of 1.8. One may thus regard the non-monotonic dependence of \( d \) on \( r \) in SEO(17.4-3.9) as “announcements” of BCC coexistence at lower molecular weights in the same composition window.

The chains of SEO(9.4-2.4) at \( r = 0.01 \) exhibit different extents of chain stretching, depending on the BCC lattice they belong to. The reason for the fact that the coexisting morphology has a lower free energy than that of a single BCC phase with intermediate chain stretching remains to be determined. Computer simulations suggest that each lithium ion is associated with six coordinating oxygen atoms.\(^{38-40}\) Perhaps, discrete chain conformations are preferred due to these interactions, and the free energy gain from adopting these conformations is large enough to offset the entropic penalty of heterogeneous salt distribution.
The nature of the coexisting BCC lattices was further studied by transmission electron tomography. We are not aware of any prior studies wherein electron tomography has been used to study the morphology of weakly ordered block copolymers in the vicinity of order-disorder transitions. Three dimensional tomograms were obtained from the $r = 0.01$ sample of SEO(9.4-2.4)/LiTFSI stained with RuO$_4$. Figure 3a shows slices of the tomogram obtained from dual-axis reconstruction of the data. The dark domains represent the RuO$_4$ stained
PEO/LiTFSI spherical domains. Electron tomography confirms that the sample contains only spheres, consistent with our interpretation of the SAXS profile. It is also evident, however, that our sample does not contain easily identifiable macroscopic regions with two different lattice constants. Some regions did, however, show evidence of BCC lattices with limited long-range order. One such region is shown in Figure 3b. Quantitative analysis of the entire tomogram is necessary to reveal correlations between the spherical domains.

**Figure 4:** (a) FFT of single slice of tomogram. Sector average was performed along the white arrow. (b) Sector averaged (red triangles) and circular averaged (black line) intensity versus scattering vector, $q$. The black arrows indicate the locations of the observed primary SAXS peaks.
Figure 4a shows the Fourier transform (FT) of a typical slice obtained by electron tomography; e.g. see Figure 3a. The anisotropy of the FT is attributed to distortion due to compression along one axis during cryo-sectioning. Figure 4b shows a sector-averaged intensity versus scattering vector, $q$, for the FT. The averaging was conducted along the non-compressed axis, indicated by the white arrow in Figure 4a. The circularly averaged FT of the same slice, shown by a continuous black line in Figure 4b is qualitatively similar to the sector-averaged FT. The FT analysis was repeated for several slices and the results of three slices are given in the supplemental information (Figure SI2). All of the FTs are very similar to that given in Figure 4b. The arrows in Figure 4b indicate the positions of the primary peaks observed in SAXS; recall that SAXS revealed the presence of two BCC lattices. There is reasonable agreement between the FT peak and the SAXS data. The relatively subtle difference in the lattice constants of the coexisting BCC structures obtained by SAXS are lost in the FT analysis. We posit that this is due to complications related to the electron tomography experiments such as missing spheres due to incomplete staining and distortions during cryo-sectioning. While our TEM data provide support for our interpretation of the SAXS profile of SEO(9.4-2.4) $r = 0.01$, it also reveals the complexity of coexisting phases that are obtained in the vicinity of order-disorder transitions.

CONCLUSION

In conclusion, we have determined the morphology of mixtures of asymmetric block copolymers and a lithium salt by SAXS and electron tomography. SAXS results show that the addition of salt to a disordered asymmetric block copolymer first leads to the formation of coexisting BCC lattices, which give way to a reentrant disordered phase at a higher salt concentration. Further increase in salt concentration results in the formation of hexagonally packed cylinders. Electron tomography showed the absence of macroscopic regions with distinct BCC lattices. However, the Fourier transforms of tomogram slices were qualitatively consistent with the SAXS results. Doubling the chain length at fixed composition (or nearly so) resulted in a single disorder-to-order transition with added salt. Reducing the asymmetry at fixed chain length (or nearly so) also resulted in a single disorder-to-order transition with added salt. These results cannot be mapped on to any of the existing theories of the thermodynamics of block copolymer/salt mixtures.9–12
