Abstract

Microfluidics has achieved integration of analytical processes in microspaces and realized miniaturized analyses in the fields such as chemistry and biology. We have proposed a general concept of integration and extended this concept to the 10-1000 nm space exploring ultimate analytical performances (e.g. immunoassay of a single-protein molecule). However, a sampling method is still challenging for nanofluidics despite its importance in analytical chemistry. In this study, we developed a femtoliter (fL) sampling method for volume measurement and sample transport. Traditionally, sampling has been performed using a volumetric pipette and flask. In this research, a nanofluidic device consisting of a femtoliter volumetric pipette and flask was fabricated in glass substrates. Since gravity, which is exploited in bulk fluidic operations, becomes less dominant than surface effects on the nanometer scale, fluidic operation of the femtoliter sampling was designed based on utilizing surface tension and air pressure control. The working principle of an 11 fL volumetric pipette and a 50 fL flask, which were connected by a nanochannel, was verified. It was found that evaporation of the sample solution by air flow was a significant source of error because of the ultra-small volumes being processed. Thus, the evaporation issue was solved by suppressing air flow. As a result, the volumetric measurement error was decreased to ± 0.06 fL (CV 0.6%), which is sufficiently low for using in nanofluidic analytical applications. This study will be a fundamental technology for the development of novel analytical methods for femtoliter volume samples such as single molecule analyses.

Introduction

Recently, microfluidics, lab on a chip or micro total analysis systems (μ -TAS)^{1,2} have achieved the miniaturization/ integration of analytical processes into microspaces to realize improved analytical performance and are expanding in the fields of chemistry and biology. The benefits of integration and miniaturization include faster reactions due to a higher surface-to-volume ratio, smaller amounts of reagent and waste, and ease of automation, etc. Our group has proposed a general concept of integration, called micro-unit operation (MUO).³ In MUO, the chemical process is first divided into individual operations such as mixing, reaction, extraction, and cell culture, and then each operation is performed at the micrometer scale. Finally, serial or parallel combinations of MUOs are used to integrate chemical processes in a microchip system. Nowadays, various kinds of complex chemical processes including blood tests,⁴ drug synthesis^{5,6} and environmental analysis⁷ have been integrated into single microchip and microfluidic systems, and such analytical applications are now in a practical development phase.

The concept of MUO has been further extended to smaller dimensions, i.e., 10-1000 nm on glass substrates, which we have designated “extended nanospaces”,⁸ and thus pioneered the field of nanofluidics. Fundamental technologies for nanofluidics including top-down technology for nano-fabrication of 10-1000 nm channels on glass substrate⁹ and highly sensitive methods to detect non-fluorescent molecules in nanochannels utilizing wave optics and the thermal lens effect were developed.¹⁰ Using these fundamental technologies, we have been seeking the ultimate analytical

1
2
3
4 method for characterization of single molecules at the femtoliter (fL; 10^{-15} L) level. For example, a
5
6
7 liquid chromatography (LC) system utilizing pressure-driven flow in a nanochannel was used to
8
9
10 separate a femtoliter sample in a very short time (seconds) with very high efficiency (7,100,000
11
12
13 plates/m), contrasting strongly with that of a commercial high-pressure LC system.¹¹ Also,
14
15
16 implementation of an immunoreaction in an extended nanospace (\sim fL) permits almost 100% capture
17
18
19 of target proteins utilizing a smaller reaction field than in molecular diffusion (\sim 10 μ m on a seconds
20
21
22 time scale).¹² This efficient reaction field permitted analysis of a single protein molecule by integration
23
24
25 of an enzyme linked-immunosorbent assay (ELISA) into a nanochannel.¹³ It is anticipated that such
26
27
28 nanofluidics regimes will be eminently suited to novel analytical devices that process ultra-small
29
30
31 sample volumes (e.g., single cell/single molecule analysis).
32
33

34
35 However, while the analytical process consists of three components, i.e., sampling, chemical
36
37 processing and detection, the means for the initial sampling is still challenging in nanofluidic devices
38
39
40 despite its importance. Several researchers have reported downsizing of the sampling method using
41
42
43 microfluidics, but these methods are difficult to implement in nanofluidics. In one case, for example,
44
45
46 aqueous picoliter droplets in an oil phase were generated and manipulated by surface acoustic waves
47
48
49 ^{14,15} or by electrowetting.¹⁶ However, use of an aqueous/oil interface can result in cross contamination
50
51
52 whereas application of an electric current can bias sampling. In the work of Huang *et.al.*, a nanoliter
53
54
55 liquid sampling method based on a microfluidic pneumatic valve was proposed,¹⁷ which involved
56
57
58 deformation of a soft material (e.g., polydimethylsiloxane) by pneumatic pressure; however,
59
60

1
2
3
4 fabrication of nanochannels in soft material is problematic using current technology.
5
6

7 In the present study, a sampling method for femtoliter volume measurement and sample transport
8
9 was developed. In analytical chemistry, conventional sampling and transfer operations for liquids are
10
11 performed at a microliter to liter scale, normally using volumetric pipettes and flasks. In this work,
12
13 downscaling of the volumetric pipette and flask to the femtoliter was achieved. Given that gravitational
14
15 effects, which are exploited in bulk fluidic operations, become much smaller than surface effects in a
16
17 nanospace, we developed fluidic operations of the femtoliter volumetric pipette and flask which
18
19 exploited the surface tension of the sample solution. To realize unbiased femtoliter sampling, the
20
21 formation of a gas/liquid interface that was free from cross-contamination and controlled by surface
22
23 tension and air pressure was required. We note that the concept of femtoliter sampling is incorporated
24
25 in our most recent paper to achieve living single-cell protein analysis by nanofluidics.¹⁸ Here, we report
26
27 device design, principle verification, evaluation of performance, and development of fluidic operation
28
29 with avoiding femtoliter sample evaporation. A nanofluidic device, which incorporated an 11 fL
30
31 volumetric pipette and a 50 fL volumetric flask, was designed and fabricated, and the performance for
32
33 volume measurement and transport was evaluated.

51

52 **Working principle**

53
54

55 Fig. 1 shows schematic diagrams of traditional and femtoliter volumetric pipettes and flasks. In a
56
57 conventional volumetric pipette (Fig. 1(a)), a sample solution is sucked up by a mechanical pump until
58
59
60

1
2
3
4 it reaches the marked calibration line (volume measurement), and is then transported to the flask by
5
6
7 gravity transport. Based on this approach, we propose a femtoliter volumetric pipette and flask that
8
9
10 operates as shown in Fig. 1(b). The design challenges for a femtoliter volumetric pipette include the
11
12
13 need for precise volume control and (2) a surface tension effect in the nanochannel as a replacement
14
15
16 for gravity. With regard to the latter topic, Laplace nanovalves were selected to utilize the so-called
17
18
19 Laplace pressure caused by the liquid surface tension.¹⁹ As depicted in Fig. 1(b), the Laplace pressure
20
21
22 exerts a force on the gas/liquid interface, and the Laplace pressure is governed by the surface
23
24
25 wettability and the channel size as represented by the Young-Laplace equation:

$$P = -\frac{2\gamma \cos\theta}{r} \quad \#(1)$$

26
27
28
29
30
31 where γ is the surface tension, θ is the surface contact angle and r is the equivalent radius of the
32
33
34 channel ($r = HW/(H + W)$ where H and W are height and width of nanochannel respectively). When
35
36
37 the surface is hydrophobic ($\theta > 90^\circ$), P takes a positive value and works as a pressure barrier against
38
39
40 the introduction of liquid. For operation of the femtoliter volumetric pipette, two different Laplace
41
42
43 valves were configured for use in the nanofluidic device. Laplace valve 1 utilized a difference in
44
45
46 surface wettability and was used to halt the sample solution when no pressure was applied (initial state).
47
48
49 Laplace valve 2 was situated in the main channel to define the sampling volume. To precisely control
50
51
52 the sampling volume at the femtoliter level, the Laplace pressure was controlled via the channel size.
53
54
55 According to Eq. (1), the Laplace pressure P is inversely proportional to the channel size r ;
56
57
58 consequently, a narrower channel has a higher Laplace pressure and can function as a valve. Using a
59
60

1
2
3
4 nanofabrication procedure it is possible to control the width, depth and length of the nanochannel with
5
6
7 a resolution of 10 nm, which is appropriate for femtoliter volume control. A circular shape was adopted
8
9
10 for the femtoliter flask, since this shape can accommodate and smoothly transport the sample via
11
12
13 pneumatic pressure in the nanochannel where the surface tension dominates gravity.
14
15

16 The operation of the femtoliter volumetric pipette and flask is illustrated in Fig. 1(c). All operations
17
18 are controlled by application of external pressure. Initially, without application of pressure, the sample
19
20 solution is introduced to the main channel by capillary action but is stopped at the intersection point
21
22 of the main channel and the air channel by Laplace valve 1. Then, when a pressure P_1 (greater than the
23
24 Laplace pressure at the intersection point, P_{L1} , but smaller than the Laplace pressure in the narrow
25
26 channel, P_{L2}) is applied, the solution moves up to Laplace valve 2. Next, the solution in the air channel
27
28 is removed by applying a pressure P_2 from the air channel and a pressure P_3 from the right side of the
29
30 main channel. Here, P_2 is greater than P_{L2} and less than the sum of P_{L2} and P_3 . Consequently, only the
31
32 solution from the intersection point of the main channel and the air channel to the Laplace valve 2 is
33
34 left in place; this volume (*the volume measurement*) is at the femtoliter level and depends on the
35
36 channel size and the distance to the Laplace valve 2. Finally, the solution is transported to the flask by
37
38 removing pressure P_3 (*transport*).

55 **3. Experimental**

56 *3.1 Design and fabrication of the femtoliter volumetric pipette and flask*

57
58
59
60

1
2
3
4 As shown in Fig. 2(a), the volumes of the femtoliter volumetric pipette and flask were designed to
5
6
7 be 11 fL and 50 fL, respectively. The femtoliter volumetric pipette had a width of 1600 nm for the
8
9
10 wider channel and 900 nm for the narrower channel. The diameter of the femtoliter flask was 10 μm
11
12
13 and the width of the downstream channel was 2100 nm. The depths of the femtoliter volumetric pipette
14
15
16 and flask were 700 nm. In this design, P_{L1} and P_{L2} were estimated to be 100 and 130 kPa, respectively,
17
18
19 assuming $\theta = 110^\circ$ (contact angle measured in bulk octadecylsilane at surface) and $\gamma = 72.75 \text{ mN/m}$
20
21
22 in Eq. (1).
23
24

25 The nanofluidic device was fabricated using a process described elsewhere⁸. A Pyrex substrate (0.7
26
27
28 mm thick, 70 mm wide and 30 mm long) with microchannels (500 μm wide and 100 μm deep)
29
30
31 fabricated by photolithography and wet etching was purchased from the Institute of Microchemical
32
33
34 Technology Co. Ltd., Japan. Nanochannels were fabricated in fused silica (0.17 mm thick, 70 mm
35
36
37 wide and 30 mm long) by electron beam lithography and reactive ion etching. Then, the two substrates
38
39
40 were treated with Piranha solution and oxygen plasma and bonded before being heated at 110°C for 3
41
42
43 hours. The fabricated device is shown in Fig. 2(b). The width and depth of the nanochannels were in
44
45
46 agreement with the target values.
47
48

49 The surfaces of the nanochannels were then modified with hydrophobic molecules
50
51
52 (octadecylsilane). Octadecyldimethyl-N,N-diethylaminosilane (ODS-DEA), synthesized from
53
54
55 diethylamine and octadecyldimethylchlorosilane (ODS-Cl), was used according to a procedure
56
57
58 described elsewhere.²⁰ First, all of the nanochannels were flushed with toluene at 70°C for 30 min.
59
60

1
2
3
4 Then 20% (v/v) ODS-DEA/toluene was introduced from the bottom side of the vertical channel at 5
5
6
7 kPa and 70°C for 4 hours, flushing the solution once after two hours. After this modification, the
8
9
10 channels were washed with toluene, hexane, acetone, ethanol and water (in that order) and dried by
11
12
13 introducing air to all of the channels. Then, a part of nanochannel was silanolized by introducing 1M
14
15
16 sodium hydroxide. The boundary between the sodium hydroxide solution and the air was controlled
17
18
19 by adjusting the air pressure. Once the boundary reached the intersection point, the pressure was set at
20
21
22 5 kPa for 15 min. After silanolization, all nanochannels were washed with water and dried by passage
23
24
25 of air.
26
27

28 *3.2 Experimental setup*

29
30

31 A schematic of the experimental setup for the operation of femtoliter volumetric pipette and flask
32
33
34 is given in Fig. 2(a). An inverted microscope (IX71, Olympus, Japan) equipped with a CMOS camera
35
36
37 (ORCA, Hamamatsu Photonics K.K, Japan) was used to observe the movement of solution in the
38
39
40 nanochannels. An LED light source (Lumencor, USA) was used for excitation of sample fluorescence.
41
42
43 The fabricated nanofluidic device was fixed on an aluminum chip holder and placed on the microscope
44
45
46 stage. The inlets of the microchannels were connected with PEEK (polyether ether ketone) tubing via
47
48
49 O-rings and Teflon screws (UF-C, Institute of Microchemical Technology Co. Ltd, Japan). The PEEK
50
51
52 tubing was connected to vials containing reagents, which were linked to pressure controllers
53
54
55 (MFCSTM-EZ, Fluigent, France), and an air compressor. Water, air and surface-modification reagents
56
57
58 were introduced into the microchannels and nanochannels through the PEEK tubing, according to a
59
60

1
2
3
4 programmed pressure-control sequence. The outlets of the microchannels were either connected with
5
6
7 PEEK tubing for discharge to waste or sealed with Teflon screws for precise pressure control.
8
9

10 11 12 13 **4. Results and Discussion**

14 15 16 *4.1 Confirmation of the stop/go function of the Laplace nanovalves*

17
18
19 An illustration of the stop/go mode of operation is given in Fig. 3. To check the stop/go function of
20
21
22 the Laplace valves, water was introduced into the device, and the movement of the water/air interface
23
24
25 was observed as the air pressure was increased. When the applied pressure was 70 kPa, the air/water
26
27
28 interface remained at Laplace valve 1, while the interface moved forward when the applied pressure
29
30
31 was over 80 kPa. Thus, the stop/go function of Laplace valve 1 was confirmed. The stop/go function
32
33
34 of the Laplace valve 2 was next investigated. When the applied pressure was adjusted to 140 kPa the
35
36
37 water/air interface was at Laplace valve 2, while the interface moved beyond this point when the
38
39
40 applied pressure attained 150 kPa. Thus, the stop/go function of Laplace valve 2 was confirmed. The
41
42
43 estimated Laplace pressures on Laplace valves 1 and 2 were 70-80 kPa, and 140-150 kPa respectively,
44
45
46 while the respective theoretical values were 100 kPa and 130 kPa. The estimated Laplace pressure on
47
48
49 Laplace valve 1 was 20-30 kPa lower than the theoretical value. This difference in pressure may be
50
51
52 attributed to the mitigation of surface hydrophobicity with the sodium hydroxide treatment. In the case
53
54
55 of Laplace valve 2, the estimated Laplace pressure was 10-20 kPa higher than the theoretical value.
56
57
58
59
60

1
2
3
4 The surface roughness of the nanochannel (10 nm) may have caused an enhancement of the
5
6
7 hydrophobicity.
8
9

10 *4.2 Operating conditions for the femtoliter volumetric pipette*

11
12

13 The operating conditions for the femtoliter volumetric pipette were next investigated. After water
14
15
16 was introduced to the femtoliter volumetric pipette, a pressure of 400 kPa was applied to the air channel
17
18
19 to cut and isolate the sample. As shown in Fig. 4(a) top, although the sample was successfully cut, it
20
21
22 disappeared within 4 s of cutting. There are two possible explanations for this phenomenon: leakage
23
24
25 of the water (loss of both solute and solvent) or evaporation (loss of solvent). In an attempt to clarify
26
27
28 the reason for the sample loss, the same operation was conducted but with the use of a fluorescent
29
30
31 solution as the sample. As shown in Fig. 4(a) bottom and 5, the fluorescence intensity of the sample
32
33
34 remained constant, but the total volume of the solution decreased dramatically. Based on the
35
36
37 consideration that the fluorescence intensity corresponded to the number of fluorescence molecules
38
39
40 contained within the solution, it was concluded that evaporation was responsible for the decrease in
41
42
43 solvent while the amount of solute within the nanochannel was retained. Noted that decrease of the
44
45
46 fluorescence intensity after 3 s as shown in Fig. 5 is considered to be because of concentration
47
48
49 quenching by high concentration of fluorescence molecules with the loss of solvent. This evaporation
50
51
52 was attributed to airflow caused by the applied pressure. When 400 kPa was applied to the air channel,
53
54
55 all of the air (nanoliter volume) passed over the sample solution (femtoliter volume) in seconds,
56
57
58
59
60

1
2
3
4 causing evaporation to occur. This suggests that when the sample volume is at the femtoliter level, as
5
6
7 is often the case in nanofluidic devices, evaporation by airflow would be a significant issue.
8
9

10 To overcome the evaporation issue, static pressure was adopted (Fig. 4(b)) rather than dynamic
11
12 pressure (Fig. 4(a)). As shown in Fig. 4(b), applying air pressure from both sides of the air channel
13
14 minimized the overall air flow (static pressure). The time-course for the sample volume in this
15
16 approach is shown in Fig. 6. Compared to the operation using dynamic pressure, the use of a static
17
18 pressure effectively reduced the rate of evaporation by *ca.* 10 times.
19
20
21
22
23
24

25 Consequently, static pressure was selected as the operating mode for the femtoliter volumetric
26
27 pipette. Also, the operating time was set as 0.7 s so that the loss of sample solution by evaporation was
28
29 kept to a minimum (less than 1%) as shown in Fig. 6.
30
31
32
33

34 *4.3 Demonstration of femtoliter volumetric pipette and flask*

35
36

37 To demonstrate the working principle of the femtoliter volumetric pipette and flask, the operation
38
39 of sampling defined in the section 4.2 was conducted using pure water as a model sample. Fig. 7(a)
40
41 shows the time-course microscopic images for femtoliter-scale sampling and transport. First, water
42
43 was introduced to the femtoliter volumetric pipette by application of pressure $P_1 = 100$ kPa (Fig. 7(a)
44
45 top). Then, air was introduced from both the upper and lower sides of the air channel by application
46
47 of a pressure of $P_2 = 200$ kPa, while applying a back pressure of $P_3 = 140$ kPa from the right side of
48
49 the main channel (Fig. 7(a) middle). After 0.1s, pressure P_3 was turned off and the sample solution
50
51 was transported to the femtoliter flask (Fig. 7(a) bottom). As shown in Fig. 7(a), the liquid sample was
52
53
54
55
56
57
58
59
60

1
2
3
4 successfully introduced, cut, and transported to the flask. Thus, the working principle of the femtoliter
5
6
7 volumetric pipette and flask was verified. Since the effect of airflow on the evaporation of liquid
8
9
10 sample was minimized, the sampling of 11 fL, which is 85 times smaller than our most recent report,¹⁸
11
12
13 was realized.
14
15

16 Performance of the femtoliter volumetric pipette was quantitatively evaluated. Here, the variation
17
18 of fabrication, surface modification, and liquid operation were considered as error factors. The volume
19 of fabrication, surface modification, and liquid operation were considered as error factors. The volume
20 of sampling chamber of the femtoliter volumetric pipette was 11.74 ± 0.73 fL (CV 6.2%) with repeated
21
22 fabrication, whereas the designed volume was 11.20 fL (width \times depth \times length = $1600 \times 700 \times 10000$
23
24 nm). The variation of hydrophobic-surface modification by octadecylsilane (ODS) was $103.3 \pm 1.0^\circ$
25
26 (CV 1.0%) as the value of the static contact angle. As shown in Fig 7(b), the variation of the measured
27
28 sampling volume was 10.83 ± 0.06 fL (CV 0.6 %) based on pixel counting for 10 repeated liquid
29
30 operations when the volume of fL sampling chamber was 11.06 fL (width \times depth \times length = $1580 \times$
31
32 700×10000 nm). Effect of above factors on the accuracy and precision of femtoliter volumetric pipette
33
34 were discussed. The size variation of fabrication affects the accuracy but not the precision of the
35
36 sampling volume because the femtoliter volumetric pipette is integrated in a nanofluidic device and
37
38 repeatedly used. The variation of surface modification can affect the Laplace pressure up to 9.8 kPa,
39
40 but as the pressure tolerance of Laplace valve 1 and 2 are designed 25.1 kPa, it does not affect the
41
42 operational pressure. Thus, in principle, the variation of surface modification does not affect the error
43
44 of sampling. In contrast, the variation of liquid operation can affect both accuracy and precision of
45
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3
4 sampling volume owing to the different meniscus volume of the air/liquid interface at each time of
5
6
7 operation. Comprehensively, the accuracy of sampling volume was affected by the difference of
8
9
10 fabricated volume (+4.6%) and sampled liquid volume by operation (-2.1%) from the designed volume
11
12
13 while the precision was affected by the variation of sampled liquid volume by operation (0.6%).
14
15
16 Although the precision was three times larger than that for pipetting in a traditional volumetric analysis
17
18
19 (about 0.2%), we consider this performance is acceptable for quantitative applications at femtoliter
20
21
22 level because the error is less than 1% of sample volume.
23
24

25 In addition to pure water as a model sample used in the present study, the concept of the femtoliter
26
27
28 volumetric pipette and flask was applied to real samples of aqueous solution in our recent report, in
29
30
31 which sampling of cell culture medium and protein standard solutions were demonstrated.¹⁸ In contrast,
32
33
34 currently, sampling of organic solvents (e.g. methanol, acetonitrile, etc), is difficult because the surface
35
36
37 of the nanochannel is hydrophobic but oleophilic. In the future, sampling of organic solvents can be
38
39
40 achieved by applying oleophobic surface²¹ to a surface of femtoliter volumetric pipette. On the other
41
42
43 hand, in many cases of analytical chemistry, it is necessary to measure different calibrated volumes.
44
45
46 Regarding a usage of the femtoliter volumetric pipette as a graduated pipette, a multiple of 11 fL (the
47
48
49 sampling volume of current femtoliter volumetric pipette) is feasible by repeating the sampling
50
51
52 operation with desired times.
53
54

55 Utilizing the femtoliter sampling method, high-performance nanofluidic analytical devices
56
57
58 exploiting single-molecule ELISA¹³ and attoliter-to-femtoliter chromatography with one-million
59
60

1
2
3
4 theoretical plates¹¹ can be realized. For example, we have realized the quantification of countable-
5
6
7 number proteins secreted from single cell, which is an important achievement for single cell life
8
9
10 sciences.¹⁸ Accordingly, the present study developed the femtoliter sampling method in nanochannel,
11
12
13 which has been missing part of three components of analysis (sampling, chemical processing and
14
15
16 detection) in nanofluidics, and will lead to novel analytical applications such as single-molecule or
17
18
19 single-cell analyses.

25 **5. Conclusions**

26
27
28 In the context of nanofluidics, we developed a femtoliter volumetric pipette and flask which utilize
29
30
31 air pressure and surface tension for operation. The nanofluidic device incorporating an 11 fL
32
33
34 volumetric pipette and a 50 fL flask was fabricated in glass substrates and reliable operation conditions
35
36
37 required for manipulation of the gas/liquid interface in the nanochannels using Laplace valves was
38
39
40 established. Initially, evaporation of the liquid sample owing to the airflow generated during cutting
41
42
43 of the liquid sample was significant, but we suppressed the evaporation by minimizing the airflow and
44
45
46 shortening the operational time to 0.7 s, less than the time for evaporation. Finally, the working
47
48
49 principle of the femtoliter volumetric pipette and flask with 11 fL sample volume was verified. The
50
51
52 sampling volume was measured as 10.83 ± 0.06 fL (CV 0.6 %) with repeated operations. Generally,
53
54
55 the sampling process is fundamental in analytical chemistry. The present study realized the sampling
56
57
58 at femtoliter volume in nanofluidic device, which is a key technology for analyses of single cell or
59
60

1
2
3
4 analyses at single-molecule level, and hence advance knowledge in various fields including biology
5
6
7 and medicine.
