Heavy metals are highly toxic and exposure to contaminated water threatens millions of people around the world. Capacitive deionization (CDI) and electrosorption have shown promise as cost and energy-efficient methods to desalinate and deionize water. Developing efficient CDI methods to remove heavy metal ions can be an effective approach for more sustainable water treatment and purification.
Capacitive Deionization and Electrosorption for Heavy Metal Removal

Raylin Chen,* Thomas Sheehan,* Jing Lian Ng,* Matthew Brucks,* and Xiao Su*

Capacitive deionization (CDI) technologies have gained intense attention for water purification and desalination in recent years. Inexpensive and widely available porous carbon materials have enabled the fast growth of electrosorption research, highlighting the promise of CDI as a potentially cost-effective technology to remove ions. Whereas the main focus of CDI has been on bulk desalination, there has been a recent shift towards electrosorption for selective ion separations. Heavy metals are pollutants that can have severe health impact and are present in both industrial wastewater and groundwater leachates. Heavy metal ions, such as chromium, cadmium, or arsenic, are of great concern to traditional treatment technologies, due to their low concentration and the presence of competing species. The modification/functionlization of porous carbon and recent developments of Faradaic and redox-active materials have offered a new avenue for selective ion-binding of heavy metal contaminants. Here, we provide an extensive review on the progress in electrosorptive technologies for heavy metal separations. We provide an overview of the wide utility and extensive studies using carbon-based electrodes for heavy metal removal. In parallel, we highlight the trend toward modification of carbon materials, new developments in Faradaic and redox-active materials, and the underlying physico-chemical mechanisms that promote selective heavy metal separations.

1. Introduction

There is no formal definition for “heavy metals”, the term broadly refers to metals with high density or atomic weights.1 Heavy metals present environmental concern because they are hazardous to human health, even at trace concentrations, with effects ranging from acutely toxic to carcinogenic after chronic exposure.2 Heavy metals contamination originates from both natural and anthropogenic sources. Millions of people are exposed to contaminated soil and drinking water where naturally occurring heavy metals in rock and sediment leach into water sources.3 Even in regions with clean drinking water, contamination continues to be a problem because heavy metals can be ingested from contaminated food.4 These toxic compounds are continuously discharged into the environment from industries such as electronic-circuit production, steel and other metal processing, and fine-chemical production. Heavy metal toxicity is worsened as heavy metals move up the food chain and bioaccumulate in living organisms.5, 6

Conventional processes for heavy metal removal, such as chemical precipitation and coagulation-flocculation, struggle with selectively removing heavy metals and produce large quantities of toxic solid sludge.6 Processes that are typically used for desalination can, in principle, be used to remove heavy metal ions, but they may become inefficient because heavy metal contamination exists at much lower concentrations than typical salts.7 Amidst research into novel ways to remove metals, such as various membrane,8, 9 bioelectrochemical,10 and photocatalytic processes,11, 12 electrosorption processes are emerging as an efficient and facile way to remove heavy metals and other ions from water.13-15

Electrosorption refers to adsorption of a dissolved species onto an electrode, and the surface binding is promoted by an electric field.16 A typical electrosorption cell consists of two electrodes sandwiching a feed of water (Figure 1a). Electrosorption is induced by polarizing the electrodes with an applied voltage bias. Broadly, electrode materials are either redox active or non-redox active. In the case of non-redox active electrodes, charge is built up at the surface of the electrodes. In order to satisfy charge neutrality, ions of opposite charge are attracted to the polarized electrode by coulombic forces and electric charge is built up at the surface of the electrode, much like in an electric capacitor. At the surface of the polarized electrode, the ions form an electric double-layer.17 Utilizing this phenomenon to remove ions from solution, with non-redox active materials, is referred to as capacitive deionization (CDI). Ions are held in the double layer until the applied bias is stopped or reversed to discharge the electrodes. Upon discharge, the ions are liberated and the electrodes are regenerated. Because the CDI process stores charge, the energy used in an electrosorption process can partially be recovered, making them possibly more energy efficient than other ion removal techniques.18 For redox active materials, ions are captured to neutralize the change imbalance created by the redox reaction, as opposed to capturing ions in an electric double layer. Redox

Reactions involving the removal (or addition) of an electron from the electrode demand the addition of an anion (or cation) to satisfy charge neutrality. This process is sometimes referred to as electrochemical ion exchange. While the physical phenomena is slightly different, operation of electrosorption via electrochemical ion exchange is the same as with CDI. Regeneration of the electrode occurs when the opposite bias is applied, reversing the redox reaction and expelling the ions. Examples of electrode materials for electrochemical ion exchange include polyvinylferrocene and polypyrrole. Other redox materials that can remove metal ions are ion intercalation electrodes. These materials incorporate metal ions into the electrode crystalline structure though a redox reaction. While more commonly used as electrodes for batteries, a few of these materials have also been used for heavy metal ion removal. Electrosorptive and capacitive deionization processes are modular and can be combined with other ion removal technologies such as membranes, ion-exchange resins, and microbial desalination techniques to improve efficiencies and leverage the advantages of the individual processes.

CDI research has focused on water desalination and CDI has emerged as an energy and cost efficient method for removing salt at low concentrations from water. Materials such as activated carbon (AC) have frequently been used in CDI desalination studies because they are inexpensive and have high specific surface areas. CDI is most effective when the electrode has a high specific surface area, enabling much of the electrode material to participate in double-layer formation. While porous carbon materials are great for indiscriminately capturing all ionic species from water, electrosorption research is moving toward designing materials that can selectively remove certain ions of interest from competing ions.

This review provides an overview of recent and current research on electrosorption/CDI for As, Cd, Cr, Cu, Fe, Ni, Pb, V, U, Zn. In addition to porous carbon materials, we also focus on recent studies of surface modification of carbon, which can be used to control ion selectivity, as well as non-carbon materials that are being engineered to enhance ion selectivity and uptake capacity.

2. Heavy Metal Electrosorption

2.1 Arsenic

While technically a metalloid, arsenic is often grouped with heavy metals because of its similar density and toxicity. Arsenic...
is a toxic and carcinogenic element that can cause skin lesions, vomiting, diarrhea, convulsions, and death.\textsuperscript{3} Arsenic is primarily released into the environment from As-enriched minerals and arsenic contaminated drinking water threatens over 100 million people in Bangladesh, Cambodia, China, India, Laos, Myanmar, Nepal, Pakistan, Taiwan, and Vietnam.\textsuperscript{32} The World Health Organization (WHO) recommended limit of arsenic in drinking water is 10 µg/L and the United States Environmental Protection Agency (EPA) Maximum Contaminant Level (MCL) for arsenic is also 10 µg/L.\textsuperscript{33, 34}

Arsenic is most commonly found in the +3 and +5 oxidation states and As(III) is more toxic than As(V).\textsuperscript{35, 36} Under oxidizing conditions and at slightly acidic pH values, inorganic arsenic is most commonly found in the pentavalent form as H\textsubscript{3}AsO\textsubscript{3}. At higher pH values, this becomes HAsO\textsubscript{2}\textsuperscript{−}. In reducing conditions and at pH values below 9.2, arsenic is generally found in the +3 oxidation state as the neutral species H\textsubscript{3}AsO\textsubscript{3}.\textsuperscript{37} During As(III) electrosorption, it is common for As(III) to be oxidized to As(V) at the anode.\textsuperscript{38, 39}

Arsenic electrosorption studies have focused on AC electrodes (Table 1). The As uptake of AC electrodes can be enhanced when combined with other materials to make composite electrodes. Recently, redox-active polymer, poly(vinylferrocene), has been shown to be an extremely selective adsorbent for As electrosorption.\textsuperscript{40}

### 2.1.1 Activated Carbon Electrodes

Electrosorption using electrodes made from wood AC powder (Sinopharm Chemical Reagent Company, China) removed As(III) and simultaneously oxidized As(III) into As(V) at the anode.\textsuperscript{38}

The amount of As(III) that was oxidized increased with pH, but the adsorption As declined in highly alkaline solutions (pH > 11) due to competition from OH\textsuperscript{−} ions. These wood AC power electrodes removed 4.73 mg As/g AC from a 1 mmol As/L (75 mg/L) solution at 1.0 V. Commercially available granular AC Darco 1220 removed 0.066 mg As/g AC at 1.0 V and 0.3 mg/g at 1.5 V from a 100 µg As/L and 500 mg NaCl/L solution.\textsuperscript{41} When 100 µg Cr/L was added to these 100 µg As/L solutions, the arsenic uptake was enhanced. This enhanced uptake was likely due to the formation of an insoluble As-Cr compound because As and Cr were removed in a 1:1 molar ratio.

Around pH 6, AC (Filtrasorb 400, Chemviron Carbon Inc.) electrodes have a higher capacity for As(V) (10.31 mg/g) than for As(III) (7.57 mg/g) when adsorbing As from a 200 µg/L solution at a 1.2 V potential.\textsuperscript{39} The lower adsorption uptake for As(III) may have been because around pH 6, As(V) exists predominantly as anionic H\textsubscript{2}As\textsubscript{4}O\textsubscript{4}−, while As(III) exists predominantly as neutral H\textsubscript{3}AsO\textsubscript{3} and therefore a large fraction of As(III) was not electrostatically attracted to either electrode. In order for uncharged As(III) species to be electrosorbed, they needed to be oxidized at the anode to anionic As(V). The adsorption capacity of these Filtrasorb 400 AC electrodes decreased significantly when NaCl or natural organic matter (NOM, humic acid, Aldrich) was added to the arsenic containing solution. Negative Cl\textsuperscript{−} ions and negatively charged NOM compete with arsenic for adsorption sites.

The Filtrasorb 400 AC electrodes were effective at removing arsenic from contaminated ground water and decreased the As concentration from 0.13 mg/L to 0.03 mg/L from a sample of As-contaminated ground water.44

2.1.2 Carbon-based Composite Electrodes

The arsenic adsorption capacity of AC electrodes can be greatly enhanced when combined with other materials to make composite electrodes. The addition of TiO₂ to AC fiber felt electrodes raised the adsorption capacity from 4.05 mg As/g (for the felt alone) to 8.09 mg As/g (Langmuir fit maximum) at 1.5 V despite the decrease in specific surface area for the TiO₂-AC, as noted in Table 1.46 Electrodes made of AC and reduced graphene-iron composite (Fe-rGO) removed 13.00 mg As/g from a 10 mg/L solution at 1.2 V.43 Without the Fe-rGO, the AC alone removed just 6.57 mg/g. Composite electrodes containing AC powder and poly(vinylidene fluoride) removed 98.80% of the arsenic from a 1 mg/L solution upon the application of a 2 V potential.45 This 98.8% removal lowered the final concentration to 0.012 mg/L, very close to WHO and US EPA standards. Films containing carbon nanotubes (CNTs) and redox-active polymer poly(vinylferrocene) were able to adsorb about 75 mg As/g from a 1 mM As(V) (75 mg/L), 20 mM NaCl (1169 mg/L) solution upon the application of a 0.8 V vs Ag/AgCl potential.40 Rather than holding As ions in an electric double-layer, poly(vinylferrocene), when oxidized, binds to arsenic oxyanions through charge transfer between the positive ferrocenium units and the negative oxyanions. Arsenic anions were selectively adsorbed over competing Cl⁻ ions because the arsenic anions were more polarizable than Cl⁻ and transferred more charge to the oxidized poly(vinylferrocene) resulting in a higher binding energy for arsenic anions than for Cl⁻.

2.2 Cadmium

Chronic cadmium exposure is associated with kidney disease, osteoporosis, cardiovascular disease, and cancer.47, 48 Cadmium contamination and exposure is most prevalent in Asian countries such as China, Japan, Thailand, and Sri Lanka.49-51 Many people in these countries irrigate rice paddies using river water downstream from industrial sites, where cadmium-containing ore is refined for electronic devices and batteries. As a result, cadmium builds up in the rice and in other crops, and exposure occurs through consumption of these crops.47, 52 In Jiangxi Province, China, researchers from the World Health Organization have determined that 99.5% of the residents' cadmium intake originated locally grown crops due to the presence of tungsten ore processing plants upstream from farming communities.49 The WHO guideline value for Cd in drinking water is 3 μg/L and the US EPA MCL for Cd in drinking water is 5 μg/L.53 Various electrode materials used for Cd electrosorption are listed in Table 2.

2.2.1 Carbon-based Electrodes

AC cloth (ACC, FM70) electrodes removed 31.85% of the Cd²⁺ present in a 0.5 mM Cd²⁺ (56.2 mg/L) solution at pH 3.8 and 1.2 V.13 In competitive adsorption experiments, with the addition of 0.5 mM Cr³⁺ (26 mg/L) and 0.5 mM Pb²⁺ (104 mg/L), these FM70 ACC electrodes struggled to remove Cd. The Cd removal efficiency dropped from 31.85% in the individual removal experiment to 13.57% in the competitive removal experiment. Meanwhile, the removal efficiency for Cr only dropped from 52.48% to 46.22% and the removal efficiency for Pb increased from 42.62% to 45.53% between the individual heavy metal removal experiments and the competitive removal experiment. Among the Cd, Cr, and Pb individual removal tests, Cd electrosorption showed the lowest electrosorption rate. Cd²⁺ electrosorption was hypothesized to be slower than Pb²⁺ and Cr³⁺ due to its hydraulic radius and charge. Ions with higher charge and smaller hydraulic radius are preferred in adsorption.13 Among the three ions, Pb²⁺ has the smallest hydraulic radius (Pb²⁺ < Cd²⁺ < Cr³⁺) which allowed it to be adsorbed quickly. While Cr³⁺ has the largest hydraulic radius, it adsorbed quickly because it has a higher charge than Pb²⁺ and Cd²⁺. The combination of these two effects may have caused Cd²⁺ to be out competed by the other ions in the competitive removal experiment. Carbon aerogels removed 97.5% of the Cd from a 200 mg/L solution at 1.2 V and pH 6.54 At lower pH values, the H⁺ concentration increases and H⁺ competes for adsorption sites in the aerogel pores.

Modifying AC fiber electrodes with manganese (IV) oxide (ACF/MO) increased the electrodes’ adsorption capacity from 2.33 mg/g for the AC fiber alone to 14.88 mg/g (Langmuir fit max.) at 1.5 V.55 It is likely the incorporation of MO allowed for Cd(II) removal via ion intercalation. Simulations of Cd(II) adsorption onto MnO₂ (reduced from MnO₂) showed a greater energetic reward than adsorption onto graphene layers. These ACF/MO electrodes removed 65.12% of the Cd from a 200 μg Cd(II)/L solution. When the ionic strength of the 200 μg Cd(II)/L solution was raised by adding 0.1 mol/L NaCl (5.84 g/L), the Cd removal increased to 79.63%. However, raising the ionic strength again by increasing the NaCl concentration to 0.2 mol/L (11.7 g/L) decreased the removal back to 65.12%.

2.2.2 Other Electrodes

Electrodes made from birnessite, a manganese oxide commonly used for supercapacitors, removed 900.7 mg Cd/g from 2200 mg/L solution at pH 6 and 0.9 vs SCE.56 While these birnessite electrodes showed great uptake capacity, Mn²⁺ leached out of the birnessite during the discharge process. In the absence of Cd²⁺, 3.40% of the Mn in the birnessite electrodes leached out and at 2200 mg/L Cd²⁺, 38.02% of the Mn in the birnessite electrodes leached out.

Electrodes made by depositing polypyrrole on chitosan removed 51.1% of Cd from a 1000 mg/L solution at 1.5 V.20 Polypyrrole captures Cd²⁺ through an electrochemical ion exchange mechanism. Polypyrrole typically has poor stability as an electrode so the chitosan was added to improve the stability of the polypyrrole. These polypyrrole/chitosan electrodes showed >97% regeneration through 10 charge/discharge cycles.
2.3 Chromium

Chromium is a common pollutant due to its widespread industrial use and elevated levels of chromium in water and soil have been found in the US, UK, Brazil, India, Mexico, Australia, Poland, Slovenia, China, Russia, and Italy. Chromium is mainly found in the environment in two oxidation states: Cr(III) and Cr(VI). The most common Cr(VI) species are CrO\(_4^{2-}\), CrO\(_2^{2-}\), HCrO\(_4\), and H\(_2\)CrO\(_4\). Cr(III) species are generally anionic, toxic and carcinogenic. Most Cr(III) species also include Cr\(_{2+}\), Cr\(_{3+}\), and Cr\(_{4+}\). Cr(VI) species are generally anionic while Cr(III) species are generally cationic, so the two different oxidation states of chromium will be attracted to different electrodes. Since Cr(VI) species are strong oxidizing agents, they are readily reduced to Cr(III) species:

\[
\text{Cr}_2\text{O}_7^{2-} + 14 \text{H}^+ + 6\text{e}^- \rightarrow 2 \text{Cr}^{3+} + 7\text{H}_2\text{O}
\]

As a result, electrochemical removal of chromium often involves the reduction of Cr(VI) species to Cr(III) species. The pH of the solution can affect the removal of Cr in several different ways. In general, a decrease in pH is associated with a decrease in Cr(III) adsorption, an increase in Cr(VI) adsorption, and an increase in the amount of Cr(VI) reduction. The WHO guideline value for Cr in drinking water is 50 µg/L and the US EPA MCL for Cr in drinking water is 100 µg/L.

2.3.1 Activated Carbon Electrodes

As with arsenic and cadmium electrosorption, AC is a popular material for the chromium electrosorption of due to its high specific surface area, good conductivity, and electrochemical stability and its popularity can be seen in Table 3. Different forms of plant waste have been used as carbon sources to make AC electrodes. AC derived from peach pits, corncobs, and AC prepared from tea waste biomass, and AC prepared from *Limonia acidissima* (wood apple) shell have been shown to be effective materials for treating Cr-containing water. Three different ACs: a commercially available AC (Loba Chemie, Mumbai, India), AC prepared from tea waste biomass, and AC prepared from *Limonia acidissima* were used to remove Cr(VI) and F\(^-\) from 10 mg Cr/L, 10 mg F/L solutions. Under a potential of 1.2 V, the commercially available AC showed the highest Cr(VI) uptake and most effective reduction of of both Cr(VI) and F\(^-\) after two hours (Table 3). The AC from *L. acidissima* shells performed slightly worse, removing only 92.2% of Cr(VI) under the same conditions, and the AC from tea waste biomass had the lowest removal percentage of the three at 88.5%.

removal rate was the higher than the removal rates for Cd\(^{2+}\) and Pb\(^{2+}\) under the same conditions (0.5 mM Cd\(^{2+}\) (56.2 mg/L) or Pb\(^{2+}\) (104 mg/L)), likely because Cr\(^{3+}\) has a greater charge than the other two ions. In a competitive heavy metal removal test, 0.5 mM Pb\(^{2+}\) and 0.5 mM Cd\(^{2+}\) were added to the 0.5 mM Cr\(^{3+}\) solution and the ability of the electrode to remove Cr\(^{3+}\) decreased only slightly in the presence of Cd\(^{2+}\) and Pb\(^{2+}\) as the removal efficiency decreased from 52.48% to 46.22%.

Treatment of AC fiber felt with nitric acid increased the felt surface area, and the resulting material could adsorb 17.75 mg/g, whereas the untreated AC fiber felt could only adsorb 11.47.

### 2.3.2 Other Carbon and Composite Electrodes

Other forms of carbon such as aerogels and nanotubes can serve as electrode materials for the treatment of solutions containing chromium. Carbon aerogel electrodes have lower resistivity than activated carbon electrodes and do not require binding polymers that may degrade over time or obstruct adsorbent sites. However, a large portion of their surface area is inaccessible because their pores are often so small that the pore dimensions are of similar size as the thickness of the double layer, resulting in electrical double layer overlap.

Carbon aerogels were used to selectively lower the Cr concentration in groundwater from 30-35 ppb to 8 ppb with the application of a 1.2 V potential. Two carbon aerogels with 0.8 Ah charge placed between could achieve greater than 99% removal of Cr from a 2 mg/L solution at a pH of 2. These same carbon aerogels also showed greater than 90% removal in experiments with 8 mg/L chromium and experiments with only 0.3 Ah charge (Table 3). However, the performance of these electrodes dramatically decreased at more alkaline pH values as species such as Cr(OH)\(_3\) began to form. At constant concentration 8 mg/L and charge 0.8 Ah, 75% of the Cr was removed at pH compared to 96.5% at pH 2.

Electrodes made of vertically aligned CNTs grown on stainless steel mesh, reduced and adsorbed Cr(VI) simultaneously. These CNT electrodes could reduce 96% of the Cr(VI) in a 12 mg/L solution at a potential of -1.4 V in 115 minutes and adsorbed 746 mg/m\(^2\). Single-wall CNT coated stainless steel net electrodes (SWCNTs@SSN) also removed Cr(VI) by simultaneous reduction and adsorption. At a potential difference of 1 V, the SWCNTs@SSN electrodes only removed 6.5% of the total chromium. However, at a potential difference of 2.5 V, 97.4% of the total chromium was removed.

![Figure 2 Selective capture-and-release of Cr using polyvinylferrocene coated electrodes. These electrodes captured Cr(VI) and converted Cr(VI) to a less toxic Cr(III) upon release. (a) These electrodes showed great stability and recyclability over several discharge cycles; complete recovery of Cr was obtained for every cycle after the first. (b) The E-pH diagram for Cr speciation showing the conditions at which adsorption and desorption occurred. (c) Schematic of the Faradaic reactions that occur at each electrode during adsorption and desorption. Reproduced from ref. 40 with permission from Springer Nature, copyright 2019.](image-url)

</tbody>
</table>
Across the tested range of pH 2-5, total chromium removal was maximized at pH 4. At higher pH, Cr(Ⅵ) was less likely to be reduced to Cr(Ⅲ) and at lower pH, Cr(Ⅲ) can form a large hydrated complex \( \text{Cr(H}_2\text{O})_6^{2+} \) which may black itself from being adsorbed.

### 2.3.3 Synergetic Capture of Cr(Ⅵ) and Conversion to Cr(Ⅲ)

As presented in the studies previously mentioned, reduction of Cr(Ⅵ) to Cr(Ⅲ) often occurs concurrently with Cr electroosorption. A number of Cr electroosorption processes have components specifically designed to reduce Cr(Ⅵ) to Cr(Ⅲ), both using redox-active platforms as well as activated carbon.

Redox-active systems are attractive for selective separation and conversion due to their chemical tunability, reversibility of the electron-transfer process, electrocatalytic properties, and associated energy storage capabilities. Ferrocene-containing systems in particular can be heterogeneously immobilized onto conductive films, presenting electroresponsive properties in the heterogeneous form.

Films containing redox-active polymer poly(vinyl)ferrocene (PVF) and CNTs were used as an adsorbent to remove Cu and As species from water. This PVF-CNT composite showed a maximum uptake above 100 mg Cr/g at 0.8 V vs Ag/AgCl from a 1 mM Cr (52 mg/L) solution. The application of a positive potential oxidized the PVF ferrocene units into ferrocenium, which then formed ion pairs with the Cr(Ⅵ) species. PVF selectively adsorbed Cr(Ⅵ) and As(V) oxyanions in the presence of ClO₄⁻ or Cl⁻. This selectivity was largely dictated by charge transfer interactions between the positive ferrocenium and negative anions. Since ClO₄⁻ and Cl⁻ are more electronegative and less polarizable than the Cr(Ⅵ) species, ClO₄⁻ and Cl⁻ transferred less charge to the oxidized PVF and bonded weakly. Upon applying a reducing potential, Cr(Ⅵ) was converted to the less toxic Cr(Ⅲ) and desorbed from the electrode (Figure 2). A photocatalysis-CDI system (PCS) reduced Cr(Ⅵ) to Cr(Ⅲ) while removing it from solution using CDI. The positive potential was made of photocatalyst MIL-53(Fe), and the negative electrode was made of AC. Upon exposure to light, anionic Cr(Ⅵ) species embedded in the MIL-53(Fe) electrode were reduced to Cr(Ⅲ), which are cationic. These Cr(Ⅲ) cations then migrated to and adsorbed onto the AC electrode, allowing both electrodes to participate in electroosorption. This system could achieve up to 81.6% removal of Cr(Ⅵ) from a 50 ppm solution with an applied voltage of 1.3 V after 160 minutes, higher than the removal percentage achieved by photocatalysis or by AC adsorption alone (Figure 3).

### 2.4 Copper

Copper is a common heavy metal pollutant released from industrial processes such as circuit printing and metal plating and from corroding copper plumbing. Copper concentrations in drinking water vary widely as Cu levels in running and fully flushed water tend to low while Cu levels in standing or partially flushed water can be much higher. Elevated levels of copper contamination in drinking water have been recorded in various locations across the US, Canada, Sweden, and Germany. Although acute toxicity requires very high levels of copper, individuals with genetic disorders such as Wilson’s disease can suffer from the accumulation of copper in their brain, kidneys, and liver. In some cases, high levels of copper can cause liver damage. The WHO guideline value for copper in drinking water is 2 mg/L and the US EPA Action Level for copper is 1.3 mg/L.

Copper is one of the most commonly studied heavy metals in electrosorptive processes. Generally, Cu removal through electroosorption or CDI is most effective in slightly acidic solutions. Table 4 lists the best electrosorptive performances reported by various studies and most of them occur at pH 4 or 5. In more acidic solutions, there is more competition between Cu²⁺ and H⁺ for adsorption sites, and in alkaline solutions, copper can form an insoluble hydroxide compound. In some cases, the reduction and deposition of Cu metal can impact the performance of electrosorptive or CDI systems.

### 2.4.1 Activated Carbon Electrodes

ACs from a wide variety of sources have been used as electrode material for Cu removal. Commercially available AC (Filtrasorb 400, Chemviron Carbon Inc.) had a maximum uptake of 24.57 mg/g under a potential of 0.8 V, showed good regenerative ability, and remained effective in the presence of natural organic matter (NOM) and NaCl. The removal capacity of this Filtrasorb 400 AC electrode from a 50 mg Cu/L solution changed from 2.48 to 2.39 to 2.21 mg/g as the NaCl concentration increased from 0.001 to 0.01 to 0.1 M. A different AC electrode (named AG-3V) reached uptakes up to approximately 30 mg/g from 500 mg/L at 0 V vs Ag/AgCl.

Polyacrylonitrile-based AC fiber cloths modified with either a chitosan solution or by a nitric acid wash showed increased removal capacity after modification. Although these treatments resulted in a lower surface area, the HNO₃ and chitosan modifications improved uptake from 24.7 mg/g (unmodified) to 32.8 mg/g (nitric acid) and 54.3 mg/g (chitosan). Increased uptake was attributed to the increase of functional groups (carboxyl groups for the nitric acid treated AC and the increase in hydroxyl and amine groups for the chitosan modified AC) that promote binding to heavy metals.

### 2.4.2 Other Carbon Electrodes

Carbon aerogels can also be used to specifically adsorb Cu²⁺ ions. Carbon aerogels can be synthesized by stirring together resorcinol and formaldehyde in the presence of a sodium carbonate solution as a catalyst. The resorcinol to catalyst (R/C) ratio of carbon aerogels synthesized in this manner impacts their surface properties and their adsorption capacities. Aerogels made with five different R/C ratios between 330 and 1530 showed Cu²⁺ capacities ranging from 29.7 mg/g for 1030 R/C to below 10 mg/g for 830 R/C in a 100 mg/L CuSO₄ solution and under a potential of 1.2 V. A more comprehensive list is given in Table 4.

Modification of aerogel electrodes, such as combining aerogels with other materials to make composite electrodes and doping aerogels with heteroatoms, can improve the capacity of aerogel electrodes. Under a 1.2 V potential,
unmodified carbon aerogels had a capacity of 30.35 mg/g, while aerogels modified with FeO\textsubscript{3}, CeO\textsubscript{2}, and TiO\textsubscript{2} had capacities from about 41.42, 49.28, 57.13 mg/g, respectively.\textsuperscript{94} The aerogels modified with TiO\textsubscript{2} also showed excellent stability, retaining 96% of their capacity after 1000 adsorption-desorption cycles. The uptake of Cu\textsuperscript{2+} onto 3D graphene aerogel could be controlled by sulfur and/or nitrogen heteroatom doping.\textsuperscript{95} S-doped aerogels had a maximum capacity of 166.5 mg/g and were more effective than the N-doped gels or the S, N-codoped gels which had capacities of 119.9 mg/g and 124.4 mg/g, respectively. This is consistent with Hard-Acid-Soft theory. Since S is softer than N, the S-doped aerogels should therefore interact more favorably with soft heavy metal ions. The removal ratio for Cu\textsuperscript{2+} was higher than the ratio for Pb\textsuperscript{2+}, Hg\textsuperscript{2+}, and Cd\textsuperscript{2+} in these S/N doped aerogels, possibly because Cu\textsuperscript{2+} has the smallest hydrated radius.

Ordered mesoporous carbon (OMC) electrodes were able to adsorb 56.62 mg Cu/g from a 200 mg Cu/L solution under a potential of 0.9 V, substantially more than electrodes made of a commercially available AC (AW ACF) (16.02 mg/g) under the same conditions.\textsuperscript{84} While the AW ACF electrodes had a much higher specific surface area (1294 m\textsuperscript{2}/g) than the OMC electrodes (487 m\textsuperscript{2}/g), most of the surface area of the AW ACF electrodes was formed by micropores, which were too small for the Cu\textsuperscript{2+} ions to access. The addition of a chelating agent, such as citric acid or ethylenediaminetetraacetic acid (EDTA), to Cu-containing solutions can increase the electrosorption capacity of ordered mesoporous carbon.\textsuperscript{96} While free Cu\textsuperscript{2+} is generally adsorbed to the cathode, Cu-EDTA complexes are negatively charged and are attracted to the anode. In the absence of chelating agent, OMC electrodes removed 35.9 mg Cu/g from 50 mg/L solution at pH 4. The addition of a chelating agent in a 10/L Cu/chelating agent ratio increased the adsorption capacity to 70.18 mg/g for citric acid and 59.26 mg/g for EDTA.

CNTs and carbon nanofibers (CNFs) are commonly used electrode materials for Cu electroadsorption due to their high specific surface areas and good electrical conductivity.\textsuperscript{97, 98} CNF films used to electrosorb Fe\textsuperscript{3+}, Cu\textsuperscript{2+}, Zn\textsuperscript{2+}, and Na\textsuperscript{+} had ion electroadsorption capacities in the order of Fe\textsuperscript{3+} > Cu\textsuperscript{2+} > Zn\textsuperscript{2+} > Na\textsuperscript{+}.\textsuperscript{70} This order can be explained by the charge and hydrated radii of the ions. Ions with higher charge were more easily adsorbed onto the electrode under the effect of an electric field. For ions with the same charge, the size of their hydrated radius dictates adsorption behavior. Ions with a smaller hydrated radius adsorb more easily and, in this case, the hydrated radius of Cu\textsuperscript{2+} is smaller than that of Zn\textsuperscript{2+} so Cu\textsuperscript{2+} is preferentially adsorbed compared to Zn\textsuperscript{2+}. Electroadsorption tests on N-doped graphene nanosheets showed a similar trend, with the electrosorption rate of Fe and Cu ranking first and second among 9 different metal ions.\textsuperscript{90} Cu adsorbed quickly onto the N-doped graphene nanosheets because Cu\textsuperscript{2+} has a strong affinity to complex with hydroxyl groups on the surface of the graphene nanosheets.

### 2.4.3 Metal-Oxide and Metal-Sulfide Composite Electrodes

Modifying carbon electrodes with metal-oxide and metal-sulfide materials to make composite electrodes can improve their Cu uptake capacity. A Fe\textsubscript{3}O\textsubscript{4}/porous graphene nanocomposite was able to remove more Cu\textsuperscript{2+} from 0.03 mM Cu\textsuperscript{2+} (1.91 mg/L) solution than pure porous graphene from 0.03 mM Cu\textsuperscript{2+}, and these graphene electrodes also removed Pb\textsuperscript{2+} and Cd\textsuperscript{2+} at efficiencies very similar to their Cu\textsuperscript{2+} removal efficiencies.\textsuperscript{100} Porous graphitic carbon nanosheets from sugarcane bagasse functionalized with Fe\textsubscript{3}O\textsubscript{4} nanoparticles removed more than 90% of every heavy metal ion from a mixture of 0.5 mg/L Mg\textsuperscript{2+}, Zn\textsuperscript{2+}, Cu\textsuperscript{2+}, Cd\textsuperscript{2+} and Pb\textsuperscript{2+} each.\textsuperscript{101} A composite material containing reduced graphene oxide and TiO\textsubscript{2} nanoparticles (rGO-TNT) could achieve a Cu\textsuperscript{2+} uptake of 253.25 mg/g from an 80 mg/L Cu\textsuperscript{2+} solution under a potential of 1.2 V.\textsuperscript{102} On a molar basis, the rGO-TNT electrodes showed a strong preference for Cu\textsuperscript{2+} (3.99 mmol/g) or 253.5 mg/g over Pb\textsuperscript{2+} (1.17 mmol/g or 242.4 mg/g), possibly due to the smaller size and higher reduction potential of Cu\textsuperscript{2+} ions. The addition of ZnS improved the adsorptive capacity of carbon felt electrode more than FeS.\textsuperscript{86} The addition of FeS or ZnS to active carbon felt (ACF) electrodes improved Cu\textsuperscript{2+} adsorption from 12 mg/g (ACF) to 18 mg/g (ACF-FeS) or 27.4 mg/g (ACF-ZnS) from 100 mg Cu\textsuperscript{2+}/L solution at -0.2 V. Adding 150 mg/L Cr\textsuperscript{3+} only decreased the ACF-ZnS Cu\textsuperscript{2+} electrosorption capacity from 27.4 mg/g to 23.5 mg/g.

A MnO\textsubscript{x}/carbon fiber composite electrode had a maximum adsorption capacity of 172.88 mg/g under a potential of -0.8 V.\textsuperscript{85} Birnessite, a redox active manganese oxide-based mineral, has shown an electrosorption capacity of 372.3 mg/g after 30 charge-discharge cycles between 0.4-0.9 V vs SCE.\textsuperscript{103} These electrodes captured Cu\textsuperscript{2+} by intercalating cations when the Mn(IV) in birnessite was reduced to Mn(III). The adsorption capacity of the birnessite electrodes increased after each charge-discharge cycle because Cu\textsuperscript{2+} formed stable inner-sphere complexes with birnessite. As a result, Cu\textsuperscript{2+} was not completely desorbed during the oxidation of birnessite and accumulated with each cycle.

### 2.4.4 Polymer Electrodes

Several different organic polymers have been investigated for their ability to remove Cu\textsuperscript{2+}. A poly(m-phenylenediamine) (PmPD) electrode was found to have an uptake of 123 mg/g in a 3 mM Cu\textsuperscript{2+} (191 mg/L) solution.\textsuperscript{104} The optimal voltage for Cu\textsuperscript{2+} removal was -0.3 V vs SCE as decreasing the potential below -0.3 V vs SCE reduced water and showed bubbles on the surface of the PmPD electrode. The negative potential not only increased the electrostatic attraction between the Cu\textsuperscript{2+} ions and the PmPD electrode, it also increased the presence of imine structures in the polymer that chelate Cu\textsuperscript{2+}. Electrodes PmPD on reduced graphene oxide exhibited similar behavior had a 376.8 mg/g capacity at a 5 mM Cu\textsuperscript{2+} removal rate.

A PD electrode, it also increased the presence of imine structures in the polymer that chelate Cu\textsuperscript{2+}. Electrodes PmPD on reduced graphene oxide exhibited similar behavior had a 376.8 mg/g capacity at a 5 mM Cu\textsuperscript{2+} removal rate.

A composite electrode made from chitosan and polypyrrole, a conductive polymer, showed Cu\textsuperscript{2+} uptake as high as 99.67 mg/g, and it removed other metal ions such as Ag\textsuperscript{+}, Pb\textsuperscript{2+}, and Cd\textsuperscript{2+} at rates similar to its Cu\textsuperscript{2+} removal rate.\textsuperscript{80} An electrode containing polypyrrole, chitosan, and CNTs showed Cu\textsuperscript{2+}
uptakes of up to 19.2 mg/g, which was slightly less than its capacity for Fe$^{3+}$ (22.3 mg/g) but more than its capacity for Ag$^+$ (17.9 mg/g). An electrode made from chitosan and sodium phytate supported on polyethylene glycol terephthalate could remove 88% of Cu$^{2+}$ from a 10 mg/L stream when a potential of 1.2 V was applied.

### 2.4.5 Membrane-augmented CDI

Figure 4 Schematics of a combined CDI-electrodeionization (EDI) water remediation apparatus. This CDI-EDI system purifies wastewater through a combination of electrosorption and ion exchange. For this system, the wastewater stream of CuSO$_4$ is fed into the anode and cathode chambers and a concentrate salt solution of Na$_2$SO$_4$ is fed into the middle chamber. The cathode and anode chambers are filled with their corresponding resins to further increase the chamber’s affinity for ions of a specific charge. The first step is to pass the feed through the apparatus with <4.0 mA so Cu (II) in the anode chamber is removed from solution in a 3-step process. In step one, the feed stream is passed into each of the electrode chambers. In the anode chamber, Cu (II) can either bind to the cation exchange resin or pass through the cation membrane into the salt concentrate chamber. In the cathode chamber, the Cu (II) ions can undergo electrosorption. The second step involves resin regeneration with acid and base generated by hydrolysis. In this study, the current was raised above 4.0 mA to generate protons in the anode chamber that could regenerate the cation resin so the Cu (II) can flow into the concentrate chamber. In the cathode chamber, hydroxide ions can displace the SO$_4^{2-}$ into the concentrate. The final step is to regenerate the electrodes by reversing the potential across the electrodes. While the potential is reversed, the effluents from the anode and cathode chambers are recycled into the opposite chamber to remove the remaining ions. This technology was able to achieve a 95.7% and 87.6% removal efficiency for the anode and cathode chambers, respectively, with a starting Cu (II) concentration of 42.9 mg/L and a specific surface area of 2100 m$^2$/g. Reproduced from ref. 26 with permission from Elsevier, copyright 2019.
Membrane CDI with AC fiber electrodes was used to remove Cu\(^{2+}\) and Zn\(^{2+}\) from water, and the adsorption capacity at 1.2 V in a 500 mg/L solution was found to be 108.7 mg/g for Cu\(^{2+}\) and 122.6 mg/g for Zn\(^{2+}\). At voltages from 0.4 to 0.6 V, Cu\(^{2+}\) adsorption capacities were greater than adsorption capacities of Zn\(^{2+}\), possibly due to the smaller hydrated radius of Cu\(^{2+}\). At voltages between 0.8 – 1.2 V, the amount of Zn\(^{2+}\) adsorbed was greater than that of Cu\(^{2+}\), likely because at voltages above 0.6 V, Cu\(^{2+}\) reduced and deposited on the electrode as Cu and Cu\(_2\)O, which decreased the surface area of the electrode.

A novel CDI-electrodeionization process combining ion-exchange membranes and resins was able to remove 95.7% of the copper from a 42.9 mg/L solution. This system involved three chambers separated by ion-exchange membranes: an anode chamber, a cathode chamber, and a concentrated chamber located between them. CuSO\(_4\) was adsorbed onto AC electrodes in the anode and cathode chambers while being enriched in the concentrated chamber, making it a useful technology for both water purification and resource recovery (Figure 4).

---

### Table 4 Copper Membrane CDI with AC fiber electrodes was used to remove Cu\(^{2+}\) and Zn\(^{2+}\) from water, and the adsorption capacity at 1.2 V in a 500 mg/L solution was found to be 108.7 mg/g for Cu\(^{2+}\) and 122.6 mg/g for Zn\(^{2+}\). At voltages from 0.4 to 0.6 V, Cu\(^{2+}\) adsorption capacities were greater than adsorption capacities of Zn\(^{2+}\), possibly due to the smaller hydrated radius of Cu\(^{2+}\). At voltages between 0.8 – 1.2 V, the amount of Zn\(^{2+}\) adsorbed was greater than that of Cu\(^{2+}\), likely because at voltages above 0.6 V, Cu\(^{2+}\) reduced and deposited on the electrode as Cu and Cu\(_2\)O, which decreased the surface area of the electrode.

2.5 Iron

Iron poisoning typically occurs due to the accidental ingestion of large doses of iron, and it can lead to vomiting, diarrhea, and liver damage. Iron in ground water originates from iron-containing rock and is common to find iron in ground water in many geographical areas around the globe because iron is very abundant; iron makes up about 5% of the Earth’s crust. Comparatively little research has been done on the removal of iron from solutions through electrosorption or CDI (Table 5).

2.5.1 Carbon Electrodes

Graphene nano-flakes were used to remove FeCl$_3$ from water through electrosorption and had a maximum electrosorptive capacity of 0.88 mg/g at an applied potential of 2.0 V.$^{109}$ Because Fe$^{3+}$ is more highly charged than many other cationic species, it is generally easier to remove by electrosorptive processes so despite having the largest hydrated radius, the graphene nanoflakes removed Fe$^{3+}$ more rapidly than Ca$^{2+}$, Mg$^{2+}$, and Na$^+$. A CNTs-CNFs composite film electrode could remove Fe$^{3+}$ more rapidly than Cu$^{2+}$, Zn$^{2+}$, and Na$^+$, again, because Fe$^{3+}$ is more charged than the other ions.$^{70}$ Fe$^{3+}$ had the fastest removal rate onto N-doped graphene nanosheet electrodes despite the presence of many other metal cations with a 2+ charge.$^{99}$ This was likely because Fe$^{3+}$ was oxidized to Fe$^{3+}$. Fe$^{3+}$ could out-compete the other ions for adsorption sites because of its higher charge and greater affinity for hydroxyl groups on the electrode surface.

2.6 Nickel

Nickel is a potential carcinogen and can cause other health problems such as gastrointestinal distress and pulmonary fibrosis.\textsuperscript{3, 111} Reports of high nickel concentration in water typically arise from nickel leaching out of stainless steel plumbing.\textsuperscript{113} The WHO guideline value for nickel in drinking water is 70 µg/L.\textsuperscript{34} Various nickel electrosorption results are reported in Table 6.

2.6.1 Carbon-based Electrodes

Multi-walled CNTs were used to remove Ni\textsuperscript{2+} had maximum uptake of 145.73 mg/g.\textsuperscript{110} The CNTs performed better in more alkaline solutions since Ni\textsuperscript{2+} had less competition from H\textsuperscript{+} for adsorption sites. Nanoneedle-structured α-MnO\textsubscript{2}/carbon fiber paper composite (MnO\textsubscript{2}/CFP) electrodes were synthesized and showed an uptake of 16.4 mg Ni\textsuperscript{2+}/g upon the application of a -1.3 V potential.\textsuperscript{111} This uptake was much higher than the uptake of carbon fiber paper alone (0.034 mg/g) under the same conditions. However, during nickel removal, Mn\textsuperscript{2+} ions were released by partial reduction of MnO\textsubscript{2}. An asymmetric electrode cell, consisting of a MnO\textsubscript{2}/CFP positive electrode and an AC negative electrode was used to removal the leached Mn\textsuperscript{2+} and could decrease the Mn\textsuperscript{2+} concentration from 100 ppm to less than 2 ppm.

2.6.2 Other Electrodes

Birnessite, a mineral containing MnO\textsubscript{2}, was combined with CNTs to make HB/CNT electrodes with increased specific area and conductivity.\textsuperscript{112} The composite could adsorb 155.6 mg Ni\textsuperscript{2+}/g after 12 hours under a potential of 0 V vs SCE. This adsorption capacity was higher than that of the birnessite alone (96.6 mg/g) or CNTs alone (~0 mg/g). Electrosorption was induced by reduction of manganese in the electrode from Mn(IV) to Mn(III) and Mn(II) and this reduction is accompanied the insertion of Ni\textsuperscript{2+} or Zn\textsuperscript{2+}.

2.7 Lead

Lead is used in many processing industries such as ammunition, battery, paint, alloy, and glass making operations. Large amounts of lead have been discharged in into the environment as a result of poorly controlled industrial activity.\textsuperscript{114} Exposure to lead is especially common in low and middle-income countries.\textsuperscript{115} Marginalized populations in places such as La Oroya, Peru\textsuperscript{116} and Torreon, Mexico\textsuperscript{117} are more likely to live close to toxic waste sites. Consumption of lead contaminated water can cause damage to liver, kidney, brain and nervous system.\textsuperscript{13} Due to its high toxicity and tendency to bioaccumulate, lead was listed by the US Environmental Protection Agency as one of the priority pollutants.\textsuperscript{118} The WHO guideline value for lead in drinking water is 10 µg/L and the US EPA Action Level for lead in drinking water is 15 µg/L.\textsuperscript{34, 53}

2.7.1 Activated Carbon Electrodes

AC can be obtained easily from a wide range of raw materials through thermal or chemical activations.\textsuperscript{119} AC obtained from date stones achieved an adsorption capacity of 17.71 mg/g and desorption capacity of 17.02 mg/g from a 5 mg Pb/L solution at 0.13 V vs SCE.\textsuperscript{120} When a negative potential is applied, the electrode reduces water into hydrogen gas and hydroxyl ions. This increases the pH of the solution at the electrode surface and enables Pb\textsuperscript{2+} ions bind to hydroxyl and carboxylic acid groups by reactions such as:\textsuperscript{120, 121}

\[
R–COOH + OH\rightarrow R–COO⁻ + H₂O \\
2R–COO⁻ + Pb²⁺ \rightarrow (R–COO)₂Pb²⁺ \\
\]

When reversing the applied potential, the AC acts as the anode and oxidizes water, decreasing the pH at the electrode. The reaction will be reversed, and the electrode can be regenerated:

\[
2H₂O \rightarrow 4H⁺ + O₂ + 4e⁻ \\
(R–COO)₂Pb²⁺ + 2H⁺ \rightarrow 2R–COOH + Pb²⁺ \\
\]

2.7.2 Other Carbon Electrodes

Graphene is another carbon-based material that is effectively used for electrosorption because it has a large theoretical specific surface area, 2630 m\textsuperscript{2}/g, and has higher conductivity than other carbon materials.\textsuperscript{122} However, the graphene lamellae tend to agglomerate due to the strong π–π interaction between graphene sheets.\textsuperscript{123} This agglomeration greatly reduces the specific surface area and conductivity of graphene. A three-dimensional framework structure was developed from graphene sheets to address this issue and the interconnected hierarchical porous structure of this three-dimensional graphene (3DG) further enhanced ability to uptake lead as an electrode material in electrosorption.\textsuperscript{124} Under an applied
voltage of 1.4 V and pH 6, a 3DG electrode grafted with ethylenediamine triacetic acid (EDTA) achieved a high Pb\(^{2+}\) removal efficiency of 99.9% from a 140 mg Pb/L solution and desorbed 94.3% of the Pb after 8 cycles. The addition of EDTA to the electrode enables Pb\(^{2+}\) ions to be captured through a chelation reaction, which provided another driving force in addition to the electrostatic attraction of Pb\(^{2+}\) to the electrode. Graphene’s selectivity for Pb\(^{2+}\) could be controlled with nitrogen doping. Graphene doped with softer pyrrolic-N showed a greater affinity toward soft Pb\(^{2+}\) ions than graphene doped with harder pyridinic-N (Figure 5). The performance of electrodes made with these N-doped graphenes is listed in Table 7.

Graphene sheets can also be rolled up to produce carbon nanotubes (CNTs) and the hollow and layered structure of CNTs makes them a good electrode material in capacitive deionization.\(^{126}\) CNT electrodes oxidized with nitric acid (EDTA) achieved a high Pb\(^{2+}\) adsorption capacity of 15.6 mg/g.\(^{126}\) The electro sorption performance of CNTs can be enhanced greatly when combined with other materials in composite electrodes. A single walled-CNT coated stainless steel net (SSN) electrode achieved Pb\(^{2+}\) removal efficiencies ranging from 97.2% to 99.6% from aqueous solutions with Pb\(^{2+}\) concentration varied between 20 mg/L to 150 mg/L after 90 minutes under an applied potential of -2.0 V vs SCE.\(^{114}\) Activating CNT electrodes by air-plasma to produce P-air electrodes increased the BET specific surface area from 95 to 106 m\(^2\)/g and increased the adsorption capacity of the electrodes from 1.36 mg/g (untreated) to 2.40 mg/g (P-air) in Pb\(^{2+}\) solutions of 5 mg/L at a voltage of 450 mV.\(^{117}\)

Electrodes made by electrodepositing reduced graphene oxide (rGO) on a SSN achieved an overall better performance compared to the SSN alone.\(^{128}\) The advantage of synthesizing the composite electrode via electrodeposition versus using polymeric binders is that binders can destroy the electrode surface and increase its electrical resistance.\(^{129}\) The rGO coating also provides high protection against corrosion and supplies active sites for Pb\(^{2+}\) adsorptions. This feature enhanced the effectiveness of rGO/SSN electrode for lead treatment in wastewater. The removal efficiency of rGO/SSN electrode reached 97.2% of 1000 mg Pb/L, which was about 12% higher than the SSN electrode with a 4.45 times higher removal rate.\(^{128}\)

Graphene aerogels (GAs), made from graphene oxide (GO), showed improved ability to remove Pb\(^{2+}\) when doped with nitrogen to make nitrogen-doped graphene aerogels (NGAs).\(^{130}\) The NGAs could remove about 42% of the Pb\(^{2+}\) from a 1 mM Pb\(^{2+}\) (207 mg/L) solution at -0.3 V vs SCE while the GAs could only remove about 39% of the Pb\(^{2+}\) and reduced graphene oxide (rGO) could only remove about 36% of the Pb\(^{2+}\) at the same conditions. The enhanced electrosorptive ability was attributed to the intrinsic charges on NGAs attracting Pb\(^{2+}\), the greater surface area of the NGAs (434.4 m\(^2\)/g for NGAs, 393.4 m\(^2\)/g for GAs, and 16.9 m\(^2\)/g for rGO), and coordination between doped nitrogen atoms and Pb\(^{2+}\). These effects contributed to the NGAs high electrosorption capacity (650.4 mg/g). Crumpled nitrogen-doped graphene (CNG) nanosheets used for membrane-CDI (MCDI) achieved an electrosorption capacity of 521 mg Pb\(^{2+}\)/g from 200 ppm Pb\(^{2+}\) at 1.2 V.\(^{99}\) This high electrosorption capacity was attributed to the CNG providing a large ion-accessible
were also highly effective at removing Pb and had an electro sorption capacity of 663 mg/g from an initial concentration of 100 mg/L at 1.2 V.\textsuperscript{12} This GO/NF had a negative surface and owed many oxygenous functional group which could adsorb Pb even without the application of an electric field (193.5 mg/g at open circuit). X-ray photoelectron spectroscopy showed the relative area of hydroxyl-character carbon reduced from 26.98% of the total carbon before adsorption to 7.98% after adsorption of Pb suggesting hydroxyl groups complexed with Pb. This complexation, in addition to the electrostatic attraction from an applied electric field, explains the high electro sorption capacity of GO/NF.

### 2.7.3 Composite Electrodes

Various composite electrodes have been derived from carbon materials with improved electrosorptive properties.\textsuperscript{119, 131} Reduced graphene oxide/Titanate Nanotubes (rGO/TNT) composite electrodes removed 241.65 mg Pb/g within 2 hours from an 80 ppm Pb solution at 1.2 V.\textsuperscript{102} The RGO/TNT composite had a high BET surface area of 511.226 m\(^2\)/g, and had an electrosorption capacity of 663 mg/g from an initial concentration of 100 mg/L at 1.2 V.\textsuperscript{121} This GO/NF had a negative surface and owed many oxygenous functional group which could adsorb Pb even without the application of an electric field (193.5 mg/g at open circuit). X-ray photoelectron spectroscopy showed the relative area of hydroxyl-character carbon reduced from 26.98% of the total carbon before adsorption to 7.98% after adsorption of Pb suggesting hydroxyl groups complexed with Pb. This complexation, in addition to the electrostatic attraction from an applied electric field, explains the high electro sorption capacity of GO/NF.

\textit{J. Name.}, 2013, \textit{00}, 1-3 | 15
Functional materials such as conducting polymers are alternatives to carbon-based electrodes for use in capacitive deionization. Conductive polymers have attracted attention as electrode materials because of their unique properties such as high stability under ambient conditions and variable conductivity. The hetero N atoms in polyaniline (PANI) are capable of removing Pb\(^{2+}\) ions through chelation. A composite electrode using PANI and attapulgite (ATP), a natural clay mineral with a high specific surface area and known affinity for heavy metal ions, achieved an adsorption capacity of 15.42 mg/g with from 1 mM Pb\(^{2+}\) (207 mg/L) at -0.3 V vs SCE after 10 minutes. The removal of Pb\(^{2+}\) ions by PANI/ATP electrode was driven by a combination of the chelation reaction, electrostatic interactions, and the physisorption brought from ATP.

### 2.7.5 Effects of pH on Pb Electrosorption

The pH of the contaminated solution can greatly affect the electrosorption of Pb\(^{2+}\). Pb\(^{2+}\) capture using single wall CNT on stainless steel nets showed the highest Pb removal rates at pH 6.50 and the lowest removal rates at pH 2.00 across a tested range of pH 2-6.5. Other experiments have shown the same pattern of decreased electrosorption at low pH. Across a range of pH 2 to pH 7, electrosorption using AC showed maximum efficiency at pH 5 with a removal efficiency of 97.55%. The slow removal rate of Pb\(^{2+}\) ions at low pH was due to the competition between hydrogen ions and Pb\(^{2+}\) ions for adsorption sites. In a low pH environment, the concentration of H\(_3\)O\(^+\) ions is significantly greater than that of Pb\(^{2+}\) ions and as a result, most of the electrode surface is occupied by the H\(_3\)O\(^+\) ions. As the pH increases, the concentration of H\(_3\)O\(^+\) ions decreases, increasing the amount of exposed metal binding sites carrying negative charges, which attract more Pb\(^{2+}\) ions. At higher pH (> 6) precipitation of lead to form lead hydroxide inhibits adsorption.

### 2.8 Uranium

Uranium is a significant component of nuclear energy production, and the development of nuclear energy has caused uranium to be widely released into the environment as hexavalent U(VI) ions. The U(VI) ions pose a great threat towards the environmental health due to its high chemical and radiological toxicity. The WHO guideline value for uranium in drinking water is 30 µg/L and the US EPA MCL for uranium in drinking water is also 30 µg/L. Various uranium electrosorption results are listed in Table 8.

### 2.8.1 Carbon-Based Electrodes

Carbon-based materials are commonly used for uranium ion electrosorption because they have high specific surface areas, good electrical conductivity, and are inert to a wide variety of chemicals. A phosphate functionalized graphene hydrogel (HGP), made by activating graphene oxide with phosphate groups using phytic acid (PA), had a maximum adsorption capacity of 545.7 mg/g at 1.2 V and pH 5.0. The hydrogels had an interconnected 3D network structure with hierarchical pores, which greatly increased its specific surface area. In addition to the high adsorption capacity, the electrode also achieved a high desorption ratio of 90.9% at via HNO\(_3\) eluting at open circuit. The HGP electrodes removed more mg Pb/g than plain reduced graphene electrodes because the HGP electrodes included additional phosphate groups which captured Pb\(^{2+}\) via chemisorption.

Table 8 Uranium
Carbon fiber electrodes, produced by a catalytic vapor-deposition process, removed up to 99.85% of the uranium from a 100 mg/L uranium feed solution at -0.6 V vs Ag/AgCl, which corresponded to an uptake of 1.2 g/g.\textsuperscript{140} An AC fiber electrode (Osaka Gas Co., FN-200PS-15) removed more than 99% of the uranium present lagoon sludge containing 100mg/L of uranium at pH 4 and -0.9 V vs Ag/AgCl.\textsuperscript{145} More than 99% of the adsorbed uranium was discharged at a potential of +1.2 V vs Ag/AgCl and pH 3.

### 2.8.2 Composite Electrodes

A half-wave rectified alternating current electrochemical (HW-ACE) method effectively removed uranium from at low concentrations from seawater with an amidoxime functionalized carbon electrode.\textsuperscript{146} This electrode has contained amidoxime which provides chelation sites that preferably bind with uranyl ions (UO$_2^{2+}$).\textsuperscript{147} These chelation sites allow uranyl ions to selectively bind to the surface of the electrode and be reduced to charge neutral U(IV) species, such as UO$_2^{2+}$. When the applied potential is released, UO$_2$ stays bound to the electrode while other ions are rejected into the solution again. Reapplying the potential adsorbs and reduces more uranyl ions and the UO$_2$ particles on the electrode surface grow bigger. The HW-ACE method achieved a uranium extraction capacity of 1932 mg/g, which is ninefold higher than conventional physiochemical methods.\textsuperscript{146}

### 2.9 Vanadium

Vanadium is a rare heavy metal that can pose a serious threat to environmental health, especially in its most toxic form, V(V).

Vanadium causes a variety of toxic effects including, but not limited to, hemolysis, embryotoxicity, and functional lesions in the liver and kidneys.\textsuperscript{148} Vanadium mining and smelting has caused environmental pollution in countries such as Russia, China, and South Africa.\textsuperscript{149} V-containing wastewater commonly has high salinity and low biodegradability, making it difficult to treat by conventional methods. Adsorption-based techniques are therefore a promising field of research for processing V-containing wastewater.\textsuperscript{150}

### 2.9.1 Carbon and Composite Electrodes

A high-area carbon cloth could remove about 80% of VO$_2^+$ in a water sample upon the application of a 0.1 mA galvanostatic current.\textsuperscript{151} CDI can also potentially be used in removing vanadium from the acid leaching solutions commonly used in vanadium extraction.\textsuperscript{152} Electrodes containing ion exchange resins on activated carbon have been investigated for their ability to selectively recover vanadium from a complex acid leaching solution.\textsuperscript{142-144} Out of three cation exchange resin/mineral active carbon electrodes tested for their ability to remove vanadium, the electrodes made from D860 cation exchange resin had the highest adsorption capacity at 15.67 mg VO$_2^+/g$ material from a solution containing 300 mg/L VO$_2^+$, 300 mg/L Fe$^{3+}$ and 300 mg/L Al$^{3+}$ at an 1.5 V.\textsuperscript{144} The D860/active carbon electrode was selective for VO$_2^+$ because VO$_2^+$ has a relatively high affinity for the resin material and a smaller hydrated radius compared to the hydrated radii of other metals present in the acid leaching solution, allowing it to pass through the pores of the electrode more easily. Additionally, the D860/active carbon electrode showed good regenerative

ability. The same D860 resin on coconut shell activated carbon had a much higher capacity of about 170 mg V(V)/g material. Replacing the D860 with an anion exchange resin (D314) made electrodes that could adsorb about 230 mg V(V)/g. The electrosorption performance of electrodes made with different resins is listed in Table 9. The electrosorption these resin/active carbon electrodes did not change significantly when the applied voltage was changed between 0.2 V and 1.2 V, suggesting that physisorption and/or chemisorption dominated over electrosorption. The adsorption capacity of the anion exchange resin/active carbon electrodes decreased significantly at a pH of 1.5 because at low pH, cationic VO\textsuperscript{3+} is more prevalent than the anionic vanadium species that react with the resin.

2.10 Zinc
Zinc is essential for many enzymes, but in high enough levels it can cause health problems including impairment of the immune system, vomiting, and anemia.\textsuperscript{83, 153} Zinc contamination is prevalent in various parts of China due to zinc smelting activity.\textsuperscript{154} To prevent the precipitation of Zn(OH)\textsubscript{2}, Zn removal through electrosorptive means is generally carried out in acidic solutions.\textsuperscript{153}

2.10.1 Activated Carbon Electrodes
AC from a wide variety of sources, including petroleum coke, coconut shell, and phenolic resin have been used in the electrosorptive removal of Zn (Table 10).\textsuperscript{87, 91} About 40% of Zn from a 100 mg/L solution was removed onto AC cloth after 1000 s under a potential of 1.2 V.\textsuperscript{155} AC fiber electrodes showed a Zn\textsuperscript{2+} uptake of 122.6 mg/g from a 500 mg/L Zn\textsuperscript{2+} solution with a potential of 1.2 V.\textsuperscript{87} Powdered banana peels treated with sulfuric acids were found to have a maximum adsorption capacity of ~3.4 mg/g.\textsuperscript{156} Beyond AC, other forms of carbon such as a CNT/carbon nanofiber composite and N-doped graphene nanosheets have also been used as electrode materials in removing Zn\textsuperscript{2+}.\textsuperscript{70, 99}

processes. Mercury can be removed via electrosorptive processes, but this has not been extensively studied. Instead, mercury has been effectively removed via electrochemical alloy formation on platinum electrodes. While not extensively studied, non-metal environmental contaminants such as selenium can be removed via electrosorption. The man-made element technetium, mainly long-lived radioactive isotope Tc-99, has been introduced into the environment in increasing amounts due to the operation of nuclear fuel facilities and nuclear weapon testing. Technetium-99 is of concern because it has a long half-life and, similar to many other heavy metals, it has high environmental mobility. Because Tc predominately exists as the oxyanion perrhenate TcO$_4^-$, it can also be removed via electrosorption.

3. Concluding Remarks and Research Directions
As presented in this review, there is a large and growing body of work investigating heavy metal removal using capacitive deionization and electrosorption. However, it can be noticed that there lacks, across the various sources, a unified or standard approach to studying electrode materials for heavy metal electrosorption. The traditional metrics that quantify electrosorption performance, adsorption uptake and percent removal, are not truly intensive; they are highly dependent upon the experimental variables like the initial concentration of ions, the volume of water used, and the electrode mass used. As a result, it can be misleading to directly compare adsorption uptake and percent removal between different studies. It may be more useful to directly compare Langmuir isotherm equilibrium constants, which fully define adsorption capacity as a function of equilibrium ion concentration. Using the Langmuir model constants would account for variations in some of the experimental parameters between different studies. While many studies already report adsorption model constants, not all of them do. However, even this Langmuir descriptor cannot account for performance differences across different water matrices where different competing ions can take up adsorption capacity. Also, the Langmuir model is not always a suitable model for irregular surfaces such as AC electrode surfaces. When comparing results between different studies, it is recommended that readers be aware of these shortcomings and take note of experimental parameters such as competing ion or supporting electrolyte concentration and pH.

In the interest of developing selective electrode materials, we suggest the inclusion of relative separation factors for studies that investigate selective materials for heavy metal electrosorption. The separation factor between two ions A and B, typically denoted as $\alpha$, is defined as:

$$\alpha_{A,B} = \left( \frac{N_{A,ads}/N_{B,ads}}{N_{A,l}/N_{B,l}} \right)$$

(1)

Where the N’s indicate molar quantities and subscripts refer to A and B adsorbed (ads) or in the liquid phase (l). When multiple ions are present in solution, they compete for surface sites in reactions such as:

$$A + B_{ads} \rightleftharpoons k_+ A_{ads} + B$$

(2)

The separation factor, by definition, is exactly the equilibrium constant of this reaction:

$$K_{eq} = \frac{[A_{ads}][B]}{[A][B_{ads}]} = \frac{k_+}{k_-} = \alpha$$

(3)

As a result, separation factors directly quantify the free energy difference of equation (2) and could be used to quantify differences in affinity of the electrode with different heavy metal ions and other competing ions.

3.1 Ion selectivity
Several factors govern ion selectivity including ion radius, ion charge, and an ion’s physicochemical affinity for the electrode. While ion selectivity is complex and system dependent, a rule of thumb is that ions of higher charge are preferentially removed over ions of lower charge and between ions of the same charge, ions with smaller hydrated radii are preferentially removed. Individual removal experiments of Cr$^{3+}$, Cd$^{2+}$, and Pb$^{2+}$ using AC cloth (ACC, FM70) showed the highest removal efficiency for Cr$^{3+}$ (52.48% for Cr$^{3+}$, 42.62% for Pb$^{2+}$, 31.85% for Cd$^{2+}$) after 2 hours from 5 mM solutions at 1.2 V. It was noted that at open circuit (0 V), Cr$^{3+}$ and Pb$^{2+}$ were still significantly adsorbed (41.52% removal for Cr$^{3+}$, 29.59% for Pb$^{2+}$) while Cd$^{2+}$ was not (4.20% removal). These results suggest that Cr$^{3+}$ and Pb$^{2+}$ had some intrinsic affinity for the AC cloth and adsorbed much more quickly due to physical adsorption attractions. Between the three ions, Pb$^{2+}$ has the smallest hydrated radius, followed by Cd$^{2+}$, then Fe$^{3+}$. Between Pb$^{2+}$ and Cd$^{2+}$, Pb$^{2+}$ is preferentially adsorbed because it has a smaller ionic radius. Despite having the largest hydrated radius, Cr$^{3+}$ was preferentially adsorbed due to its higher charge. Nitrogen-
doped graphene nanosheets, used to remove 9 different divalent cations (Pb\textsuperscript{2+}, Cu\textsuperscript{2+}, Fe\textsuperscript{2+}, Cd\textsuperscript{2+}, Co\textsuperscript{2+}, Ni\textsuperscript{2+}, Zn\textsuperscript{2+}, Mg\textsuperscript{2+}, Ca\textsuperscript{2+}) showed the quickest removal rate for Fe\textsuperscript{2+} and the slowest removal rate for Cd\textsuperscript{2+}.\textsuperscript{99} This is consistent with the previously presented study. It was noted that Fe\textsuperscript{2+} was likely oxidized to Fe\textsuperscript{3+}, which allowed it to out compete all of the other divalent cations. Cd\textsuperscript{2+}, again, was least favorably adsorbed due to its larger hydrated radius. Electrosorption of Fe\textsuperscript{3+}, Cu\textsuperscript{2+}, Zn\textsuperscript{2+}, and Na\textsuperscript{+} using carbon nanotubes and carbon nanofibers (CNTs-CNFS) composite electrodes showed adsorption favoured Fe\textsuperscript{3+} > Cu\textsuperscript{2+} > Zn\textsuperscript{2+} > Na\textsuperscript{+}.\textsuperscript{70} Again, this order can be explained by ion charge and hydrated radius. Overall, Fe\textsuperscript{3+} was preferentially adsorbed due to its high charge and Cu\textsuperscript{2+} adsorption was favoured over Zn\textsuperscript{2+} adsorption due to Cu\textsuperscript{2+} having a smaller hydrated radius.

Heteroatom doping of carbon materials has been shown to increase selectivity and/or electrosorption capacity for heavy metal ions. Graphene aerogels doped with sulfur (SGAs) had a higher electrosorption capacity than graphene aerogels doped with nitrogen (NGAs).\textsuperscript{95} This was explained with the Hard-Soft-Acid-Base principle where sulfur, the softer heteroatom between sulfur and nitrogen, showed stronger interactions with soft heavy metal atoms. Not only does the identity of the heteroatom affect electrosorption, but the chemical environment of the heteroatom affects how it interacts with heavy metal ions. This was shown with graphene doped with nitrogen in two ways: the first forming more nitrogen with pyridinic character and the second forming more nitrogen with pyrrolic character. The pyridinic N-doped graphene showed greater affinity for hard ions (H\textsuperscript{+}, Na\textsuperscript{+}) while the pyrrolic N-doped character showed greater affinity for soft ions (Pb\textsuperscript{2+}).\textsuperscript{125}

New faradaic electrode materials have been shown to selectively capture heavy metal ions. Poly(vinylferrocene), a redox-active metallopolymer, has been shown to selectively capture chromium and arsenic oxyanions over perchlorate and chloride competing ions.\textsuperscript{140} When oxidized, the ferrocenium cations on the polymer act as adsorption sites and bind anions through charge transfer. Chromium and arsenic oxyanions were shown to bind strongly to poly(vinylferrocene) because these oxyanions are highly polarizable and willingly donate electron density toward the positive ferrocenium sites. Perchlorate and chloride were less polarizable and did not bind strongly to poly(vinylferrocene).

These studies have demonstrated the ability to tune ion selectivity through molecular modification and design. As the field of heavy metal electroosorption grows and differentiates itself from desalination work, we anticipate a greater focus on molecular design of selective electrosorbents and building an understanding for the mechanisms that govern ion selectivity.

3.2 Viability of Electrosorption and Capacitive Deionization for Heavy Metal Removal

Electrosorption and capacitive deionization have a bright future in applications for heavy metal capture. These processes are efficient for ion removal when ion concentrations are low, which is often the case for heavy metal contamination, and can be augmented with other ion removal techniques such as membrane processes.

Research on the commercial performance of CDI plants, especially when applied to heavy metal removal, is extremely limited.\textsuperscript{165} However, CDI has the potential to be a highly energy-efficient methods to remove heavy metal ions from water. For example, in applications other than heavy metal removal, such as desalination, CDI is projected to be more energy efficient than leading industrial technologies such as reverse osmosis for salt concentrations less than 60 mM.\textsuperscript{166} The minimum energy required by CDI to reduce the total dissolved solids (TDS) in water from 1000 mg/L to 10 mg/L has been estimated to be as low as 0.1 kWh/m\textsuperscript{3}. A bench-scale industrial-type process using a carbon aerogel electrode could achieve the same TDS reduction using 0.594 kWh/m\textsuperscript{3}, much lower than the 2.03 kWh/m\textsuperscript{3} required for electrodialysis reverse systems.\textsuperscript{28} Additionally, the large-scale production of electrode materials such as AC and carbon aerogels has already been shown to be viable.\textsuperscript{167} A key factor in the energy efficiency of CDI processes is the potential for energy recovery during the desorption stage. At low salt concentrations, energy recovery as high as 83% has been achieved in membrane CDI processes.\textsuperscript{165} While these studies regarding the energy required for large-scale CDI processes suggest that CDI and electrosorption may be viable alternatives to other ion removal processes, more detailed technoeconomic analysis is required to determine if electrosorption of heavy metals is viable at a large scale. The viability of a large-scale heavy metal electroosorption process will depend upon electrode capacity, ion selectivity, electrode regeneration and stability, and energy recovery.

3.3 Future Directions

A large fraction of the electrode materials covered in this review are porous carbon materials. These are great materials for electrosorption because they have high surface areas and they are inexpensive and widely available. However, heavy metal electrosorption research trends toward functionalizing carbon materials and designing new electrode materials to selectively target heavy metal ions in the presence of competing ions. Future electrosorption research is expected to shift towards heteroatom functionalization and more advanced Faradaic materials, including energy storage ion-intercalation and ion-binding platforms.\textsuperscript{21, 168} Rather than storing charge in an electric double layer, these materials store charge by intercalating ions within a crystalline matrix, or binding ions onto polymeric site, and can thus enhance both adsorption capacity and selectivity.

Thus, both Faradaic and non-Faradaic composite materials are expected to grow in interest for heavy metal removal. Finally, a trend which we also expect is the integration of different treatment steps for various ions through the design of novel materials, which can reduce competitive adsorption and maximize process efficiency.
