Optical and X-ray spectroscopy studies reveal the location and role of Fe³⁺ sites incorporated through direct synthesis in NH₂-MIL-125(Ti). Fe K-edge XAS analysis confirms its metal-oxo cluster node coordination while time-resolved optical and X-ray transient absorption studies disclose its role as an electron trap site, promoting long-lived photo-induced charge separation in the framework. Notably, XTA measurements show sustained electron reduction of the Fe sites into the microsecond time range. Comparison with an Fe-doped MOF generated through post-synthetic modification indicates that only the direct synthesis approach affords efficient Fe participation in the charge separated excited state.

Efficient photocatalysis for solar energy applications requires materials that exhibit long lived charge separation properties and reversible electron transfer behavior of the catalytic sites. Hybrid materials, such as metal-organic frameworks (MOFs), offer new opportunities in this field through their rich chemical and structural diversity that allows incorporating accessible catalytic sites and tailoring optoelectronic properties. MOFs are porous solid state networks composed of self-assembled metal ions or clusters connected through coordination bonds with organic linkers. 1 Photocatalytic behavior in MOFs can be promoted through inclusion of transition metal centers with multiple stable oxidation states and linker sites that can accommodate stable radical entities in the excited state. MIL-125 is a titanium-based MOF, containing octameric Ti-oxo clusters connected in three dimensions by terephthalate linkers. 2 The reversible Ti⁴⁺/Ti³⁺ redox conversion at the metal node sites within the framework is accessible through photo-induced linker-to-metal cluster charge transfer (LMCCT) but requires UV-wavelength light irradiation. Borrowing from the heteroatom doping strategies used in traditional inorganic semiconductors like TiO₂, 3 analogous modifications of MIL-125 and other Ti-based MOFs have been explored to tune the range of usable absorption wavelengths and photoredox properties without simultaneously introducing high rates of charge recombination.4 Introducing an amino group auxochrome to the terephthalate linker precursor for example, red shifts the LMCCT absorption band into the visible region for the modified MOF, NH₂-MIL-125(Ti). 5 This and other linker substituents tune the overall electronic structure of the MIL-125 framework, 4a,4c but without significantly impacting the unoccupied orbitals localized on the Ti-oxo nodal cluster and therefore the reductive potential of the photoexcited MOF. 4a,6 To modify these unoccupied frontier orbitals, the metal cluster composition should be adjusted as revealed by a recent theoretical investigation of NH₂-MIL-125(Ti) upon substitution of different heterometals into the Ti-oxo core. 7 Furthermore, possible experimental validation can be found in recent reports of Cu-incorporated NH₂-MIL-125(Ti) frameworks that demonstrated enhanced photocatalytic activity for CO₂ reduction compared to the parent NH₂-MIL-125(Ti) catalyst. 4b,4d Despite these promising first steps, the local coordination of the heterometal in the MOF cluster has not been experimentally confirmed nor has its direct participation in the photoinduced charge separated excited state tied to the photocatalytic reaction.

In this communication, the coordination environment and excited state contribution of a heterometal incorporated in NH₂-MIL-125(Ti) nodal cluster is definitively revealed for the first time. Specifically, we focus on an iron-doped version, NH₂-MIL-125(Ti,Fe) with targeted stoichiometry of one Fe³⁺ center per octameric cluster (Figure 1a) as a model system. Since doping TiO₂ with Fe was found to increase photoactivity by lowering the conduction band, and creating trap states that delays charge recombination, 8 we expected that upon population of the LMCCT state of NH₂-MIL-125(Ti,Fe), the photo-excited electron would analogously localize onto the Fe³⁺ sites, generating long-lived transient Fe²⁺ species.

X-ray absorption spectroscopy (XAS) is ideally suited for probing the Fe site coordination and electronic structure dynamics associated with the LMCCT state. X-ray transient absorption (XTA) measurements can track electronic structure changes induced by laser excitation and, because of its ele-
NH₂-MIL-125(Ti) was synthesized following literature procedures. NH₂-MIL-125(Ti,Fe) was generated using a modified LMCCT and subsequent charge separation.

As shown in Figure 1c and d, the NH₂-BDC linker, NH₂-metal-oxo clusters.

For the MOF systems, this band extends into the visible region needed to confirm the participation of the Fe sites in the photochemistry of both molecular8 and solid-state10 metal-based systems, including other Fe-containing MOFs.11 Here Fe K-edge XAS and XTA are used along with optical transient absorption (OTA) spectroscopy to confirm the location of the Fe sites and investigate the nature and dynamics of the transient absorption spectrum.

Nh₂-MIL-125(Ti) was synthesized following literature procedures.6 Nh₂-MIL-125(Ti,Fe) was generated using a modified direct synthesis method, where stoichiometric amounts of titanium (IV) tert-butoxide and iron (III) chloride precursors were combined with the 2-aminoterephthlic acid (NH₂-BDC) linkers under anhydrous DMF and methanol solvent conditions to achieve a target average doping level of about one Fe site per Ti-oxo cluster as confirmed by atomic absorption spectroscopy (see Supporting Information). Both MOF syntheses included cetyltrimethylammoniumbromide (CTMAB) surfactant to promote nanoparticle formation and suspension.

Nh₂-MIL-125(Ti,Fe) and several Fe references are depicted in Figure 2a, and b. The XANES pre-edge feature and edge shift is similar to those of Fe₂O₃ indicating comparable Fe°° octahedral speciation in the MOF devoid of metallic Fe, or residual FeCl₃ impurities. Comparisons with the reference XAFS spectra further verify the distinct Fe coordination environment in the framework. XAS also reveals how the Fe coordination in the MOF generated using this direct synthesis method diverges from that attempted through a transmetalation approach that involved soaking Nh₂-MIL-125(Ti) in FeCl₃ solution. The XANES pre-edge feature for that system indicates lower symmetry Fe coordination environment and the XAFS spectrum notably shows longer average first shell scattering path distances in the post synthetically doped MOF. Together, these XAS characteristics signify possible outer-cluster incorporation and/or residual FeCl₃ species trapped within the pores.

Quantitative coordination information is provided by fitting the Nh₂-MIL-125(Ti,Fe) XAFS spectrum (Figure 2c) using a model derived from the reported crystal structure of Nh₂-MIL-125(Ti) in which a titanium site is substituted with iron (Figure S3). As summarized in Table S1, the fit includes Fe-O scattering paths from a distorted octahedral coordination environment, as well as contributions from scattering paths beyond the first shell, including neighboring Ti sites within the node and the closest C sites of the surrounding linkers. The fit reveals longer average first shell Fe-O bond lengths compared to those of the Ti sites found in the parent MOF, which is expected given the typical range reported for these metals in other oxide forms.13 The expanded Fe-O coordination shell appears to be compensated by further changes to the Fe position relative to the neighboring Ti sites as evidenced by the Fe-Ti scattering path distances derived from the fit. To be clear, this XAFS analysis cannot rule out the possibility that some metal-oxo clusters

charge separated excited state and its metal-oxo node location.

To better understand how the iron is incorporated within the framework, steady state XAS measurements were conducted at the Fe K-edge. Both XANES and XAFS spectra of Nh₂-MIL-125(Ti,Fe) and several Fe references are depicted in Figure 2a, and b. The XANES pre-edge feature and edge shift is similar to those of Fe₂O₃ indicating comparable Fe°° octahedral speciation in the MOF devoid of metallic Fe, or residual FeCl₃ impurities. may contain more than one Fe site (or that some contain no Fe sites), but the fit beyond just the first coordination shell, together with the PXRD results, which show analogous, single phase structure for NH₂-MIL-125(Ti,Fe) and NH₂-MIL-125(Ti), provides strong evidence that Fe is indeed occupying octahedral sites in the octameric metal-oxo ring cluster.

Optical transient absorption characterization provides our first window into the nature and earliest time dynamics of the initial photoexcited state in these materials. Ultrafast OTA data for NH₂-MIL-125(Ti) NH₂-MIL-125(Ti,Fe), and the NH₂-BDC linker are shown in Figure 3 and the multiexponential fitting results for the kinetics are summarized in Table S2. The spectra of the linker exhibit a TA band that appears within the instrument response time, at λ_max=585 nm and subsists well beyond the experimentally available delay range with more than 80% of the signal remaining at 1 ns delay time. The spectra of NH₂-MIL-125(Ti,Fe) show a similar transient absorption feature that overlaps with an additional broad, unstructured TA band that extends throughout the visible and NIR wavelength range while those of the all-Ti version of this MOF are dominated by this broad redshifted band only. Based on the spectral signatures identified through reported spectro-electrochemical characterization of aminoterephthalate dimethyl ester and a TiO₃ tert-butoxide molecular cluster complex, the sharper transient absorption band around 585 nm is assigned to the formation of the NH₂-BDC radical cation with the hole localized on the amine and the broad absorption band observed throughout the visible and NIR range is attributed to the radical anion of the metal-oxo cluster node. Comparing the OTA kinetics reveals that both NH₂-MIL-125(Ti) and NH₂-MIL-125(Ti,Fe) exhibit shorter sub-ns lifetime components. However, while the signal appears to have completely decayed for NH₂-MIL-125(Ti) by 1 ns, nearly half of the TA signal remained at this delay time for NH₂-MIL-125(Ti,Fe), indicating contribution from substantially longer lifetime components. Notably, our findings for NH₂-MIL-125(Ti) diverge from previous OTA characterization of this MOF, which reported nearly identical OTA data (spectra and kinetics) to those we found for the NH₂-BDC linker. While we observed similar results for NH₂-MIL-125(Ti) samples after initial washing, we found that further purification was needed to fully remove residual linker that was presumably trapped within the porous structure. Extensive washing and careful isolation of suspended MOF nanoparticles consistently yielded the OTA data presented here. The appearance of the TA feature around 585 nm in NH₂-MIL-125(Ti,Fe), that is mostly absent from the NH₂-MIL-125(Ti) TA spectra may indicate a more localized hole on the linker associated with a charge separated state and the larger contribution of longer lifetime components may be attributed to the Fe dopant acting as a “trap” site and serving to delay electron-hole recombination.

Fe K-edge XTA was used to further elucidate the nature and dynamics of the charge separated state, particularly the role of the Fe dopant, following LMCCT excitation in NH₂-MIL-125(Ti,Fe). Figure 4a highlights the changes observed between the XTA spectra collected using the X-ray bunch synchronized with the laser pump pulse at nominal time zero delay (“laser on”) and those collected using pre-time zero X-ray bunches (“laser off”). A significant edge shift to lower energy is observed for the “laser on” spectrum and the derivative like feature in the corresponding difference spectrum with peak maximum aligned with the rising edge. This edge shift clearly indicates transient reduction of the iron sites upon population of the LMCCT excited state. Notably, no signal changes were observed in XTA spectra collected for the Fe-doped MOF generated using the post-synthetic modification
approach. This comparison further supports the novelty of the direct synthesis approach for incorporating the Fe sites within the metal-oxo nodes and suggests that this method of heterometal doping is required for efficient Fe participation in the CS excited state.

Time scans collected by monitoring the XTA difference signal maximum at 7.123 keV for NH$_2$-MIL-125(Ti,Fe) produce the kinetic trace, shown in the inset of Figure 4a. Successive X-ray bunches, after the synchronized one, were simultaneously collected during these time scans to produce the extended kinetics depicted in Figure 4b. Kinetic fitting, as summarized in Table S3, reveals a faster 2.3 ns lifetime component, and at least two longer-lived components. While too few data points on the microsecond time scale are available to obtain these longer lifetimes, the signal clearly extends into the 10’s of microseconds time range. This exceptionally long lifetime indicates that excitation into the LMCCT band of NH$_2$-MIL-125(Ti,Fe) promotes localization of an electron that remains on the Fe site, preventing charge recombination. The different lifetime components may be associated with the probability of the charge recombination event, as it depends on the position of the electron-trapping Fe site relative to the linker containing the hole. Future studies aim to test this theory by assessing the Fe site, preventing charge recombination. The different
