DOI:00.0000/xxxxxxxxx

The double-helical topology of DNA molecules observed at room temperature in the absence of any external loads can be disrupted by increasing the bath temperature or by applying tensile forces, leading to spontaneous strand separation known as DNA melting. Here, continuum mechanics of a 2D birod is combined with statistical mechanics to formulate a unified framework for studying both thermal melting and tensile force induced melting of double-stranded molecules: it predicts the variation of melting temperature with tensile load, provides a mechanics-based understanding of the cooperativity observed in melting transitions, and reveals an interplay between solution electrostatics and micromechanical deformations of DNA which manifests itself as an increase in the melting temperature with increasing ion concentration. This novel predictive framework sheds light on the micromechanical aspects of DNA melting and predicts trends that were observed experimentally or extracted phenomenologically using the Clayperon equation.

² 1 Introduction

Double-stranded DNA (dsDNA) consists of two helical sugar-3 phosphate backbones held together by complementary base pair-4 ing. DNA melting or DNA denaturation is the separation of ds-5 DNA into two single strands (ssDNA). The transition can be trig-6 gered by increasing the bath temperature or by applying tensile 7 loads on the molecule. DNA melting is important in various bi-8 ological processes such as DNA replication and DNA transcrip-9 tion, and ultimately impacts gene-expression. The first step in 10 gene expression is the transcription of DNA to mRNA-it initi-11 ates via localized DNA melting caused by the protein RNA poly-12 merase¹. DNA replication and repair also initiate via localized 13 melting caused by DNA helicases^{2,3}. Several experimental tech-14 niques⁴⁻⁶ such as fluorescence microscopy, optical tweezers and 15 calorimetry provide evidence for in-vitro DNA melting-both ther-16 mal and force-induced^{7,8}. The transition of a single base pair 17 from bound to melted state is impacted by neighbouring base 18 pairs; if the neighbouring base pairs are melted, it has higher 19 probability of melting-this property is known as cooperativity. Ex-20 periments suggest that the dsDNA→ssDNA transition is strongly 21 cooperative^{9,10}. This property manifests itself as a sudden melt-22 ing transition resembling a first-order phase transition; the in-23 crease in inter-strand distance with temperature is sudden as op-24 25 posed to a mere incremental linear thermal expansion. We illustrate this point in the appendix by a simple model which embodies 26

the basic concept and outcomes of cooperativity.

Here, a double-stranded elastic rod model¹¹ is combined 28 with statistical mechanics¹² to capture various characteristics 29 of the melting transition. Although thermal melting of DNA 30 has been studied extensively for some decades now 13,14, a 31 mechanics-based model which simultaneously captures both 32 temperature-driven and tensile force-driven melting is yet to 33 be explored. The novelty in the model proposed here is three 34 fold: i) it goes beyond the existing Clausius-Clayperon based 35 phenomenological description and provides a unified statisticalmechanics based framework to explain both temperature-driven 37 and force-driven strand separation, ii) the model provides a 38 mechanical basis for cooperativity in the melting transition 39 by relating it to the bending resistance of the base pairs, and 40 iii) the model accounts for the dependence of the electrostatic 41 energy on the mircromechanical deformation of the birod which 42 ultimately leads to familiar trends in melting temperature versus 43 ion concentration and melting force versus ion concentration. 44

The sharp transition characterizing cooperative DNA melting 46 depends on various factors⁴ such as i) the internal base pair sequence: DNA fragments with higher GC content have higher 48 melting temperatures, ii) the tensile force: experimental evidence 49 suggests that the melting temperature decreases as the tensile 50 load increases, and iii) the ion concentration: the melting force 51 and melting temperature both increase with an increase in ion 52 concentration. Most attempts to model the melting transition 53 rely on using the Clausius-Clayperon equation to get empirical re-54 lations between the various quantities of interest such as melting 55 temperature versus tensile force or over-stretching force versus 56

135

the ion concentration et cetera^{8,15}. Since these empirical models 57 interface directly with the experimental data, they have superior 58 predictive capabilities and produce experimentally verifiable 59 predictions. However, this approach abstracts out the underlying mechanics and biochemistry driving the process. To circumvent 61 this drawback to some extent, several statistical mechanics based 62 models^{16,17} have been proposed which begin by positing an 63 energy functional that reproduces the characteristics of the coop-64 erative melting transition observed experimentally. The detailed 65 description sheds light on the underlying mechanism-cooperative 66 H-bond disruption-and enables one to clearly discern the effect 67 of various parameters such as, the cooperativity parameter and 68 asymmetric interactions, on the melting transition. However, 69 the inherent analytical intractability involved in evaluating the 70 path integrals central to these approaches limits their application 71 to relatively simple energy functionals. Molecular dynamics 72 simulations have also been used to study several problems 73 related to the melting transition, unzipping of DNA, and other 74 structural transformations in DNA^{18,19}. The interaction poten-75 tials are available for various chemical bonds in DNA thereby 76 permitting a very detailed description of the structure, shape, 77 and chemistry crucial to the problem. The results from the 78 simulations agree well with the experimental data, but they 79 entail a large computational burden. 80

Here, DNA is modelled as a 2D elastic birod. The elastic birod 82 model has previously been used to study phenomenon such 83 as allosteric interactions in DNA^{20,21} where the double-helical 84 geometry and micromechanical deformations of base pairs are 85 important. In this paper, DNA is assumed to be a straight ladder-like birod for analytical tractability. We import ideas from 87 statistical mechanics to show that the average distance between 88 the two strands in a birod increases steeply in an unbounded 89 fashion as the temperature reaches the melting point. A similar 90 effect can be achieved by increasing the tensile load while 91 keeping the temperature constant. A non-quadratic interaction 92 between the strands is essential to achieve this effect. For a 93 quadratic interaction, the equipartition theorem implies that the 94 average change in the distance between the two strands is zero 95 even as the temperature increases. Despite simplifying assump-96 tions, the model presented here captures the key mechanical 97 characteristics of DNA such as the entropic elasticity of long 98 oligomers, the cooperative melting transition, and the effect of 99 tensile force and ion concentration on melting. 100

101

81

¹⁰² The paper is organised as follows:

- Kinematics and energetics: The section discusses the devel opment of the model by highlighting key kinematic variables
 and their respective elastic constitutive relations.
- 2. Force-extension curve: The force-extension curve for a birod is computed and the key features of the entropic elasticity exhibited by the birod are demonstrated.
- 3. *Melting transition:* Temperature-driven and tensile force-driven melting transitions are discussed in detail. The focus

is to quantitatively describe these transitions within the presented framework, and examine the interplay between the tensile force and the melting temperature.

- 4. *Effect of cooperativity:* The bending resistance of the base pairs is identified to be the cause of cooperativity observed in the melting transition. By varying only one parameter in the model, we are able to capture the experimental trends in both force- and temperature-driven melting transitions.
- 5. *Effect of ion concentration* The section uses the Poisson-Boltzmann formalism to compute the electrostatic energy for the birod. By accounting for the dependence of the electrostatic energy on the outer-radius of DNA in the birod model, it can be shown that both the melting temperature and melting force increase with ion concentration.

The model improves upon the existing statistical mechanics approaches ^{16,17} by computing (as opposed to positing) the energy functional from the kinematic description of the birod, so that the key features – temperature-induced melting, force-induced melting and the cooperativity – emerge naturally.

2 Kinematics and energetics

We closely follow the birod framework presented in Moakher and Maddocks¹¹. We envision a straight ladder-like birod acted upon by an external force F as shown in fig.1. We assume small displacements throughout and confine ourselves to deformations in a plane. The two outer strands and the web connecting them are

Fig. 1 (a) Cartoon of a straight birod acted upon by identical forces on both the strands. The two strands are referred to as \pm strands. (b) Attachment of base pairs to the outer-strands. The short web representing the base pairs is welded to the outer strands.

elastic. The birod lies in $\mathbf{e}_1 - \mathbf{e}_2$ plane as shown in fig.1. The axial coordinate x is along \mathbf{e}_1 : $x \in [0, L]$ where L is the contour length. The reference configuration of the \pm outer strands denoted by \mathbf{r}_0^{\pm} is 139

$$\mathbf{r}_0^{\pm} = x\mathbf{e}_1 \pm a\mathbf{e}_2. \tag{1}$$

For a general 2-D deformation in the $\mathbf{e}_1 - \mathbf{e}_2$ plane, the deformed configuration of the strands is:

$$\mathbf{r}^{\pm} = \int_0^x (1+\zeta) \mathbf{d}_1 \, dx \pm (a+v) \mathbf{d}_2 \pm u \mathbf{d}_1, \tag{2}$$

where, $\mathbf{d}_1 = \cos\theta \mathbf{e}_1 + \sin\theta \mathbf{e}_2$, and $\mathbf{d}_2 = -\sin\theta \mathbf{e}_1 + \cos\theta \mathbf{e}_2$. 142 Note that $\mathbf{r} = \frac{\mathbf{r}^+ + \mathbf{r}^-}{2} = \int_0^x (1+\zeta) \mathbf{d}_1 \, dx$ denotes the deformed 143

190

200

centerline (global/macro displacement), while u and v denote 144 the displacements of the \pm strands relative to the centerline 145 (micro-displacements). They are related to the shearing and 146 stretching of the base pairs, respectively. In the entire paper, 147 we use a small strain assumption²² together with a moderate 148 rotation approximation 23,24 which means: θ^2 , v, $\theta_x \sim O(\varepsilon)$, which 149 implies $\cos \theta \sim 1 - \frac{\theta^2}{2}$ and $\sin \theta \sim \theta$. Any terms higher than $O(\varepsilon)$ 150 such as $v\theta_x$, $\theta\theta_x$, and $u\theta_x$ are neglected. The moderate rotation 151 hypothesis is applicable when the applied force is large, which is 152 indeed the case for DNA melting. 153

154

161

Heretofore, ()_x denotes derivative w.r.t x. Hence, $\mathbf{d}_{1x} = \theta_x \mathbf{d}_2$ and $\mathbf{d}_{2x} = -\theta_x \mathbf{d}_1$. Now, $\mathbf{r}_x^{\pm} = (1 + \zeta \pm u_x \mp a\theta_x)\mathbf{d}_1 \pm v_x \mathbf{d}_2$. We assume that the outer strands are inextensible which implies $|\mathbf{r}_x^{\pm}| = 1$. Hence, $\zeta \pm u_x \mp a\theta_x = 0$, which gives $\zeta = 0$, and $u_x = a\theta_x$. Or, $u = a\theta$. For the \pm strands, the tangent is $\mathbf{t}^{\pm} = \mathbf{d}_1 \pm v_x \mathbf{d}_2$, so the curvature is $\kappa^{\pm} = |\mathbf{t}_x^{\pm}| = \theta_x \pm v_{xx}$, respectively.

We now focus on the stretching, shearing and bending of the 162 base pairs. Here we assume that the small rods-representing the 163 base pairs-are welded to the outer long strands-representing the 164 phosphate backbones (fig.1(b)). Such an arrangement permits 165 the base pairs to exert both force and bending moment on the 166 strands. For DNA, the base pairs are stacked on top of each other 167 in a regular fashion, the space constraints and repulsion from 168 neighbouring bases in this crowded environment prevents the 169 bases from moving freely. A simplistic approach is to penalize the 170 relative motions of the bases via elastic bending and stretching 171 potentials, as done in this paper. This approach is similar to sev-172 eral previous studies²⁵⁻²⁸ where elasticity of base pairs has been 173 shown to play an important role. A detailed study regarding the 174 actual nature of the bonds is beyond the scope of the current work 175 176

As mentioned, the tangent vectors to the \pm strands are $\mathbf{t}^{\pm} = \mathbf{d}_1 \pm v_x \mathbf{d}_2$, hence the respective normal vectors are $\mathbf{n}^{\pm} = \mp v_x \mathbf{d}_1 + \mathbf{d}_2$. The rotation matrices $\mathbf{Q}^{\pm} = [\mathbf{t}^{\pm}, \mathbf{n}^{\pm}]$ can be decomposed as,

$$\mathbf{Q}^{\pm} = \begin{bmatrix} \cos\theta & -\sin\theta\\ \sin\theta & \cos\theta \end{bmatrix} \begin{bmatrix} 1 & \mp v_x\\ \pm v_x & 1 \end{bmatrix}.$$
 (3)

180 $\mathbf{Z} = \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix}$ depends on the deformation of the center- **181** line, while $\begin{bmatrix} 1 & \mp v_x \\ \pm v_x & 1 \end{bmatrix}$ depends only on the displacements of **182** the strands about the center-line. \mathbf{Q}^{\pm} can be used to compute the **183** micro-rotation tensor \mathbf{P} and macro-rotation tensor \mathbf{Q} (for details **184** see¹¹).

$$\mathbf{P}^{2} = \mathbf{Q}^{+} \mathbf{Q}^{-T} = \mathbf{Z} \left(\mathbf{I}_{2 \times 2} + \begin{bmatrix} 0 & -2\nu_{x} \\ 2\nu_{x} & 0 \end{bmatrix} \right) \mathbf{Z}^{T},$$
(4)

where $I_{2\times 2}$ is the identity tensor. Hence,

$$\mathbf{P} = \begin{bmatrix} 1 & -\nu_x \\ \nu_x & 1 \end{bmatrix},\tag{5}$$

and

$$\mathbf{Q} = \mathbf{P}\mathbf{Q}^{-} = \mathbf{Z} = \mathbf{d}_1 \otimes \mathbf{e}_1 + \mathbf{d}_2 \otimes \mathbf{e}_2.$$
 (6)

The stretching and shearing of the base pairs are proportional to $\xi = \mathbf{Q}^T \mathbf{w} - \mathbf{w}_0^{-11}$, where $\mathbf{w} = \frac{\mathbf{r}^+ - \mathbf{r}^-}{2}$, $\mathbf{w}_0 = \frac{\mathbf{r}_0^+ - \mathbf{r}_0^-}{2}$, and $\xi = a\theta\mathbf{e}_1 + v\mathbf{e}_2$.

Just like the stretching and shearing of the base pairs can 191 be computed from the difference in the displacements of the 192 outer-strands, the bending of the base pairs can be computed 193 from the rotations on the + and - strand. In fact, the moment 194 transferred by the web is proportional to the Gibbs vector of 195 the micro-rotation tensor P^{11} . In a 2D-setting, this moment 196 can be easily computed; since the directions of the rotations are 197 fixed, there is no twisting, and bending is proportional to v_x (see 198 fig.1(b) for details). 199

We now discuss the energy associated with each kinematic de-201 viation from the reference configuration. The bending energy 202 per unit length for the outer \pm strands is $E_s = \frac{EI}{2}(\kappa^{+2} + \kappa^{-2}) =$ 203 $EI(\theta_x^2 + v_{xx}^2)$ where EI is the bending resistance of the outer 204 strands. The energy associated with shearing the base pairs is 205 $E_{sh} = L_1 a^2 \theta^2$, where L_1 is the associated elastic constant. For the 206 stretching of the base pairs, we use an assymetric energy profile 207 of the form $f(x) = (e^{-\lambda x} - 1)^2$ known as the Morse potential. 208 This approach is meant to penalize the steric hindrance between 209 the two strands and has been previously used in literature^{16,17}. 210 Hence, the energy per unit length required to stretch the base 211 pairs $E_{st} = L_2(e^{-\lambda v} - 1)^2$. The energy associated with the bending 212 of the base pairs is $E_{bb} = H_1 v_x^2$. Altogether, the energy of the birod 213 is. 214

$$E_{e} = \int_{0}^{L} dx \left(E_{b} + E_{sh} + E_{st} + E_{bb} \right)$$

$$= \int_{0}^{L} dx \left(EI(\theta_{x}^{2} + v_{xx}^{2}) + L_{1}a^{2}\theta^{2} + L_{2}(e^{-\lambda v} - 1)^{2} + H_{1}v_{x}^{2} \right),$$
(7)

where both *v* and θ are functions of *x*. This energy will enter the 215 statistical mechanical model for the birod. We use the following 216 values of elastic constants: $EI = 0.15 \ pNnm^2$, $L_1 = 80 \ pN/nm^2$, 217 $L_2 = 1280 \ pN/nm^2$, $H_1 = 0.33 \ pN$, $a = 1 \ nm$, and $\lambda = 0.5 \text{\AA}^{-1}$. 218 The values of the constants were chosen in a way that melting 219 temperature of DNA at zero tensile force is approximately 75°C 220 (fig. 3 of the main text). Also, the constants were tweaked to 221 get the variation of the melting temperature with tensile force in 222 the right region (fig.5(c) of the main text). One could use other 223 criteria as well, such as the persistence length of B-DNA at room 224 temperature and stretch moduli of B-DNA et cetera. However, the 225 experimental values are for a 3D helical DNA which might not 226 give the correct melting temperature in our model. Since, the fo-227 cus here is on the melting of DNA, we chose to stick to the former. 228

²³⁰ 3 Force-extension curve for a thermally fluctuating²³¹ birod

In this section, we discuss the force-displacement curve for the ladder-like birod. We already have the elastic energy of the birod given by eqn. 7. Next we need to compute the work done by external force F distributed equally on both strands. For + strand, the displacement at the free end is,

$$\Delta^{+} = \int_{0}^{L} (\mathbf{t}^{+} \cdot \mathbf{e}_{1} - 1) dx$$

$$= \int_{0}^{L} (\cos \theta - \sin \theta \, v_{x} - 1) dx = \int_{0}^{L} (-\frac{\theta^{2}}{2} - \theta v_{x}) dx.$$
(8)

Similarly, for – strand, $\Delta^{-} = \int_{0}^{L} \mathbf{t}^{-} \cdot \mathbf{e}_{1} dx - L$, which upon simplification yields $\Delta^{-} = \int_{0}^{L} (-\frac{\theta^{2}}{2} + \theta v_{x}) dx$. Summing up the individual contributions from the strands yields,

$$W_e = \frac{F}{2}(\Delta^+ + \Delta^-) = F \int_0^L -\frac{\theta^2}{2} \, dx.$$
 (9)

240 Hence, the potential energy functional of the birod is,

$$E = E_e - W_e = E(\theta(x), v(x))$$

= $\int_0^L dx \left(EI(\theta_x^2 + v_{xx}^2) + L_1 a^2 \theta^2 + L_2 (e^{-\lambda v} - 1)^2 + H_1 v_x^2 + \frac{F}{2} \theta^2 \right).$ (10)

241 The average end-to-end extension is,

$$y = \int_0^L \cos \theta \, dx \approx \int_0^L \left(1 - \frac{\theta^2}{2}\right) \, dx,\tag{11}$$

where we assumed that θ is a moderate rotation. The average end-to-end distance $\langle y \rangle$ is,

$$\langle y \rangle = L - \langle \int_0^L \frac{\theta^2}{2} dx \rangle,$$
 (12)

where $\langle \rangle$ denotes the ensemble average. We need to evaluate the partition function to compute the above average. The partition function of the birod is a path-integral given as follows,

$$Z = \int \mathscr{D}\boldsymbol{\theta}(x) \int \mathscr{D}\boldsymbol{v}(x) \, \exp(-\frac{E(\boldsymbol{\theta}(x), \boldsymbol{v}(x))}{k_B T}). \tag{13}$$

The above partition function Z can be multiplicatively decomposed: $Z = Z_{\nu}Z_{\theta}$, where Z_{ν} comprises the path-integral over the function v(x), while Z_{θ} over $\theta(x)$.

$$Z_{\theta} = \int \mathscr{D}\theta(x) \, \exp(-\frac{E_{\theta}}{k_B T}), \quad \text{and} \quad Z_{\nu} = \int \mathscr{D}\nu(x) \, \exp(-\frac{E_{\nu}}{k_B T}),$$
(14)

250 where,

$$E_{\theta} = \int_{0}^{L} dx \left(EI\theta_{x}^{2} + (L_{1}a^{2} + \frac{F}{2})\theta^{2} \right), \text{ and}$$

$$E_{v} = \int_{0}^{L} dx \left(EIv_{xx}^{2} + L_{2}(e^{-\lambda v} - 1)^{2} + H_{1}v_{x}^{2} \right).$$
(15)

Now,

$$\langle \int_0^L \frac{\theta^2}{2} \, dx \rangle = \frac{1}{Z} \int \mathscr{D}\theta(x) \int \mathscr{D}v(x) \, \left(\int_0^L \frac{\theta^2}{2} \, dx \right) \, \exp\left(-\frac{E(\theta(x), v(x))}{k_B T}\right). \tag{16}$$

Summing over all the admissible functions v(x) and canceling the 252 common factor Z_v yields, 253

$$\langle \int_0^L \frac{\theta^2}{2} \, dx \rangle = \frac{1}{Z_\theta} \int \mathscr{D}\theta(x) \Big(\int_0^L \frac{\theta^2}{2} \, dx \Big) \, \exp(-\frac{E_\theta(\theta(x))}{k_B T}), \quad (17)$$

The above expression can be evaluated by differentiating the logarithm of the partition function. 255

$$\langle \int_0^L \frac{\theta^2}{2} dx \rangle = -k_B T \frac{\partial \ln Z_\theta}{\partial F},$$
 (18)

which gives,

$$\langle y \rangle = L + k_B T \frac{\partial \ln Z_{\theta}}{\partial F}.$$
 (19)

Notice that the remaining functional is only a function of $\theta(x)$. 258 Following Su and Purohit²⁹, we discretize the domain $x \in [0,L]$ 259 into *n*-segments $(x_i, x_{i+1}]$, where $0 \le i \le n$, such that $\theta_x = \frac{\theta_i - \theta_{i-1}}{\delta}$ 260 where $\delta = \frac{L}{n}$. For the energy functional E_{θ} , the integral over the domain can be expressed as a quadratic expression in terms of 262 θ_i 's: 263

$$E_{\theta}^{n} = \sum_{i=0}^{n} \delta \left[EI \left(\frac{\theta_{i} - \theta_{i-1}}{\delta} \right)^{2} + L_{1} a^{2} \theta_{i}^{2} + \frac{F}{2} \theta_{i}^{2} \right]$$

$$= \theta \cdot \left[\frac{EI}{\delta} \mathbf{A} + \delta (L_{1} a^{2} + \frac{F}{2} \mathbf{I}) \right] \theta = \theta \cdot \mathbf{K}_{\theta} \theta,$$
(20)

where $\theta = [\theta_0, \theta_2, ..., \theta_n]^T$, **I** is an identity matrix, and **A** is another matrix as follows: 265

$$\mathbf{A}_{n \times n} = \begin{bmatrix} 1 & -1 & 0 & 0 & 0 & \dots & 0 \\ -1 & 2 & -1 & 0 & 0 & \dots & 0 \\ 0 & -1 & 2 & -1 & 0 & \dots & 0 \\ \vdots & & \ddots & & & \vdots \\ 0 & 0 & \dots & 0 & -1 & 2 & -1 \\ 0 & 0 & \dots & 0 & 0 & -1 & 1 \end{bmatrix}$$

Notice that \mathbf{K}_{θ} is a constant depending only on the elastic properties of the birod. This enables us to transform the path integral $_{267}$ Z_{θ} into a *n*-dimensional integral as follows: $_{268}$

$$Z_{\theta}^{n} = \int \mathscr{D}\theta(x) \exp(-\frac{E_{\theta}}{k_{B}T})$$

$$= \prod_{i=0}^{n} \left(\int_{-\pi}^{\pi} d\theta_{i} \right) \exp(-\frac{E_{\theta}^{n}}{k_{B}T}) = \int d\theta \, \exp(-\frac{\theta \cdot \mathbf{K}_{\theta}\theta}{k_{B}T}).$$
(21)

To evaluate the above integral conveniently, we change the limits from $-\pi,\pi$ to $-\infty,\infty$, which transforms the above expression into a *n*-dimensional Gaussian integral which can be computed 270

4 | Journal Name, [year], [vol.], 1–13

272 analytically as follows,

$$Z_{\theta}^{n} = \int_{(-\infty,\infty)^{n+1}} d\theta \, \exp(-\frac{\theta \cdot \mathbf{K}_{\theta} \theta}{k_{B}T}) = \pi^{n/2} \frac{(k_{B}T)^{n/2}}{\sqrt{\det \mathbf{K}_{\theta}}}.$$
 (22)

273 Substituting it in eqn. 19 gives,

$$\langle y \rangle = L + k_B T \frac{\partial \ln Z_{\theta}}{\partial F} = L - \frac{k_B T}{2} \frac{\partial \log \det \mathbf{K}_{\theta}}{\partial F}.$$
 (23)

An analytical derivation based on Fourier integral techniques ^{30,31} 274 is presented in appendix A2. The plot for the force-extension re-275 lation for the birod is shown in fig.2(a). At large forces (F > 20276 pN), it can be approximated by a WLC model³² with persistence 277 length 100 nm. As shown in fig. 2 (b), the end-to-end distance 278 decreases with an increase in temperature-a typical entropic elas-279 ticity characteristic. The decrease in the variance of the transverse 280 displacement ($w(x) = \int_0^x \sin \theta \, dx$) with an increase in tensile force 281 shown in fig. 2 (c) is yet another signature of entropic elasticity³¹ 282 (For analytical expression of $\langle w^2 \rangle$ see Purohit *et al.*³¹). 283

284 4 Thermal melting

At room temperature under zero tensile loads, the DNA molecule 285 exhibits a double-helical structure. However, as the temperature 286 increases and reaches the melting temperature, the complemen-287 tary base pairing is disrupted and the two strands spontaneously 288 disintegrate into two single strands. This melting transition is 289 highly cooperative³³, and the temperature at which it occurs is 290 referred to as the melting temperature. Aside from the sequence 291 dependence, the melting temperature is also highly sensitive to 292 the tensile loads and the ionic concentration of the solution^{8,15}. 293 Experimental evidence suggests that the melting temperature in-294 creases with the increase in ionic concentration and drops with 295 the increase in tensile loads on the molecule. Thermodynamics 296 based studies relying on Clausius-Clayperon equation have led to 297 various empirical relations among these quantities^{8,15,33}. To pro-298 vide a rough idea about the melting temperature, for the Na⁺ con-299 centration of 0.075 M, the melting temperature is approximately 300 $75^{\circ}C^{34}$ (see reference for the exact bp-sequence). Using the birod 301 model, we seek a relation between the average inter-strand dis-302 tance $\langle v \rangle$ and the temperature T. In this section, we assume no 303 tensile forces on the molecule, hence the elastic potential energy 304 functional E is, 305

$$E = \int_0^L dx \left(EI(\theta_x^2 + v_{xx}^2) + L_1 a^2 \theta^2 + L_2 (e^{-\lambda v} - 1)^2 + H_1 v_x^2 \right).$$
(24)

The average distance between the strands can be computed as follows:

$$\langle v \rangle = \frac{1}{Z} \int \mathscr{D}\theta(x) \int \mathscr{D}v(x) \left(\frac{1}{L} \int_0^L v(x) dx\right) \exp\left(-\frac{E(\theta(x), v(x))}{k_B T}\right),$$
(25)

where the expression for the energy E and the partition function Z can be found in eqn. 7 and eqn.13, respectively. As done in the previous section, we discretize the domain into *n*-elements which transforms the integrals into sums and the path integrals

into *n*-dimensional integrals:

$$E^{n} = \sum_{i=0}^{n} \delta \left[EI \left(\frac{(\theta_{i} - \theta_{i-1})^{2}}{\delta^{2}} + \frac{(v_{i+1} - 2v_{i} + v_{i-1})^{2}}{\delta^{4}} \right) + L_{1}a^{2}\theta_{i}^{2} + L_{2}(e^{-\lambda v_{i}} - 1)^{2} + H_{1}\frac{(v_{i} - v_{i-1})^{2}}{\delta^{2}} \right],$$

$$Z^{n} = \prod_{i=0}^{n} \left(\int_{(-\infty,\infty)^{2}} d\theta_{i} dv_{i} \right) \exp(-\frac{E^{n}}{k_{B}T}),$$

$$\langle v \rangle = \frac{1}{Z^{n}} \prod_{i=0}^{n} \left(\int_{(-\infty,\infty)^{2}} d\theta_{i} dv_{i} \right) \left(\frac{1}{n} \sum v_{i} \right) \exp(-\frac{E^{n}}{k_{B}T}).$$
(26)

In contrast to the last section where the discretization to-313 gether with quadratic energy functional enabled us to analytically 314 evaluate the partition function, the partition function above can 315 not be evaluated analytically because of the non-quadratic term 316 $(e^{-\lambda v_i} - 1)^2$. Hence, we use Monte-Carlo simulations to compute 317 $\langle v \rangle$ as a function of the bath temperature *T*. We use the Metropo-318 lis algorithm³⁵ to perform the MC simulations (for more details 319 see appendix A3). The results are recorded in fig. 3. Each individ-320 ual marker \times is one simulation. We find that as the temperature 321 increases the average inter-strand distance increases strongly in 322 a nonlinear fashion, hence can not be alluded to as mere ther-323 mal expansion. The asymmetry in the nonlinear interaction term 324 $((e^{-\lambda v}-1)^2)$ is crucial for achieving this effect; if quadratic in-325 teraction is used the average inter-strand distance is zero even as 326 the temperature increases. 327

We fit a continuous spline to $\langle v \rangle$ vs *T* data to indicate the trend. 329 In reference configuration, the average inter-strand distance is 330 10 Å. We assume that the melting of a single discrete unit as 331 shown in fig.3 occurs at 50% strain, *i.e.* when the unit is stretched 332 to 15Å or when $v_i = 5$ Å. The oligomer is considered melted when 333 more than 50% of the units are melted. We plot the fraction of 334 melted DNA $f_m = \frac{1}{n} \sum_{i=1}^n \mathbb{I}(v_i > 5\text{\AA})$, where $\mathbb{I}(v_i > 5\text{\AA}) = 1$ if $v_i > 5\text{\AA}$ 335 and 0 otherwise, as a function of temperature T in the inset. The 336 data for f_m vs T is fit using a logistic function $g(x) = \frac{1}{1+e^{-a_0(x-a_1)}}$ 337 to read off the melting temperature from the plot: $T_m \approx 360$ K, 338 which is quite close to the results for dsDNA documented in liter-339 ature^{8,15,34}. The melted ($v_i > 5$ Å) and unmelted ($v_i < 5$ Å) units 340 and the corresponding v_i are shown for T = 250K and T = 425K. 341 The contiguous strands of unmelted DNA and melted DNA ob-342 served below and above the melting temperature, respectively, 343 indicate cooperative interactions. Although the melting criterion 344 $v_i = 5$ Å was deliberately chosen so that the results from the model 345 agree with the experimental data, our main message is that the 346 birod model has the essential ingredients to account for the coop-347 erative melting transition and these crucial factors emerge natu-348 rally from the kinematic description of the birod. 349

5 Tensile force-induced melting

In this section, the effect of tensile force on the melting temperature is explored. We consider the birod shown in fig.4. Here, we apply the force on one strand as previous studies³⁶ have indicated. As before, we need to compute the potential energy of 354

328

373

Fig. 2 (a) For large force, force-extension curve of the birod is similar to a WLC model with a persistence length of $l_p = 100$ nm. (b) Effect of increase in temperature on the force-extension curve is in agreement with expectations of entropic elasticity. (c) $\langle w^2 \rangle$ vs x for various values of tensile force *F*. The boundary conditions for (a) and (b) are fixed-free while for (c) it is hinged-hinged. The values of parameters in the energy functional are $EI = 0.15 \ pNnm^2$, $L_1 = 80 \ pN/nm^2$, $L_2 = 1280 \ pN/nm^2$, $H_1 = 0.33 \ pN$, $a = 1 \ nm$, and $\lambda = 0.5\text{\AA}^{-1}$. For these calculations L = 200 nm and n = 300.

Fig. 3 (a) $\langle v \rangle$ vs *T* curve. Each green × marker is $\langle v \rangle$ computed from an individual MC simulation at that temperature, while the solid green line is a smoothed univariate spline curve plotted to indicate the trend. The inset shows the corresponding data for the melted fraction f_{m} , which is fit using a logistic function to compute the melting temperature ($T_m = 360$ K). (b) v_i and $I(v_i > 5\text{Å})$ vs i ($1 \le i \le n$) at T = 425 K. Red \circ and blue \circ markers denote the melted ($v_i > 5\text{Å}$) and unmelted ($v_i < 5\text{Å}$) discrete units at T = 250 K. The corresponding v_i are also shown; here the solid black line shows $v_i = 5\text{\AA}$ for reference. (c) v_i and $I(v_i > 5\text{\AA})$ at T = 425 K. The data in (b) and (c) are computed at the end of N = 1000000 MC steps. We observe contiguous strands of unmelted DNA below the melting temperature and melted DNA above the melting temperature, indicating cooperative interactions. Further details on MC simulations are given in appendix A3.

the birod in this configuration. The elastic energy of the birod is available in eqn.7. The work done by external force F is,

$$W_e = F \int_0^L dx \; (\mathbf{t}^- . \mathbf{e}_1 - 1). \tag{27}$$

Now, $\mathbf{t}^- = \mathbf{d}_1 - v_x \mathbf{d}_2$, hence $\mathbf{t}^- \cdot \mathbf{e}_1 = \cos \theta + v_x \sin \theta \approx 1 - \theta^2 / 2 + v_x \theta$. This implies,

$$W_e = F \int_0^L dx \; (-\frac{\theta^2}{2} + v_x \theta). \tag{28}$$

Fig. 4 The birod cartoon for studying DNA melting. Note that the force is applied only on one strand.

The elastic potential energy *E* is,

$$E = E_e - W_e$$

= $\int_0^L dx \left(EI(\theta_x^2 + v_{xx}^2) + (L_1 a^2 + \frac{F}{2})\theta^2 + L_2(e^{-\lambda v} - 1)^2 + H_1 v_x^2 - F v_x \theta \right).$ (29)

The term $Fv_{r}\theta$ is responsible for coupling the force F and the inter-strand distance v. Now for a given $\theta(x)$, the probability 361 of observing a configuration with interstand distance v(x) at 362 force F is $e^{Fv_x\theta/k_BT}$ times the probability of observing the same 363 configuration at F = 0. Granted, as the force F increases the 364 birod straightens out and θ decreases as can be inferred from 365 fig.2(b). However, for high forces (> 15 pN), the DNA molecule 366 with a persistence length 50 nm is mostly straight. In other 367 words, the $\theta(x)$ does not change much as the force increases 368 from 15 pN to 40 pN, however this makes the higher values of 369 v(x) much more likely. Based upon this qualitative argument we 370 expect that the melting temperature should decrease with an 371 increase in tensile load F. 372

The $\langle v \rangle$ vs *T* curves are presented in fig.5(a) for various tensile forces *F*, and we indeed observe that for a given temperature, the inter-strand separation increases with increasing tensile loads. We use the same criteria for computing the melting temperature

427

 T_m as in the previous section: the temperature at which the 378 fraction of melted DNA f_m exceeds 0.5. We fit the f_m vs T data 379 using a logistic function $g(x) = \frac{1}{1+e^{-a_0(x-a_1)}}$ as done previously to get the melting temperature T_m for various values of external 380 381 load F. We find that T_m decreases with an increase in F as shown 382 in fig.5(c). We use the experimental data from Zhang et al^4 to 383 conclude that the trend is correct. The slope of the line depends 384 on the elastic constants of the birod and for the values chosen 385 here a quantitative match is also achieved. 386

Fig.5(d) shows that at a constant temperature (T = 300 K), the 388 average inter-strand distance $\langle v \rangle$ increases with an increase in 389 tensile load F indicating force-induced melting. We fit the sim-390 ulation data using a smooth spline to highlight the trend. The 391 corresponding melted fraction f_m vs tensile load F is plotted in 392 the inset. The logistic function fitted to the data reveals that at 393 F = 40 pN $f_m = 0.5$ *i.e.* DNA has melted. The critical force at 394 which the DNA melts is sometimes referred to as overstretching 395 force¹⁵. Experimental data shows that this force driven melting 396 transition occurs at $F = 60 \text{ pN}^{7,37}$ (for exact details regarding the 397 pH, sequence dependence and salt concentration see references), 398 hence the value predicted by our model is in the correct region. 399 Note that we modelled DNA using a straight ladder-like birod in-400 stead of a helical one, and we restricted the formulation to planar 401 deformations-these assumptions could be causing this deviation. 402 403

6 Effect of cooperativity parameter

The structural transition from dsDNA->ssDNA is known to be 405 highly cooperative³³. The cooperativity exerts a strong influence 406 on the mechanical behavior such as determining the sharp-407 ness of the force-extension curves and influences the melting 408 temperature and overstretching force. One phenomenological 409 approach accounting for cooperativity comes from authors' 410 previous work³⁸ in which interfacial energy among various 411 phases of DNA makes the transition among them cooperative. 412 Yet, another approach is to postulate an energy functional which 413 includes terms proportional to the gradient of the inter-strand 414 distance^{16,17}. The motivation for such approaches comes from 415 Cahn-Hilliard formulation³⁹ widely used to study nucleation 416 and spoinodal decompositions in phase field modelling, where 417 the phase boundaries are energetically penalized using a term 418 proportional to the square of the gradient of the order parameter 419 $(\sim (\nabla \phi)^2)$. A similar idea for penalizing the gradients is also used 420 in the Landau-Ginzburg approach¹² to study superfluidity and 421 superconductivity transitions. In the birod formulation presented 422 here, the gradient terms proportional to v_x^2 emerge from the 423 bending rigidity of the base pairs which imparts cooperativity 424 to the model. We demonstrate the effects and outcomes of 425 cooperativity using a simple model in appendix A1. 426

We plot the fraction of melted DNA f_m versus the temperature *T* and tensile load *F* in fig. 6(a) and (b), respectively. As the bending resistance of base pairs (cooperativity parameter) H_1 increases, the melting temperature and overstretching force both increase. Experimental evidence documented in Zhang *et al*⁴ shows that as the GC content of the molecule increases, so does 433 the overstretching force and melting temperature. Higher values 434 of H_1 represent higher GC content since GC base pairs consist of 3 435 hydrogen bonds compared to 2 hydrogen bonds in AT base pairs 436 and are consequently stiffer. Higher GC content can have other ef-437 fects such as increasing the constants L_1 and L_2 as well; we deal 438 with this issue in appendix A4. In case of force-driven melting, 439 the transition becomes sharper too. This is demonstrated by fit-440 ting the logistic function $g(x) = \frac{1}{1+e^{-a_0(x-a_1)}}$ to f_m vs F transitions 441 and observing that the parameter a_0 which quantifies the width of 442 the transition increases monotonically with H_1 . The phenomeno-443 logical evidence for the sharpening can be found in authors' pre-444 vious work³⁸ in which higher interfacial energies representing 445 higher cooperativity parameters (therefore higher H_1) correspond 446 to sharper transitions. 447

7 Effect of ion concentration

Both force-induced and temperature-induced melting transitions 449 are sensitive to the ion concentration of the solution. Here, the 450 effect of changes of ion concentration on these melting transi-451 tions is explored. The phosphate backbone of DNA is negatively 452 charged, hence the positive ions in the solution cluster around 453 it. This stabilizes the double-stranded form of DNA. Therefore, 454 the melting temperature and melting force should increase with 455 an increase in ion concentration, as suggested by experimental 456 evidence⁴. Empirical relations based on the Clausius-Clayperon 457 equation connecting the melting force and melting temperature 458 to the ion concentration have been proposed^{8,40}. In this sec-459 tion we account for the effect of electrostatic interactions on the 460 melting temperature and melting force by means of a Poisson-461 Boltzmanm equation based polyelectrolyte model of DNA⁴¹. 462

448

We use a highly simplified 1D Poisson-Boltzman equation to 463 describe the electrostatics. For a detailed description refer Frank-464 Kamenetskii et al.⁴¹. The purpose of what follows is to compute 465 the electrostatic energy of the rod in a configuration described 466 by $\theta(x)$, v(x) and clearly highlight the underlying assumptions. 467 To compute the electrostatic energy, we assume that the DNA 468 molecule is almost straight *i.e.* the effect of $\theta(x)$ is negligible-a 469 complete description of electrostatics for bent DNA is beyond the 470 scope of the current study. Secondly, we assume that the radius 471 of the DNA molecule in a configuration described by v(x) is $a + v_a$, 472 where $v_a = \frac{1}{L} \int_0^L v(x) dx$. This assumption transforms the 2D PDE 473 into a 1D ODE. We consider only monovalent ions such as K^+ and 474 Na^+ . Within the scope of these assumptions, the boundary value 475 problem for the electrostatic potential U(y) can be written as, 476

$$\frac{d^2w}{dy^2} = \chi^2 \sinh(w),$$

$$w'(a+v_a) = \frac{2q}{a+v_a}, \quad w(R) \to 0 \quad \text{as} \quad R \to \infty.$$
(30)

Here, y is the coordinate perpendicular to x in fig.1, $w = \frac{eU}{k_BT}$ is 477 the nondimensional potential, e is the electronic charge, and a + 478 v_a is the average radius of the DNA helix. The dimensionless 479 charge $q = \frac{l_B}{b}$, where $l_B = \frac{e^2}{Dk_BT}$ is the Bjerrum's length, b is the 480 length of the cylinder containing negative charge e, ε_0 is vacuum 481

Fig. 5 (a) Average inter-strand distance $\langle v \rangle$ vs temperature *T* curves for different values of tensile force *F*. Here each marker × denotes one MC simulation and the solid lines are smooth splines being fit to the MC simulation data to indicate the trend. (b) Fraction of melted DNA f_m vs temperature *T* for different tensile loads. The MC simulation data is fitted using a logistic function to compute the melting temperature. (c) Melting temperature T_m vs tensile force *F* as computed from fig. (b). The experimental data is from⁴. (d) Average inter-strand distance $\langle v \rangle$ vs tensile force *F* (×) at 300 K fitted using a smooth spline (solid line). The inset shows the corresponding melted fraction f_m (×) fitted using a logistic function (solid line). *F* \approx 40 pN when $f_m = 0.5$.

Fig. 6 (a) Effect of the cooperativity parameter H_1 on temperature driven transition. Here $H_0 = 0.33 pN$ (b) Effect of the cooperativity parameter H_1 on force driven transition. The simulation data represented by marker \times is fit using the logistic function $g(x) = \frac{1}{1+e^{-a_0(x-a_1)}}$. Increasing the bending resistance of the base pairs leads to an increase in melting temperature and increases in the overstretching force. It also sharpens the force-driven transitions shown by the increasing values of a_0 as H_1 increases. The units of a_0 are K^{-1} in (a) and pN^{-1} in (b).

permittivity, and *D* is the dielectric constant of the solvent. c_0 is the concentration of monovalent ions, and $\chi^2 = \frac{2c_0e^2}{Dc_0k_BT}$. The associated electrostatic energy E^{el} per unit length is obtained by incrementally charging the backbone from 0 to q^{41} :

$$e^{el}(c_0, a + v_a) = -2k_BT \int_0^1 dt \ w(tq).$$
(31)

Note that the boundary condition on the average radius of the DNA backbone couples the electrostatic energy to the mechanical deformation of the birod. Hence, total energy per unit length $e(\theta(x), v(x))$ is the sum of the elastic (eqn.29) and electrostatic energy (eqn.31):

$$e(\theta(x), v(x)) = EI(\theta_x^2 + v_{xx}^2) + (L_1a^2 + \frac{F}{2})\theta^2 + L_2(e^{-\lambda v} - 1)^2 + H_1v_x^2 - Fv_x\theta + e^{el}$$
(32)

Having set this up, we wish to compute effect of the ion concentration on the melting temperature and melting force. There is only one parameter in the entire electrostatic formulation: q. We choose q = 0.05 for the computations. We start by examining the effect of ion concentration on thermal melting. The fraction of melted DNA f_m versus the temperature T is computed for 496 various concentrations $c_0 = 0.018 \text{mol/L}$ to 0.15 mol/L. The simulation results (\times) plotted in fig.7 (a) are fitted using a logistic 498 function $f(x) = \frac{1}{1+e^{-a_0(x-a_1)}}$. The melting temperature is reached 499 when $f_m \ge 0.5$. The simulations indicate that melting tempera-500 ture T_m increases as the concentration c_0 increases as shown in 501 fig.7(b). Next, we consider force-induced melting. The simula-502 tion data \times and the respective logistic fits are shown in fig.7(c). 503 We find that the melting force increases as the concentration in-504 creases, see fig.7(d). Previous works such as^{8,40} have used ther-505 modynamic analysis based on the Clausius-Clayperon equation 506 together with experimental data to analyse the effect of con-507 centration on thermal and force-induced melting and have re-508 ported similar results-the melting force and temperature increase 509 with increasing ion concentration. In the analysis presented here 510 the effect of ion concentration emerges from the coupling be-511 tween the micromechanical deformations of the birod v(x) and 512 the Poisson-Boltzman electrostatic model of DNA. Although, we 513 were able to account for the effect of electrostatics using an ele-514 mentary Poisson-Boltzmann model, there are several drawbacks: 515 i) the assumption that the rod is straight can not be true at force 516 F = 0, ii) the Poisson-Boltzmann model works only for weak ionic 517

concentrations at $T << T_m$, iii) eqn.30 assumes that the positive ions are a non-interacting Boltzmann gas which is not true in the vicinity of DNA helix where ion-ion correlations must be considered and iv) eqn.30 neglects the effect of divalent ions such as Mg⁺² and Ca⁺². For a detailed discussion, we refer the reader to the existing literature on solution electrostatics^{41,42}.

524 8 Conclusion

The theory of elastic birods is deployed to study temperature 525 driven and tensile force driven melting transitions in DNA. The 526 paper begins by discussing how the birod model embodies typi-527 cal characteristics of entropic elasticity. Next, the model is used 528 to study temperature induced DNA melting. The average inter-529 strand distance is found to increase monotonically with tempera-530 ture in a nonlinear unbounded fashion. The nonlinear asymmet-531 ric interaction between the strands is crucial to correctly model 532 the melting transition; for a linear-elastic interaction, leading to 533 a quadratic energy functional, the average increase in the inter-534 strand distance is zero-independent of changes in temperature. 535 Next, the model is used to study the effect of tensile force on the 536 melting temperature. The model predicts that the melting tem-537 perature decreases with increasing tensile force and by appropri-538 ately choosing the elastic parameters the prediction can be shown 539 to even match quantitatively with experimental data. The model 540 shows that at a fixed temperature an increase in tensile load also 541 leads to a melting transition and the critical force corresponding 542 to this transition predicted by the model is 40 pN whereas the ex-543 perimentally observed value is 60 pN. Various assumptions such 544 as using a straight birod to model double-helical DNA and restrict-545 ing to deformations on a plane could be responsible for the devi-546 ations. Furthermore, the birod model predicts that an increase in 547 GC content causes an increase in cooperativity leading to higher 548 melting temperature and melting forces. Finally, the interplay be-549 tween the statistical mechanics of the birod model together with 550 electrostatics from a Poisson-Boltzmann formulation accounts for 551 the increase in melting temperatures and melting force with ion 552 concentration. 553

This work demonstrates the ability of the elastic birod model to 554 accurately describe the mechanics of the DNA melting transition 555 in three ways: i) cooperativity in the melting transition, well 556 documented in literature^{4,8,16,17}, emerges naturally from the 557 elasticity of the base pairs, ii) the birod model can successfully 558 account for the intertwined effect of temperature and tensile 559 force on the melting transition, and iii) the model can be coupled 560 to the Poisson-Boltzmann formulation to account for the effect of 561 ion concentration. However, using a straight ladder-like birod to 562 model double-helical DNA is at best a first order approximation. 563 Such a model is unable to account for the 1.7 times stretching 564 during the melting transition accomplished by unwinding the 565 DNA helix. The derivation of the energy functional assumes 566 that the change in inter-strand distance is small, however this 567 is not true during the melting transition. Further study is 568 required to examine the effect of nonlinear coupling terms in the 569 model. In our formulation, the asymmetry in the applied force 570 is responsible for coupling the stretch (θ) with the interstrand 571 distance (v). As such, if equal force is applied on both ends 572

the stretch and inter-strand distance are decoupled. However, 573 this is because the DNA is modeled using a straight non-helical 574 birod. The authors' previous work (see sec. 4 in supplementary 575 materials²⁰) on double-helical birods shows how the stretch is 576 coupled to the inter-strand distance. Other crucial features of 577 DNA arising out of double-helical topology, such as twist-stretch 578 coupling, are absent in the straight ladder. Although, such a 579 model can explain the melting transition, it can not explain other 580 well documented^{4,43} transitions among various DNA phases 581 such B-DNA \rightarrow S-DNA and B-DNA \rightarrow P-DNA. Hence, a natural 582 extension of this work is to study the statistical mechanics of a 583 double-helical birod. 584

Appendix

A1: A simple model illustrating cooperativity

The concept and effects of cooperativity are demonstrated using 595 an elastic bar under a tensile load. The understanding derived 596 from this exercise helps us rationalize the observations reported 597 in the main text. Let the strain variable be v(x), hence the energy 598 functional of the bar under a tensile load is $E = \int_0^L dx \frac{v^2}{2} - F\Delta$, 599 where *L* is the contour length and Δ is the displacement at the 600 free end which can be expressed an an integral over the strain-601 $\Delta = \int_0^L v dx$. Now, we add a cooperativity term proportional to 602 v_x^2 . This is analogous to the surface energy term in the Allen-603 Cahn energy functional⁴⁴ and gradient term in Landau-Ginzburg 604 energy functional¹². In view of the above discussion, the energy 605 functional is, 606

$$E = \int_0^L dx \left(k \frac{v_x^2}{2} + \frac{v^2}{2} - Fv \right).$$
(33)

To get the $\langle v \rangle$ vs *F* curve for the bar, we have:

$$\langle v \rangle = \frac{1}{Z} \int \mathscr{D}v(x) \left(\frac{1}{L} \int_0^L v(x) dx\right) \exp\left(-\frac{E(v(x))}{k_B T}\right)$$
(34)

where $Z = \int \mathscr{D}v(x) \exp\left(-\frac{E(v(x))}{k_BT}\right)$ is the partition function. 609 Similarly, $\langle v \rangle$ vs *T* curves can also be obtained. 610

For simplicity, assume v(x) can either be relaxed or stretched: $v \in \{0,1\}$. Using the assumption, together with techniques used in the main text to numerically evaluate the partition function, we can compute the $\langle v \rangle$ vs *F* and $\langle v \rangle$ vs *T* curves. We focus on the effect of the cooperativity parameter *k* on the curves. The results are shown in fig.9. Fig.9 (a) shows that for a fixed temperature *T*, $\langle v \rangle$ decreases with an increase in the cooperativity parameter *k*, a

Fig. 8 An elastic bar undergoing a cooperative phase transition. Here v(x) is the strain variable.

similar trend is observed by increasing H_1 as shown in fig. 6(a) 619 of the main text. Regarding the force driven stretching, fig. 9(b) 620 shows that the width of the transition decreases with increasing 621 k: $\langle v \rangle$ vs F curve is almost linear for k = 0 while for k = 3.0 it is sig-622 moidal. This happens because for large cooperativity coefficient 623 k = 3.0, the units stretch simultaneously. To illustrate this point, 624 we present the stretched and unstretched units in fig.10 for val-625 ues of F below and above the melting force (F = 0.8, 1.2) using 626 cooperativity parameters k = 0 and k = 3.0. Similar sharpening 627 of transition is also observed by increasing H_1 in fig. 6(b) of the 628 main text. While in this simple model, the sharpening effect of co-629 operativity can be clearly seen as shown in fig.9(b), and fig.10, in 630 sec.6, we need to fit logistic curves to the MC simulation data to 631 quantify the sharpness. One point of departure between the two 632 models, is that the melting force increases with H_1 in fig. 6(b), on 633 the other hand it remains constant with increasing k in fig.9(b). 634 This is because in the main text, the work done by the external 635 force F is proportional to $Fv_x\theta$ and θ decreases as F increases, 636 consequently a larger force is required to melt the DNA. Based 637 upon these two similarities, we claim that H_1 is the cooperativity 638 parameter in the birod model in the main text. 639

A2: Analytical derivation of the force-extension curve

Here, we use Fourier integral techniques* to get an analytical expression for the force-extension curve ^{30,31}. The energy functional

in sec.3 is,

$$E = \int_{x} dx \Big(EI\theta_{x}^{2} + (\frac{F}{2} + L_{1}a^{2})\theta^{2} \Big).$$
(35)

Define,

$$\tilde{\theta}(q) = \frac{1}{2\pi} \int_{x} dx e^{-iqx} \theta(x)$$
 and $\theta(x) = \int_{q} dq e^{iqx} \theta(q)$. (36)

Noting that $\theta(x)^2 = \int_q \int_q dq_1 dq_2 e^{iq_1x} e^{-iq_2x} \tilde{\theta}(q_1) \tilde{\theta}(q_2)$ and $\int_x dx e^{i(q_1-q_2)x} = \delta_{q_1-q_2}$ into eqn.35, we get, 646

$$E = \int_{q} dq \left(EIq^{2} + (\frac{F}{2} + L_{1}a^{2}) \right) \tilde{\theta}^{2}.$$
 (37)

The above expression is quadratic in $\tilde{\theta}(q)$, hence, using equipartition one can evaluate 647

$$\langle \tilde{\theta}(q)^2 \rangle = \frac{k_B T}{E I q^2 + (\frac{F}{2} + L_1 a^2)}.$$
(38)

Parseval's identity $-\int_x \theta(x)^2 dx = \frac{1}{2\pi} \int_q \tilde{\theta}(q)^2 dq$ -together with the above equation yield the following expression for the average end-to-end distance:

$$< y > = L \Big(1 - \frac{k_B T}{8\sqrt{EI(F/2 + L_1 a^2)}} \Big).$$
 (39)

In the limit $F >> L_1 a^2$, the persistence length ℓ_p can be obtained by comparing the above expression to the WLC formula ($\langle y \rangle =$ $L - \frac{L}{2} \sqrt{\frac{k_B T}{F \ell_p}}$): $\ell_p = \frac{8EI}{k_B T}$. We verify this assumption by performing a simple calculation shown in fig.11. We can not do this calculation in sec. 3 to obtain the persistence length because the assumption $F >> L_1 a^2$ does not hold true, instead $F \sim L_1 a^2$. For a similar calculation of $\langle w^2(x) \rangle$, we direct the reader to Purohit *et al.*³¹.

A3: Details of MC simulations

The Monte Carlo simulations were performed using the Metropolis-Hastings algorithm³⁵. The DNA oligomer was modeled using a 2D birod fixed on one end and free on the other as shown in fig.1 of the main text. The length of oligomers was L = 40 nm and was discretized into n = 50 elements which gives 664

644

659

^{*} We thank a reviewer for this suggestion.

Fig. 9 Here × are the MC simulations while the solid lines are the smoothed spline being fit to the MC simulation data. (a) $\langle v \rangle$ vs *T* curves at F = 0, (b) $\langle v \rangle$ vs *F* curves at $k_B T = 0.5$.

Fig. 10 Here \circ denotes melted (= 1) or unmelted (= 0) state of *i*th unit at the end of the simulation (N = 100000 steps). We see a sudden transition from F = 0.8 to F = 1.2 when the cooperativity parameter is large (k = 3) in (c) and (d), respectively. On the other hand, we see smooth cross over when cooperativity parameter is low (k = 0). The values of k and F are given in the figure titles and $k_BT = 0.5$.

Fig. 11 Using $k_BT = 5$, $L_1 = 1$, EI = 1, and L = 10. Here \times data is obtained by discretizing the birod into n = 100 elements.

m = 100 dof: (θ_i, v_i) $0 \le i < n$. The total number of MC moves 665 was N = 1000000. At each move, a random degree of freedom 666 was chosen and the magnitude of perturbation was normally 667 distributed with mean 0 and standard deviation σ_v if the chosen 668 dof is v_i and σ_{θ} if the chosen dof is θ_i . The perturbed state is 669 accepted if $e^{-\frac{\Delta E}{k_B T}} > \alpha$, where ΔE is the energy difference between 670 the initial state and perturbed ($\Delta E = E_{perturbed} - E_{initial}$) and α is 671 a random floating point number uniformly distributed between 0 672 and 1 ($\alpha \sim U(0,1)$). We checked for the saturation of the energy 673 to ensure steady-state. The averages were computed on the last 674 N/2 states to discount the effects of burn-in process. The values of 675

 $\sigma_v \ (\approx 0.25 \text{ nm}) \text{ and } \sigma_{\theta} \ (\approx 0.2) \text{ were chosen such that the accepted}$ fraction of states lies between 20 – 40%. The melted fraction $f_m = \frac{1}{n} \sum_{i=1}^n \mathbb{I}(v_i > 5 \text{\AA})$, where $\mathbb{I}(v_i > 5 \text{\AA}) = 1$ if $v_i > 5 \text{\AA}$ and 0 otherwise. The DNA oligomer is considered melted when $f_m > 0.5$. For $f_m = 0.5$, we will always have $\langle v \rangle > 5 \text{\AA}$, since there will be melted links where $v_i > 10 \text{\AA}$, while for unmelted units $0 < v_i < 5 \text{\AA}$.

To access the impact of concentration, we need to compute the electrostatic free energy per unit length $E^{el}(a + v_a)$ as a function 684 of the average birod radius $a + v_a$. Note that v_a changes with each 685 MC move, and solving the ODE at each move is computationally expensive. To circumvent the issue, $E^{el}(a + v_a)$ was computed for 687 various values of $a + v_a$ and an exponential curve was fit to the 688 data. The fitted exponential curve was then used to compute E^{el} 689 in the MC simulations. For reference, we show E^{el} vs $a + v_a$ and 690 the fitted exponential curve for solution concentration $c_0 = 0.1 M$ 691 and T = 300K in fig.12. 692

A4: Effect of increasing GC content

In sec.6, the effect of the cooperativity parameter H_1 is discussed. It was observed that the melting temperature increases with increase in the value of H_1 , which in turn, is due to higher GC content. Higher GC content can have many other effects as well, such as higher stretch moduli L_1 and shear moduli L_2 , and the

Fig. 12 Plot of E^{el} vs $a + v_a$. The fitted exponential curve is used to compute E^{el} in MC simulations.

combined inter-play could be much more complex and beyond the scope of the paper. Since, the section focusses on the effect of cooperativity, we increased only H_1 and left L_1 and L_2 unchanged. Here we change all the parameters H_1 , L_1 and L_2 and show similar trends.

Fig. 13 Fraction of melted DNA f_m vs temperature T. Here, instead of changing only H_1 , we change all the parameters L_1, L_2 and H_1 . As the stiffness of the base pairs increases, the melting temperature T_m increases.
