## Abstract

The accumulation of ions at electrochemical interfaces governs the local chemical environment, which in turn determines the reaction pathways and rates of electrocatalytic processes, including electrochemical CO<sub>2</sub> reduction. Imidazolium cations have been shown to promote CO<sub>2</sub> reduction in nonaqueous electrolytes, where multiple mechanisms have been proposed for how imidazolium facilitates CO<sub>2</sub> reduction. However, many puzzles persist surrounding how imidazolium cations modify local chemical environments at electrochemical interfaces during CO<sub>2</sub> reduction. Dialkylimidazolium cations are multifunctional species that interact with adsorbed CO<sub>2</sub><sup>•-</sup> while also donating protons and forming carbene-mediated coordination complexes. In this work, we exploit the combination of independent proton donor [Et<sub>3</sub>NH]Cl and aprotic imidazolium cations, namely 1-ethyl-2,3-dimethylimidazolium ([EMMIm]<sup>+</sup>) and 1-ethyl-2,3,4,5-tetramethylimidazolium ([EM<sub>4</sub>Im]<sup>+</sup>) to further illuminate how imidazolium cations promote selective CO<sub>2</sub> electrochemical reduction. Our data indicates that the presence of an aromatic, planar delocalized charge region on imidazolium rings plays an essential role in stabilizing CO<sub>2</sub><sup>•-</sup> to promote electrocatalytic reduction. Kinetic and steady-state electrochemical analysis demonstrates that ring substituents of [EMMIm]<sup>+</sup> additionally tune local chemical environments to impact the rate and product distribution of CO<sub>2</sub> reduction by limiting the transport of proton donors. Further, we leverage surface-enhanced Raman scattering in the presence of a molecular probe of local electric fields to illustrate that the unique interface-tuning properties of [EMMIm]<sup>+</sup> stem from potential-driven assembly at cathodes. Our study highlights how imidazolium substituents can be tuned to regulate interfacial electrochemical environments and illustrates the importance of balancing CO<sub>2</sub><sup>•-</sup> stabilization and proton transport in sustaining steady-state electrochemical CO<sub>2</sub> reduction with high rate and selectivity. More broadly, our results suggest that aromatic cations promote electrochemical CO<sub>2</sub> reduction via a distinct “π<sup>+</sup>-anion” interaction that appears to be the electrostatic analog of the more commonly investigated “cation-π” interaction, which drives self-assembly in proteins and many other biological systems.

## Introduction

Electrochemical CO<sub>2</sub> reduction to chemicals and fuels could provide one avenue towards reducing carbon emissions associated with energy consumption and provide sustainable alternatives for fossil fuels in applications where decarbonization is difficult.<sup>1-3</sup> Electrochemical CO<sub>2</sub> reduction involves multiple proton-coupled electron transfers from electrodes to CO<sub>2</sub>, which usually yields a mixture of products. For instance, two-electron reduction of CO<sub>2</sub> can lead to both CO and formate (or formic acid), and more complex mixtures arise when more reduced products are generated, such as methane, methanol, and multi-

carbon products. The reduction of water always takes place in parallel, generating hydrogen as a competing side product.

The production of mixtures adds substantial energy and hardware costs for product separation.<sup>4, 5</sup> Therefore, it is desirable to develop methods to selectively direct CO<sub>2</sub> reduction towards targeted pathways, leading to controlled product selectivity. Current theories indicate that one critical aspect determining the reaction selectivity in CO<sub>2</sub> reduction is the relative adsorption energy of intermediates involved in the rate-determining step of different pathways, as the formation of more strongly adsorbed intermediates provides a larger thermodynamic driving force for the conversion.<sup>6, 7</sup>

As a result, various strategies are being developed to tune the adsorption energy of relevant intermediates. One major and conventional category of strategies is engineering electrode surface structures and electronic properties.<sup>3, 8-12</sup> For example, increasing the number of low-coordinating sites and grain boundaries on electrode surface,<sup>10, 13</sup> alloying of metal electrodes,<sup>11, 12</sup> and developing new heterogeneous catalytic materials with tunable active sites<sup>14-16</sup> are all demonstrated to increase the rate and selectivity of CO<sub>2</sub> reduction in aqueous solutions by tuning the adsorption energy of key intermediates.

Notably, electrochemical reactions occur at the electrode-electrolyte interface, meaning that electrodes comprise only one-half of an electrocatalytic interface. Indeed, there has been a resurgence in interest in studying how electrolyte properties also influence electrocatalytic reactions,<sup>17-19</sup> and many recent studies have shown that the properties of electrolytes can play at least an equally important role as electrodes in controlling reaction activity and selectivity. For instance, strategies such as increasing electrolyte pH,<sup>20-23</sup> changing the identity of supporting cations,<sup>24-26</sup> and decreasing water activity by increasing electrolyte concentration have been employed to enhance both the overall CO<sub>2</sub> conversion selectivity versus water reduction and the selective generation of multi-carbon products.<sup>27</sup>

While electrode engineering primarily influences reaction pathways through changes in adsorbate binding energies, electrolytes can influence the electrocatalytic process through multiple mechanisms, including changes in interfacial electric field gradients, alterations to proton transport, and modification of thermodynamic activity of both products and reactants.<sup>7, 24-29</sup> This multidimensional control enables distinct opportunities for studying and understanding electrochemical CO<sub>2</sub> reduction and promises to reveal new strategies for impacting other emerging electrocatalytic reactions, such as nitrate reduction and selective C-N bond formation.

Designing and modifying electrolytes based on ionic liquids is an especially promising strategy for electrolyte engineering. Ionic liquids are salts consisting of weakly coordinating organic cations and anions and are defined as exhibiting a melting point below 100°C for pure salt. Ionic liquids have highly tunable ion structures, high intrinsic conductivity, wide electrochemical windows, and can be designed to be proton donors or acceptors.<sup>30-33</sup> These properties provide many avenues for using ionic liquids as co-catalytic promoters in electrocatalysis. Further, ionic liquids are soluble in nonaqueous and aprotic solvents, circumventing competing water reduction and providing opportunities for detailed mechanistic study of proton-coupled electron transfers in electrochemical CO<sub>2</sub> reduction by introducing external proton donors.

To date, imidazolium-based ionic liquids have been the most widely used ionic liquid cation in electrochemical CO<sub>2</sub> reduction.<sup>34-38</sup> Electrolytes based on dialkylimidazolium ionic liquids, such as 1-ethyl-3-methylimidazolium tetrafluoroborate ([EMIm][BF<sub>4</sub>]), have been repeatedly demonstrated to significantly

lower the overpotential of electrochemical CO<sub>2</sub> reduction.<sup>38-41</sup> Many prior studies attributed the catalytic activity of dialkylimidazolium to the stabilization of adsorbed CO<sub>2</sub> by protons at C4/5 positions via hydrogen bonds.<sup>40-42</sup> Further, recent studies have proven that the proton at the C2 position of dialkylimidazolium can act as proton donors with high activity during electrochemical CO<sub>2</sub> reduction.<sup>43, 44</sup>

While there is a general agreement supporting the importance of both proton activity and transition state stabilization effects in dialkylimidazolium ionic liquids, the relative importance of these two functions in imidazolium ionic liquids remains unclear. Further, there are apparent discrepancies regarding if methylation of the C2 of imidazolium rings to block proton transfer promotes or inhibits CO<sub>2</sub> reduction.<sup>45</sup> For example, voltammetry studies of reaction kinetics suggest that ring methylation promotes selective CO<sub>2</sub> reduction by preventing the formation of a carbene-CO<sub>2</sub> adduct that inhibits CO<sub>2</sub> reduction.<sup>39, 40</sup> Yet, steady-state reaction rate studies suggest that C2 methylation instead inhibits CO<sub>2</sub> reduction through the formation of carbonate imidazolium precipitates that block electron transfer.<sup>38, 44</sup> Therefore, to accurately understand the function of and more efficiently use imidazolium in electrochemical CO<sub>2</sub> reduction, it is necessary to deconvolute their proton-donating and intermediate-stabilizing capabilities.

In this study, we systematically investigated the role of imidazolium without proton-donating capability in electrochemical CO<sub>2</sub> reduction by instead using an alternative organic proton donor as the proton source for CO<sub>2</sub> electroreduction. We compare the rate and product distribution of electrochemical CO<sub>2</sub> reduction on polycrystalline Ag disk electrodes in acetonitrile electrolytes of 1-ethyl-2,3-dimethylimidazolium tetrafluoroborate ([EMMIm][BF<sub>4</sub>]), 1-ethyl-2,3,4,5-tetramethylimidazolium tetrafluoroborate ([EM<sub>4</sub>Im][BF<sub>4</sub>]), and tetrabutylammonium tetrafluoroborate ([TBA][BF<sub>4</sub>]) without the imidazolium ring in the presence of the cationic proton donor triethylammonium chloride ([Et<sub>3</sub>NH]Cl).

We first demonstrate that the imidazolium ring is the core functional group involved in stabilizing CO<sub>2</sub> by comparing the selectivity and activity of electrochemical CO<sub>2</sub> reductions in [EMMIm][BF<sub>4</sub>], [EM<sub>4</sub>Im][BF<sub>4</sub>], and [TBA][BF<sub>4</sub>] electrolytes. Further, by combining kinetic analysis and studies of binary mixtures of imidazolium-based ionic liquids and [TBA][BF<sub>4</sub>], we unravel the role of C4/5-H in enhancing the surface activity of [EMMIm]<sup>+</sup> and suppressing proton transfer. Interestingly, we found that while such high surface activity of [EMMIm]<sup>+</sup> and suppressed proton transfer might contribute to higher instant electrochemical CO<sub>2</sub> reduction rate and selectivity towards CO, they largely compromise the steady-state CO<sub>2</sub> reduction rate, likely due to the rapid depletion of protons at electrochemical interfaces and the consequential discontinuation of proton-coupled electron transfer to CO<sub>2</sub>.

Taken together, our study provides a new understanding of the roles played by aprotic imidazolium cations in electrochemical CO<sub>2</sub> reduction. Our findings further highlight the necessity of balancing the suppression of proton reduction and the promotion of proton-coupled electron transfers in designing electrolytes for CO<sub>2</sub> upgrading systems.

## Results and Discussion

To date, several mechanisms have been proposed for how imidazolium-based ionic liquids promote CO<sub>2</sub> reduction. One dominating hypothesis is that the stabilization of one-electron reduced CO<sub>2</sub><sup>-•</sup> intermediate adsorbed on the electrode surface by protons at C4/5 positions (C4/5-H) through hydrogen bonds is critical for promoting selective CO<sub>2</sub> reduction.<sup>41, 42</sup> Alternatively, stabilizing electrochemical interactions between the positive aromatic ring and anionic CO<sub>2</sub><sup>-•</sup> has also been explored as a mechanism for how imidazolium cations promoted CO<sub>2</sub> reduction, but this mechanism has received less attention than

those invoking hydrogen bond interactions.<sup>46</sup> Interestingly, many studies of hydrogen bonding stabilization have focused on dialkylimidazolium cations, such as 1-ethyl-3-methyl imidazolium ([EMIm]<sup>+</sup>), with free protons at the C2 position (C2-H).<sup>40, 41</sup> While the C2-H has low acidity and was assumed to only participate in CO<sub>2</sub> reduction by forming hydrogen bonds with CO<sub>2</sub><sup>-</sup>, recent studies establish that C2-H of imidazolium can act as a proton donor during CO<sub>2</sub> reduction, which convolutes with the proposed roles of ring protons and the aromatic ring.<sup>43, 44</sup>

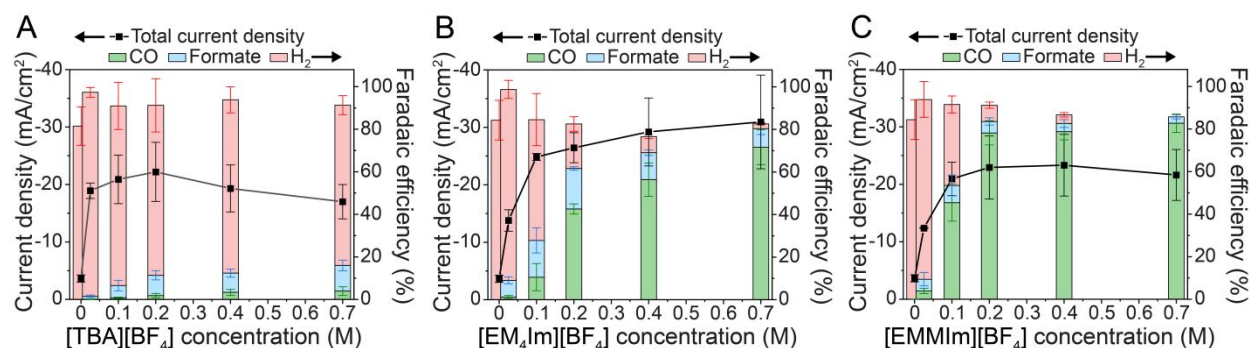

To unambiguously investigate the role of imidazolium cations in CO<sub>2</sub> reduction beyond donating C2-H as the proton source, we analyze the reaction rate and product distribution in acetonitrile electrolytes of aprotic imidazolium ionic liquids, namely [EM<sub>4</sub>Im][BF<sub>4</sub>] and [EMMIm][BF<sub>4</sub>], where protons are instead sourced from a tertiary ammonium cation. We selected these materials as [EM<sub>4</sub>Im]<sup>+</sup> only possesses the imidazolium aromatic ring with no ring protons, while [EMMIm]<sup>+</sup> has both the aromatic ring and C4/5-Hs. All ionic liquids exhibit good electrochemical stability (Fig. S2). We compare CO<sub>2</sub> reduction performance in these electrolytes with that from electrolyte [TBA][BF<sub>4</sub>], which has neither ring protons nor aromatic rings, thus serving as an “inert” control for [EM<sub>4</sub>Im]<sup>+</sup> and [EMMIm]<sup>+</sup>. Further, [Et<sub>3</sub>NH]Cl was added to all electrolytes as the independent proton donor to circumvent the extraction of proton from water absorbed by the electrolyte, which were demonstrated to release hydroxide that caused bicarbonate precipitation-induced passivation of electrochemical interfaces.<sup>38, 44, 47</sup>

**Figure 1.** Cyclic voltammetry in CO<sub>2</sub>-purged (A) [TBA][BF<sub>4</sub>], (B) [EM<sub>4</sub>Im][BF<sub>4</sub>], and (C) [EMMIm][BF<sub>4</sub>] electrolytes at concentrations ranging from 0.025 M to 0.7 M. All electrolytes contained 0.05 M [Et<sub>3</sub>NH]Cl as the proton donor and were scanned at 100 mV/s. At concentrations higher than 0.2 M, both [EM<sub>4</sub>Im][BF<sub>4</sub>] and [EMMIm][BF<sub>4</sub>] electrolytes give higher current density than [TBA][BF<sub>4</sub>] electrolytes at matching concentrations, while the highest current density was achieved in [EMMIm][BF<sub>4</sub>] electrolytes. These comparisons suggest the critical role of imidazolium ring structure in facilitating CO<sub>2</sub> reduction.

Figure 1 shows cyclic voltammetry measurements collected from electrolytes of the three ionic liquids at concentrations ranging from 0.025 M to 0.7 M on commercial polycrystalline Ag disk electrodes at a scan rate of 100 mV/s. The electrolytes were saturated with CO<sub>2</sub>, and 0.05 M [Et<sub>3</sub>NH]Cl was added to all electrolytes as the proton source. In [TBA][BF<sub>4</sub>] electrolytes, the maximum current density in each voltammetry scan shows a nonmonotonic dependence on the [TBA][BF<sub>4</sub>] concentration, and the highest current density was achieved at 0.2 M [TBA][BF<sub>4</sub>] (Fig. 1A). Further increasing the concentration over 0.2 M leads to decreases in current density, which is likely due to the smaller relative concentration of proton donor [Et<sub>3</sub>NH]<sup>+</sup> in view of the similar trend under Ar purging condition (Fig. S3).

In contrast to [TBA][BF<sub>4</sub>], the current density in [EM<sub>4</sub>Im][BF<sub>4</sub>] and [EMMIm][BF<sub>4</sub>] monotonically increases with increased ionic liquid concentration at corresponding applied potentials, indicating that the facilitation of CO<sub>2</sub> reduction brought by imidazolium cations surpasses effects brought by lower relative concentration of proton donors on the time scale of voltammetry scans. More interestingly, [EMMIm][BF<sub>4</sub>] electrolytes facilitate much higher current density than both [TBA][BF<sub>4</sub>] and [EM<sub>4</sub>Im][BF<sub>4</sub>] electrolytes at all concentrations above 0.1 M, which seems to align with prior studies concluding that [EMMIm]<sup>+</sup> is the most effective imidazolium cation to facilitate CO<sub>2</sub> reduction.

**Figure 2.** Total current density and product selectivity of electrochemical CO<sub>2</sub> reduction in (A) [TBA][BF<sub>4</sub>], (B) [EM<sub>4</sub>Im][BF<sub>4</sub>], and (C) [EMMIm][BF<sub>4</sub>] electrolytes at different concentrations with 0.05 M [Et<sub>3</sub>NH]Cl as the proton donor. For each trial, the potential was held at -2.5 V vs Ag/Ag<sup>+</sup> for 65 min under stirring (600 rpm) and CO<sub>2</sub> purging. Direct reduction of [Et<sub>3</sub>NH]<sup>+</sup> to H<sub>2</sub> is the dominant reaction pathway in [TBA][BF<sub>4</sub>] electrolytes. In contrast, both [EM<sub>4</sub>Im][BF<sub>4</sub>] and [EMMIm][BF<sub>4</sub>] electrolytes facilitate CO<sub>2</sub> reduction at concentrations higher than 0.1 M. [EM<sub>4</sub>Im][BF<sub>4</sub>] electrolytes exhibit higher steady-state total current density and thus overall CO<sub>2</sub> conversion rate by producing both formate and CO, while [EMMIm][BF<sub>4</sub>] electrolytes yield lower steady-state total current density but higher selectivity towards CO.

To further understand reaction pathways in electrolytes composed of the three ionic liquids, we conducted chronoamperometry and analyzed product distributions of CO<sub>2</sub> reduction in [TBA][BF<sub>4</sub>], [EM<sub>4</sub>Im][BF<sub>4</sub>], and [EMMIm][BF<sub>4</sub>] electrolytes at concentrations ranging from 0 to 0.7 M (Figure 2) at -2.5 V vs Ag/Ag<sup>+</sup>. For all three electrolytes, the total current density first increases with ionic liquid concentration and then tapers ([EM<sub>4</sub>Im][BF<sub>4</sub>]) or slightly decreases ([TBA][BF<sub>4</sub>] and [EMMIm][BF<sub>4</sub>]) after ionic liquid concentration exceeds 0.2 M, likely due to the decrease in the relative concentration of proton donor [Et<sub>3</sub>NH]<sup>+</sup>.

In [TBA][BF<sub>4</sub>] electrolytes at all concentrations, H<sub>2</sub> from the direct reduction of [Et<sub>3</sub>NH]<sup>+</sup> is the dominant product. In contrast, two-electron reduction of CO<sub>2</sub> to either formate or CO becomes the favorable pathway in both [EM<sub>4</sub>Im][BF<sub>4</sub>] and [EMMIm][BF<sub>4</sub>] electrolytes at concentrations higher than 0.1 M, with CO as the more dominant product. This result strongly indicates that the imidazolium ring, with or without ring protons, is the key functional group to stabilize CO<sub>2</sub> and facilitate CO<sub>2</sub> reduction.

Prior computational studies indicate that the +1 charge of tetraalkylammonium is mainly distributed on eight randomly orientated methylene hydrogens closest to the center N atom.<sup>48</sup> In comparison, the +1 charge of the imidazolium ring in [EMMIm]<sup>+</sup> is co-planarly distributed on C2, C4-H, and C5-H atoms, with the C2 atom carrying the highest partial positive charge.<sup>49, 50</sup> While rare theoretical studies are found for

[EM<sub>4</sub>Im]<sup>+</sup>, an analog to the comparison between [EMMIm]<sup>+</sup> and [EMIm]<sup>+</sup> that distributes positive charge on C2, C2-H, C4-H, and C5-H atoms suggests the distribution of the positive charge on C2, C4, and C5 atoms in [EM<sub>4</sub>Im]<sup>+</sup>, with the C2 atom still carrying the highest partial positive charge.<sup>49, 50</sup>

Additionally, spectroscopic studies and density functional theory of cation-anion interaction energetics and configurations of gas phase ion pair interactions and molecular dynamics simulations performed on neat [EMMIm]<sup>+</sup>-derived ionic liquids indicate that anions mainly interact with [EMMIm]<sup>+</sup> directly above or below the C2 position, which is the site of maximum partial positive charge density.<sup>50-52</sup> Thus, combined with our CO<sub>2</sub> reduction results, we conclude that the co-planar distribution of positive charge centered on the C2 position of imidazolium is the key to stabilizing adsorbed CO<sub>2</sub><sup>-</sup> and facilitating the reduction of CO<sub>2</sub> to CO. This “π<sup>+</sup>-anion interaction” between aromatic cations and adsorbed anionic species is an analog to the widely studied cation-π interaction that drives self-assembly of large molecules in biological systems and has important implications in designing electrolytes for electrocatalysis.<sup>53, 54</sup>

Despite the shared core ring structure, [EM<sub>4</sub>Im][BF<sub>4</sub>] and [EMMIm][BF<sub>4</sub>] electrolytes still behave distinctly in terms of rates and selectivity of electrochemical CO<sub>2</sub> reduction. [EMMIm][BF<sub>4</sub>] electrolytes almost exclusively facilitate the formation of CO. In contrast, [EM<sub>4</sub>Im][BF<sub>4</sub>] electrolytes produce a significant amount of formate in addition to CO. Meanwhile, [EM<sub>4</sub>Im][BF<sub>4</sub>] electrolytes yield a higher total current density compared to [EMMIm][BF<sub>4</sub>] electrolytes at corresponding concentrations, which in turn leads to higher overall CO<sub>2</sub> reduction current density, meaning the combined partial current density of formate and CO formation, in [EM<sub>4</sub>Im][BF<sub>4</sub>] electrolytes (Fig. S4).

Interestingly, the partial current density of formate in the electrolytes of all three ionic liquids always scales with that of H<sub>2</sub> and opposes that of CO (Fig. S2). This trend strongly suggests that the formation of H<sub>2</sub> and formate share the same intermediate, which is most likely surface-adsorbed H (H<sup>\*</sup>). Through bonding with either a proton or a CO<sub>2</sub> molecule from the electrolyte, H<sup>\*</sup> will lead to the formation of H<sub>2</sub> or formate, respectively, as proposed by prior studies.<sup>55, 56</sup> In contrast, surface adsorbed CO<sub>2</sub><sup>-</sup> leads to the formation of CO.

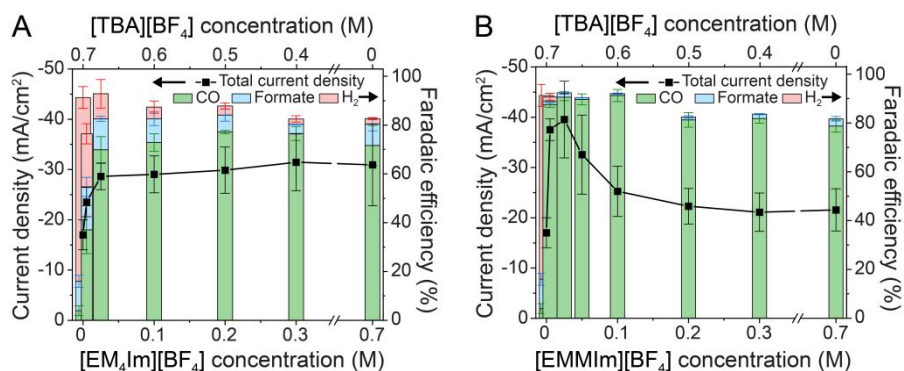

Notably, the comparison between total current densities from [EM<sub>4</sub>Im][BF<sub>4</sub>] and [EMMIm][BF<sub>4</sub>] electrolytes show opposite results in chronoamperometry (Fig. 2) and voltammetry (Fig. 1). While higher total current densities are achieved in [EM<sub>4</sub>Im][BF<sub>4</sub>] electrolytes in chronoamperometry studies, [EMMIm][BF<sub>4</sub>] electrolytes produce substantially higher current densities in voltammetry studies. This observation is consistent with further scan rate-dependent cyclic voltammetry analysis (Fig. S5), which reveals significant mass transport limiting behaviors in [EMMIm][BF<sub>4</sub>] electrolytes under CO<sub>2</sub> purging. This mass transport limit leads to a wave in the forward CV scan at low scan rates and causes the rapid drop of initial current density in chronoamperometry trials (Fig. S6). [TBA][BF<sub>4</sub>] and [EM<sub>4</sub>Im][BF<sub>4</sub>] electrolytes, however, did not show signs of mass transport limits in voltammetry (Fig. S7), and the current density observed in voltammetry roughly matches that in chronoamperometry (Fig. S8).

We hypothesize that such distinct behaviors in mass transport limitation and CO<sub>2</sub> reduction selectivity in [EM<sub>4</sub>Im][BF<sub>4</sub>] and [EMMIm][BF<sub>4</sub>] electrolytes likely result from differences between the two imidazolium structures. Since a dense layer of cations is accumulated at electrochemical interfaces under the large cathodic applied potentials associated with CO<sub>2</sub> electrochemical reduction, the presence or absence

of ring protons (C4/5-Hs) on imidazolium cations appears to cause drastically different local chemical environments, leading to different performances in CO<sub>2</sub> reduction.

We then performed further kinetic analysis to shed additional insight into the mechanism behind the structure-activity relationship of imidazolium cations in facilitating electrochemical CO<sub>2</sub> reduction. To achieve a consistent comparison, we conducted electrochemical CO<sub>2</sub> reduction in acetonitrile electrolytes of binary mixtures of [TBA][BF<sub>4</sub>] and either [EM<sub>4</sub>Im][BF<sub>4</sub>] or [EMMIIm][BF<sub>4</sub>] by keeping a constant total ion concentration at 0.7 M. Controlling for a constant total ion concentration maintains consistent electrolyte conductivity (Fig. S9) and relative concentration of proton donors, enabling a more unambiguous analysis of surface activities and reaction orders of different imidazolium cations, enabling more in-depth kinetic studies and analysis of electrochemical interfaces.

**Figure 3.** Total current density and product selectivity of electrochemical CO<sub>2</sub> reduction in binary mixtures of (A) [EM<sub>4</sub>Im][BF<sub>4</sub>]/[TBA][BF<sub>4</sub>] and (B) [EMMIIm][BF<sub>4</sub>]/[TBA][BF<sub>4</sub>]. For each trial, the potential was held at -2.5 V vs Ag/Ag<sup>+</sup> for 65 min under stirring (600 rpm) and CO<sub>2</sub> purging. The total concentration was constant at 0.7 M, and 0.05 M [Et<sub>3</sub>NH]Cl was added to all electrolytes as the proton donor. Both [EM<sub>4</sub>Im]<sup>+</sup> and [EMMIIm]<sup>+</sup> show strong surface activity by defining the product selectivity at low concentrations (< 0.05 M). Similar to single ionic liquid electrolytes, [EM<sub>4</sub>Im][BF<sub>4</sub>]/[TBA][BF<sub>4</sub>] electrolytes generally facilitate higher steady-state current density and produce both formate and CO, while [EMMIIm][BF<sub>4</sub>]/[TBA][BF<sub>4</sub>] electrolytes lead to lower steady-state current density but selectively produce CO.

Figure 3 shows the product selectivity in [TBA]/[EM<sub>4</sub>Im][BF<sub>4</sub>] and [TBA]/[EMMIIm][BF<sub>4</sub>] electrolytes with varying cation ratios at -2.5 V vs Ag/Ag<sup>+</sup> under CO<sub>2</sub> purging over 1 hour CA. Importantly, both [EM<sub>4</sub>Im]<sup>+</sup> and [EMMIIm]<sup>+</sup> show strong surface activity by determining the product distribution at low relative concentrations, meaning that even low bulk concentrations of imidazolium cations are enough to sculpt an interfacial environment that mimics that of higher concentration electrolytes composed solely of imidazolium cations. In particular, increasing the imidazolium ionic liquid concentration from 0 to 0.025 M and 5 mM for [EM<sub>4</sub>Im][BF<sub>4</sub>] and [EMMIIm][BF<sub>4</sub>], respectively, is sufficient to switch the product selectivity from mainly H<sub>2</sub> to CO<sub>2</sub> reduction products. Further, the surface activity of [EMMIIm]<sup>+</sup> is higher than that of [EM<sub>4</sub>Im]<sup>+</sup>, despite the fact that the [EM<sub>4</sub>Im]<sup>+</sup> cation should be more weakly solvated due to the presence of additional bulky methyl groups in the place of ring hydrogens. Such trends of increased CO<sub>2</sub> reduction activity at increased relative imidazolium concentration at constant total ion concentrations also

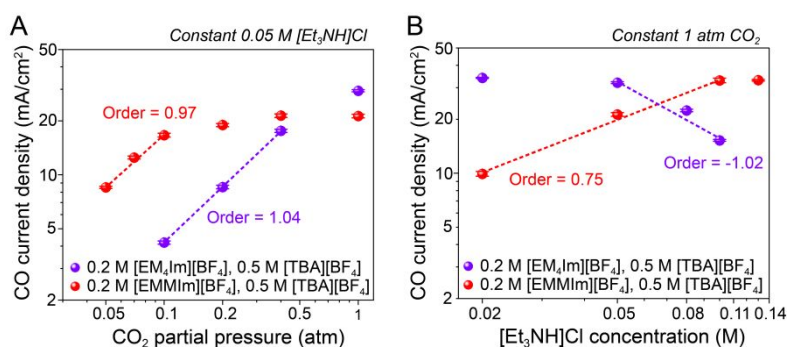

indicate the importance of having both adequate ionic strength and facilitating molecules to achieve efficient electrochemical CO<sub>2</sub> reduction.

Additionally, we find that the trend of reaction rates and product selectivity in binary mixture electrolytes are similar to single ionic liquid electrolytes. [TBA]/[EM<sub>4</sub>Im][BF<sub>4</sub>] electrolytes generally produce higher total current density and overall CO<sub>2</sub> reduction current density compared to [TBA]/[EMMIIm][BF<sub>4</sub>] (Fig. S10). Additionally, [TBA]/[EM<sub>4</sub>Im][BF<sub>4</sub>] electrolytes produce an appreciable amount of both CO and formate, while [TBA]/[EMMIIm][BF<sub>4</sub>] almost exclusively catalyzes the formation of CO. Similar to [EMMIIm][BF<sub>4</sub>]-only electrolytes, [TBA]/[EMMIIm][BF<sub>4</sub>] electrolytes also exhibit mass transport limiting behaviors as the concentration of [EMMIIm][BF<sub>4</sub>] increases. CV scans in [TBA]/[EMMIIm][BF<sub>4</sub>] showed strong scan rate dependence once the concentration of [EMMIIm][BF<sub>4</sub>] exceeds 0.1 M (Fig. S11). Apparent waves in forward scans and lower current density in reverse scans due to mass transport limits appear at lower scan rates (10 mV/s).

These mass transport limitations also cause the steady-state total current density in [TBA]/[EMMIIm][BF<sub>4</sub>] electrolytes to show a nonmonotonic dependence on [EMMIIm][BF<sub>4</sub>] concentration in CA studies (Fig. 3B). Increasing the concentration of [EMMIIm][BF<sub>4</sub>] from 0 to 0.025 M enhances the overall steady-state current density due to the facilitation of CO<sub>2</sub> reduction by [EMMIIm]<sup>+</sup>. However, further increasing the [EMMIIm][BF<sub>4</sub>] concentration invokes rapid drops of the initial CA current density (Fig. S12), eventually leading to lower steady-state current densities at [EMMIIm][BF<sub>4</sub>] concentrations higher than 0.025 M. This trend of steady-state total current density is in stark contrast to that of [TBA]/[EM<sub>4</sub>Im][BF<sub>4</sub>] electrolytes, where the steady-state total current density monotonically increases with [EM<sub>4</sub>Im][BF<sub>4</sub>] concentration until saturation.

To better understand the origin of mass transport limitations and to enable further interpretation surrounding the structural uniqueness of [EMMIIm]<sup>+</sup>, we analyzed the reactions orders of CO<sub>2</sub> reduction to CO with respect to two main reactants, namely CO<sub>2</sub> and proton donor [Et<sub>3</sub>NH]<sup>+</sup> (Fig. 4) in electrolytes consisting of 0.5 M [TBA][BF<sub>4</sub>] and 0.2 M [EM<sub>4</sub>Im][BF<sub>4</sub>] ([TBA]<sub>0.5</sub>/[EM<sub>4</sub>Im]<sub>0.2</sub>[BF<sub>4</sub>]) or [EMMIIm][BF<sub>4</sub>] ([TBA]<sub>0.5</sub>/[EMMIIm]<sub>0.2</sub>[BF<sub>4</sub>]).

**Figure 4** Reaction orders of CO formation with respect to (A) CO<sub>2</sub> and (B) [Et<sub>3</sub>NH]<sup>+</sup> in electrolytes consisting of 0.5 M [TBA][BF<sub>4</sub>] and 0.2 M [EM<sub>4</sub>Im][BF<sub>4</sub>] (purple) or 0.2 M [EMMIIm][BF<sub>4</sub>] (red). For each trial, the potential was held at -2.5 V vs Ag/Ag<sup>+</sup> for 11 min under stirring (600 rpm) and purging. (A) CO formation rate, characterized by CO partial current density, shows a first-order dependence on CO<sub>2</sub> partial pressure in both [TBA]<sub>0.5</sub>/[EM<sub>4</sub>Im]<sub>0.2</sub>[BF<sub>4</sub>] and [TBA]<sub>0.5</sub>/[EMMIIm]<sub>0.2</sub>[BF<sub>4</sub>]. In [TBA]<sub>0.5</sub>/[EMMIIm]<sub>0.2</sub>[BF<sub>4</sub>], the CO formation rate saturates at 0.1 atm CO<sub>2</sub> and achieves a maximum of around -20 mA/cm<sup>2</sup>, indicating

the existence of other factors limiting the rate of CO<sub>2</sub> reduction. In [TBA]<sub>0.5</sub>/[EM<sub>4</sub>Im]<sub>0.2</sub>[BF<sub>4</sub>], the CO formation rate continuously increases with CO<sub>2</sub> partial pressure until 1 atm CO<sub>2</sub>, where -30 mA/cm<sup>2</sup> of CO formation is achieved. (B) The CO formation rate in [TBA]<sub>0.5</sub>/[EMMIm]<sub>0.2</sub>[BF<sub>4</sub>] positively depends on [Et<sub>3</sub>NH]<sup>+</sup> concentration, suggesting the steady-state current is limited by the supply of protons. In [TBA]<sub>0.5</sub>/[EM<sub>4</sub>Im]<sub>0.2</sub>[BF<sub>4</sub>], the CO formation rate is negatively related to [Et<sub>3</sub>NH]<sup>+</sup> concentration, suggesting the competition for surface sites between H<sub>2</sub> formation and CO formation.

By keeping the [Et<sub>3</sub>NH]Cl concentration constant at 0.05 M, the rate of CO formation exhibits a first-order dependence on the partial pressure of CO<sub>2</sub> in both [TBA]<sub>0.5</sub>/[EM<sub>4</sub>Im]<sub>0.2</sub>[BF<sub>4</sub>] and [TBA]<sub>0.5</sub>/[EMMIm]<sub>0.2</sub>[BF<sub>4</sub>] (Fig. 4A). Yet, the ranges of partial pressure where the first order dependence is observed are drastically different in the two electrolytes. In [TBA]<sub>0.5</sub>/[EM<sub>4</sub>Im]<sub>0.2</sub>[BF<sub>4</sub>], an appreciable amount of CO formation occurs once the partial pressure of CO<sub>2</sub> exceeds 0.1 atm. The rate of CO formation shows a clean first-order dependence on the partial pressure of CO<sub>2</sub> up to 0.4 atm CO<sub>2</sub> and continues to increase until 1 atm of CO<sub>2</sub>, where a partial current density of CO formation over -30 mA/cm<sup>2</sup> is achieved.

In contrast, [TBA]<sub>0.5</sub>/[EMMIm]<sub>0.2</sub>[BF<sub>4</sub>] facilitates a considerable amount of CO formation when the CO<sub>2</sub> partial pressure is as low as 0.05 atm. The rate of CO formation shows a first-order dependence on CO<sub>2</sub> partial pressure in the range of 0.05 to 0.1 atm CO<sub>2</sub>. Interestingly, the rate of CO formation saturates once the partial pressure of CO<sub>2</sub> exceeds 0.1 atm. Further increasing the CO<sub>2</sub> partial pressure only leads to minimal enhancement in CO formation, and the maximum CO formation rate achieved at 1 atm CO<sub>2</sub> is around -20 mA/cm<sup>2</sup>, lower than that achieved in [TBA]<sub>0.5</sub>/[EM<sub>4</sub>Im]<sub>0.2</sub>[BF<sub>4</sub>].

The earlier onset CO<sub>2</sub> partial pressure for CO formation in the [TBA]<sub>0.5</sub>/[EMMIm]<sub>0.2</sub>[BF<sub>4</sub>] demonstrates that the electrochemical interface defined by accumulated [EMMIm]<sup>+</sup> is more effective in capturing and facilitating the reduction of CO<sub>2</sub>. More importantly, the saturation of CO formation at relatively low CO<sub>2</sub> partial pressure (0.1 atm) and lower maximum CO formation rate in [TBA]<sub>0.5</sub>/[EMMIm]<sub>0.2</sub>[BF<sub>4</sub>] strongly suggests that the accumulation of [EMMIm]<sup>+</sup> also introduces additional factors that limit CO<sub>2</sub> reduction, which is highly likely the transport of proton donors.

Analysis of the reaction order of CO formation with respect to proton donor, [Et<sub>3</sub>NH]Cl, further unveils the unique regulation of transfer of [Et<sub>3</sub>NH]<sup>+</sup> by accumulated [EMMIm]<sup>+</sup> (Fig. 4B). In [TBA]<sub>0.5</sub>/[EM<sub>4</sub>Im]<sub>0.2</sub>[BF<sub>4</sub>] electrolytes, when the partial pressure of CO<sub>2</sub> is kept at 1 atm, increasing the [Et<sub>3</sub>NH]Cl concentration above 0.02 M leads to monotonic decrease in the CO formation rate and increase in the H<sub>2</sub> formation rate (Fig. S13). A steep decrease in CO formation rate with a reaction order of -1 with respect to [Et<sub>3</sub>NH]Cl concentration occurs once the [Et<sub>3</sub>NH]Cl concentration is over 0.05 M. We attribute this negative [Et<sub>3</sub>NH]Cl reaction order to the competition of surface binding sites between hydrogen and CO<sub>2</sub><sup>-</sup> adsorption on Ag electrode surrounded by an [EM<sub>4</sub>Im]<sup>+</sup>-enriched chemical environment.

In [TBA]<sub>0.5</sub>/[EMMIm]<sub>0.2</sub>[BF<sub>4</sub>], the CO formation rate at 0.02 M [Et<sub>3</sub>NH]Cl is much lower than that in [TBA]<sub>0.5</sub>/[EM<sub>4</sub>Im]<sub>0.2</sub>[BF<sub>4</sub>]. However, increasing the [Et<sub>3</sub>NH]Cl concentration from 0.02 M to 0.1 M monotonically increases the CO formation rate, which is opposite to the trend observed in [TBA]<sub>0.5</sub>/[EM<sub>4</sub>Im]<sub>0.2</sub>[BF<sub>4</sub>]. This positive dependence of CO formation rate on [Et<sub>3</sub>NH]Cl concentration in [TBA]<sub>0.5</sub>/[EMMIm]<sub>0.2</sub>[BF<sub>4</sub>] indicates that under our standard conditions (1 atm CO<sub>2</sub>, 0.05 M [Et<sub>3</sub>NH]Cl), the supply of protons from [Et<sub>3</sub>NH]<sup>+</sup> is the limiting factor for sustaining high steady-state CO<sub>2</sub> reduction rates.

More importantly, no significant competing formation of H<sub>2</sub> from direct reduction of [Et<sub>3</sub>NH]<sup>+</sup> occurs in [TBA]<sub>0.5</sub>/[EMMIm]<sub>0.2</sub>[BF<sub>4</sub>] even in the presence of 0.1 M [Et<sub>3</sub>NH]Cl (Fig. S13). The lack of H<sub>2</sub> formation strongly suggests that the formation of adsorbed hydrogen is unfavorable in [EMMIm]<sup>+</sup>-containing electrolytes. Noticing that the formation of formate during CO<sub>2</sub> reduction was proposed to be initiated by surface-adsorbed hydrogen,<sup>55, 56</sup> the unfavored formation of surface-adsorbed hydrogen would also explain the minimal selectivity towards formate production in [EMMIm]<sup>+</sup>-containing electrolytes.

Taken together, we hypothesize that the distinct ability of [EMMIm]<sup>+</sup> to specifically promote CO<sub>2</sub> electrocatalytic reduction to CO is linked both to the presence of an aromatic imidazolium core that stabilizes the CO<sub>2</sub><sup>-</sup> transition state via a π<sup>-</sup>-anion interaction as well as a propensity to block surface access of the proton donor [Et<sub>3</sub>NH]<sup>+</sup>, which lowers the overall proton activity. These effects should simultaneously enhance the selectivity towards CO and limit the overall steady-state current density by depleting the proton donors at electrochemical interfaces, which is consistent with our measurements. To further evaluate this hypothesis on the influence of [EMMIm]<sup>+</sup>-containing electrolytes, we conducted Tafel analysis on the electrochemical reduction of [Et<sub>3</sub>NH]<sup>+</sup> to H<sub>2</sub> in electrolytes of three ionic liquids under Ar purging.

**Figure 5.** Tafel plots of H<sub>2</sub> formation in 0.2 M [TBA][BF<sub>4</sub>] (blue), [EM<sub>4</sub>Im][BF<sub>4</sub>] (purple), or [EMMIm][BF<sub>4</sub>] (red) electrolytes with 0.05 M [Et<sub>3</sub>NH]Cl under Ar purging. The slope from 0.2 M [EMMIm][BF<sub>4</sub>] in linear regime is much steeper than that from 0.2 M [EM<sub>4</sub>Im][BF<sub>4</sub>] and 0.2 M [TBA][BF<sub>4</sub>], indicating the more sluggish kinetics of proton reduction and hydrogen adsorption in 0.2 M [EMMIm][BF<sub>4</sub>], likely due to the dense layer of potential driven assembly of [EMMIm]<sup>+</sup> on Ag electrode.

The electrochemical reduction of [Et<sub>3</sub>NH]<sup>+</sup> to H<sub>2</sub> occurs through a two-step pathway:

Tafel plots are generated by plotting applied potential versus the rate of H<sub>2</sub> formation, represented by current density, on a logarithmic scale. Slopes in the linear region of Tafel plots provide mechanistic information, such as the identity of the rate-determining step (RDS) and the charge transfer coefficient if electron transfer is involved in the RDS. For instance, the Tafel slope of electrochemical H<sub>2</sub> formation with the first step (i.e., Volmer step) as the RDS is predicted to be 120 mV/dec, assuming a charge transfer coefficient of 0.5.<sup>57-59</sup> When the second step becomes the RDS, much lower Tafel slopes (< 40 mV/dec) are expected.<sup>58, 59</sup>

Figure 5 shows the Tafel plots of H<sub>2</sub> formation in 0.2 M [TBA][BF<sub>4</sub>], [EM<sub>4</sub>Im][BF<sub>4</sub>], and [EMMIm][BF<sub>4</sub>] near the onset potential of H<sub>2</sub> formation. The overpotential required to drive the same H<sub>2</sub> formation rate in three electrolytes becomes more cathodic in the order of [TBA][BF<sub>4</sub>], [EM<sub>4</sub>Im][BF<sub>4</sub>], and [EMMIm][BF<sub>4</sub>], suggesting the larger energy barrier of H<sub>2</sub> formation in 0.2 M [EMMIm][BF<sub>4</sub>].

Further, the Tafel slope of H<sub>2</sub> formation in the linear region for 0.2 M [EMMIm][BF<sub>4</sub>] is 182 mV/dec, while the Tafel slopes in the linear region for 0.2 M [TBA][BF<sub>4</sub>] and [EM<sub>4</sub>Im][BF<sub>4</sub>] are 94 mV/dec and 122 mV/dec, respectively. The Tafel slopes of H<sub>2</sub> formation in all three electrolytes are close to the characteristic Tafel slope of 120 mV/dec for pathways with the Volmer step as the RDS. However, the Tafel slope of 0.2 M [EMMIm][BF<sub>4</sub>] is much steeper than that of 0.2 M [EM<sub>4</sub>Im][BF<sub>4</sub>] and [TBA][BF<sub>4</sub>], indicating a distinctively sluggish kinetics of the transfer of the first electron and the formation of surface adsorbed H (Ag-H) in 0.2 M [EMMIm][BF<sub>4</sub>].

The slower kinetics of Ag-H formation in 0.2 M [EMMIm][BF<sub>4</sub>] can result from either a limited mass transport of [Et<sub>3</sub>NH]<sup>+</sup> in general, or a low charge transfer coefficient (< 0.5) due to the hindered approach to the surface of proton centers caused by attracted [EMMIm]<sup>+</sup> layer. The latter scenario is analogous to the slow kinetics of H<sub>2</sub> formation in electrolytes with bulky proton donors.<sup>60</sup> It is also possible, and perhaps even likely, that two scenarios are simultaneously in effect. Further experiments that leverage rotating disc electrodes to explore a wider range of mass transport, applied bias, and current density regimes are necessary to fully determine the causes of slow H<sub>2</sub> formation kinetics in [EMMIm][BF<sub>4</sub>] electrolytes.

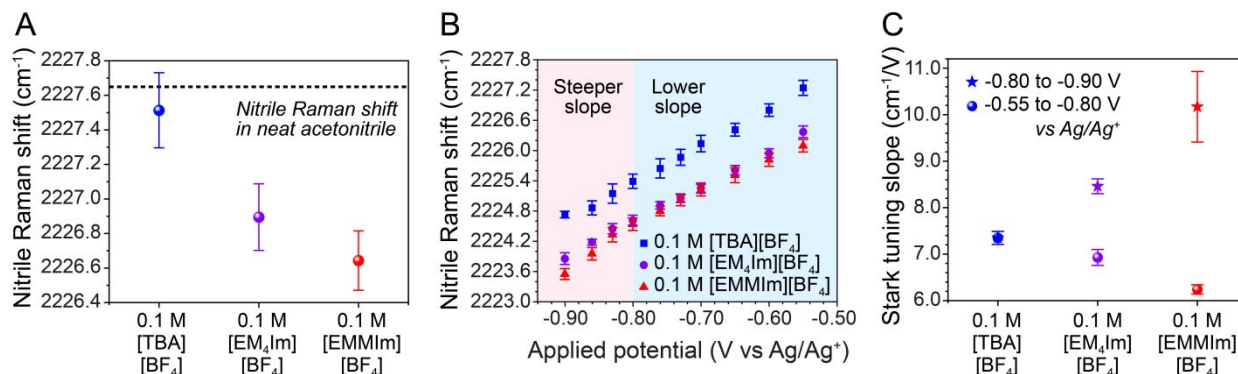

The more cathodic onset potential and the apparent slower kinetics of H<sub>2</sub> formation in the presence of [EMMIm]<sup>+</sup> are consistent with our conclusions surrounding the dual impact on electrochemical CO<sub>2</sub> reduction brought by the attracted [EMMIm]<sup>+</sup> layer on the Ag electrode. The unfavorable formation of Ag-H in the presence of [EMMIm]<sup>+</sup> layer ensures a high selectivity towards CO over H<sub>2</sub> and formate. However, the limited access of [Et<sub>3</sub>NH]<sup>+</sup> to the electrode surface also compromises the steady-state rate of electrochemical CO<sub>2</sub> reduction due to the lack of an adequate proton supply to sustain proton-coupled electron transfers.

We propose that the unique regulation on Ag-H formation brought by [EMMIm]<sup>+</sup>-containing electrolytes most likely originates from the assembly pattern of [EMMIm]<sup>+</sup> at electrochemical interfaces. The smaller H substituents at C4/5 positions of [EMMIm]<sup>+</sup> may lead to a denser assembly of [EMMIm]<sup>+</sup>, thereby promoting the high surface activity of [EMMIm]<sup>+</sup> and giving rise to a physical barrier against the approach of [Et<sub>3</sub>NH]<sup>+</sup>. This scenario is analogous to the formation of hydrophobic layers and the suppression of water reduction caused by organic coating or ion assembly on electrode surfaces in aqueous systems.<sup>25, 61, 62</sup>

In contrast, the methyl groups at C4/5 positions of [EM<sub>4</sub>Im]<sup>+</sup> cause steric hindrance for cation assembly, leading to a more loosely assembled layer of [EM<sub>4</sub>Im]<sup>+</sup>. Noticing that the interaction between imidazolium ring and adsorbed CO<sub>2</sub><sup>-</sup> is the key factor in driving CO<sub>2</sub> reduction, a denser assembly of [EMMIm]<sup>+</sup> would also explain the higher initial kinetics of CO<sub>2</sub> reduction reflected by CV studies at higher scan rates (Figure 1).

In order to gain molecular insights into the behavior of bound cation layers at electrochemical interfaces, we investigated the electrochemical interfaces using the combination of surface-enhanced Raman scattering (SERS) and a molecular probe, namely 4-mercaptobenzonitrile (4-MBN). After being

anchored on the Ag surface through the thiol group in the form of a self-assembled monolayer, the Raman shift of the nitrile group (-CN) provides information on local chemical environments around the electrochemical interfaces, mainly the strength of local electric fields that either destabilize (blue shift) or stabilize (redshift) the dipole of the probe molecule.<sup>63, 64</sup>

**Figure 6.** Raman shifts of the nitrile group from 4-MBN in 0.1 M [TBA][BF<sub>4</sub>] (blue), [EM<sub>4</sub>Im][BF<sub>4</sub>] (purple), and [EMMIm][BF<sub>4</sub>] (red). (A) Raman shifts of the nitrile group at OCP in three electrolytes. The nitrile group exhibits redshifts in all three electrolytes. The redshifts are more significant in the two imidazolium-based electrolytes, indicating the stronger stabilization of the nitrile dipole by imidazolium. (B) Potential-dependent Raman shifts of the nitrile group in the three electrolytes. Larger redshifts of the nitrile group are observed in both imidazolium-based electrolytes across the whole potential range tested, suggesting that the potential-driven assembly of imidazolium gives rise to a stronger interfacial electric field that stabilizes the nitrile dipole. Further, two distinct Stark tuning slopes were observed for both imidazolium-based electrolytes in different potential ranges. (C) Potential-dependent Stark tuning slopes in three electrolytes. Compared to 0.2 M [TBA][BF<sub>4</sub>], both 0.2 M [EM<sub>4</sub>Im][BF<sub>4</sub>] and [EMMIm][BF<sub>4</sub>] exhibit lower slopes under less cathodic applied potentials and steeper slope under more cathodic applied potentials, suggesting the ordered pre-assembly and more efficient potential-driven assembly of imidazolium in two potential ranges, respectively.

Figure 6 shows key SERS results of 4-MBN on a roughened Ag surface in 0.1 M [TBA][BF<sub>4</sub>], [EM<sub>4</sub>Im][BF<sub>4</sub>], and [EMMIm][BF<sub>4</sub>]. Full sets of potential-dependent SERS spectra of nitrile are included in the Supplementary Information (Fig. S14). At open-circuit potential (OCP), all three cations drive redshifts of the nitrile group, indicating the stabilization of nitrile dipole in all three electrolytes. The significance of nitrile redshift increases in the sequence of [TBA]<sup>+</sup>, [EM<sub>4</sub>Im]<sup>+</sup>, and [EMMIm]<sup>+</sup>, with the redshifts driven by [EM<sub>4</sub>Im]<sup>+</sup> and [EMMIm]<sup>+</sup> being closer to each other and much larger than that caused by [TBA]<sup>+</sup>.

The dipole within the nitrile group points from the C atom (partially positive) to the N atom (partially negative). Therefore, the trend of nitrile Raman shift in three electrolytes indicates that the nitrile group experiences a stronger inward pointing local electric field (cathodic) and is more stabilized in two imidazolium-based electrolytes through the interaction with co-planar delocalized positive charges even at open-circuit potential. This trend suggests the preferential accumulation of imidazolium cations at electrochemical interfaces and explains their high surface activity illustrated in our CO<sub>2</sub> reduction results (Fig. 3).

To understand the behavior of three cations at electrochemical interfaces under cathodic applied potentials, we tracked the potential-dependent Raman shift of the nitrile group in 0.1 M [TBA][BF<sub>4</sub>], [EM<sub>4</sub>Im][BF<sub>4</sub>], and [EMMIm][BF<sub>4</sub>] under applied potentials ranging from -0.55 V to -0.90 V vs Ag/Ag<sup>+</sup> (Fig. 6B). Importantly, the nitrile Raman shift in 0.1 M [EMMIm][BF<sub>4</sub>] exhibits the largest redshift across the whole potential range among three electrolytes, indicating the strongest stabilization of nitrile by [EMMIm]<sup>+</sup>. We further extracted the rate of change in nitrile Raman shift with respect to applied potentials (Figs. 6B and 6C), which is often referred to as the Stark tuning slope when the linear relationship holds. The stark tuning slope reflects the sensitivity of the local electric field with respect to externally applied potentials as a result of ion rearrangements in electric double layers.

While the 0.1 M [TBA][BF<sub>4</sub>] exhibits a constant Stark tuning slope of 7.3 cm<sup>-1</sup>/V across the whole potential range, both 0.1 M [EM<sub>4</sub>Im][BF<sub>4</sub>] and 0.1 M [EMMIm][BF<sub>4</sub>] show changing slopes depending on the applied potentials. Both imidazolium-based electrolytes give slopes slightly lower than that in 0.1 M [TBA][BF<sub>4</sub>] in the potential range of -0.55 to -0.80 V vs Ag/Ag<sup>+</sup>, and steeper slopes in the potential range of -0.80 to -0.90 V vs Ag/Ag<sup>+</sup>. Interestingly, as shown in Figures 6B and 6C, 0.1 M [EMMIm][BF<sub>4</sub>] gives the lowest Stark tuning slope of 6.2 cm<sup>-1</sup>/V under less cathodic applied potentials (-0.55 to -0.80 V vs Ag/Ag<sup>+</sup>) and the steepest slope of 10.2 cm<sup>-1</sup>/V under more cathodic applied potentials (-0.80 to -0.90 V vs Ag/Ag<sup>+</sup>).

Similar potential-dependent changes in Stark tuning slopes were reported in [EMIm][BF<sub>4</sub>] electrolytes, which was related to the structural transformation of the electric double layer containing [EMIm]<sup>+</sup> under more cathodic potentials.<sup>65, 66</sup> We interpret such structural transformation as a result of the pre-ordering and potential-driven assembly of aromatic cations under cathodic potentials. The trend of nitrile Raman shift in three electrolytes at OCP suggests the preferential accumulation of imidazolium at electrochemical interfaces, which means that the surface potential of the electrode could be better screened or even overscreened at OCP, which was previously reported for several ionic liquid electrolytes.<sup>67-69</sup> Therefore, less ion rearrangement is required in imidazolium-containing electrolytes under less cathodic applied potentials, leading to lower sensitivity of the interfacial electric field to applied potentials and lower Stark tuning slopes.

However, once the applied potential exceeds the screening capability of bound cations, the rearrangement of ions within the electric double layer becomes necessary to fully screen the surface potential of electrodes. In this case, cations that can be more easily assembled at OCP will also more efficiently rearrange and screen the surface potential, leading to steeper Stark tuning slopes. Therefore, the steepest Stark tuning slope in 0.1 M [EMMIm][BF<sub>4</sub>] at more cathodic applied potentials illustrates the most efficient potential-driven assembly of [EMMIm]<sup>+</sup> and the strongest stabilization of nitrile. The relatively lower Stark tuning slope of 0.1 M [EM<sub>4</sub>Im][BF<sub>4</sub>] suggests the moderate assembly efficiency and nitrile stabilization of [EM<sub>4</sub>Im]<sup>+</sup>. In contrast to the two imidazolium-based electrolytes, 0.1 M [TBA][BF<sub>4</sub>], with the potential-independent Stark tuning slope and the lowest Stark tuning slope under more cathodic applied potentials, exhibits the lowest assembly efficiency and stabilization of nitrile groups.

Overall, the trends of OCP nitrile Raman shift position and potential-dependent Stark tuning rate in 0.1 M [TBA][BF<sub>4</sub>], [EM<sub>4</sub>Im][BF<sub>4</sub>], and [EMMIm][BF<sub>4</sub>] illustrate that imidazolium with co-planarly delocalized positive charges generally exhibit higher assembly efficiency and better stabilize nitrile by interfacial electric field across the whole range of applied potentials. Although the monolayer of 4-MBN

cannot directly probe interfacial properties at more cathodic applied potentials due to 4-MBN desorption, an extrapolation of nitrile Raman shift using the Stark tuning slopes for more cathodic applied potentials implies the even higher interfacial electric field brought by accumulated  $[\text{EMMIIm}]^+$  and  $[\text{EM}_4\text{Im}]^+$  at applied potentials applicable for electrochemical  $\text{CO}_2$  reduction.

Imidazolium cations are known to collectively reorientate to parallel alignment with respect to the electrode surface under cathodic applied potentials.<sup>44, 70, 71</sup> Such reorientation aligns imidazolium cations with each other and reduces the average distance between the imidazolium charge center and electrode surface, which together may contribute to the efficient assembly of imidazolium and better stabilization of surface adsorbed molecules under cathodic applied potentials. Particularly,  $[\text{EMMIIm}]^+$ , with smaller ring substituents, would undergo the reorientation more easily and exhibit more ordered assembly compared to  $[\text{EM}_4\text{Im}]^+$ , leading to stronger interfacial electric fields.

The trends of the structure-dependent cation assembly and interfacial electric field under cathodic applied potentials are expected to be further relevant under conditions for  $\text{CO}_2$  reduction. Adsorbed  $\text{CO}_2^-$  possesses an overall molecular dipole along the same direction as the nitrile group, so the trend of nitrile stabilization by cations should also be consistent with the trends of the relative stabilization of the  $\text{CO}_2^-$  transition state. Therefore, instant  $\text{CO}_2$  reduction kinetics is predicted to increase in the order of  $[\text{TBA}][\text{BF}_4]$ ,  $[\text{EM}_4\text{Im}][\text{BF}_4]$ , and  $[\text{EMMIIm}][\text{BF}_4]$ , which corresponds well to our CV results (Fig. 1). At the same time, the particularly dense and ordered assembly of  $[\text{EMMIIm}]^+$  also hinders the transport of proton donors and the adsorption of hydrogen, leading to slower  $\text{H}_2$  transfer kinetics and compromised steady-state  $\text{CO}_2$  reduction rate that depends on the supply of protons (Fig.7).

**Figure 7.** Imidazolium cations promote and regulate  $\text{CO}_2$  reduction. The interaction between co-planar delocalized positive charge in imidazolium and anionic intermediate  $\text{CO}_2^-$  (dashed green circle) is the most essential to promote  $\text{CO}_2$  reduction. Therefore, both (B)  $[\text{EM}_4\text{Im}]^+$  and (C)  $[\text{EMMIIm}]^+$  can facilitate efficient  $\text{CO}_2$  reduction. However, a steady supply of protons is necessary to complete electron transfer and to sustain the current (dashed purple circle). Therefore, (C)  $[\text{EMMIIm}]^+$  that exhibits a more ordered assembly at the interface limits the supply of proton, which compromises the steady-state current density.

## Conclusion

By comparing electrochemical  $\text{CO}_2$  reduction in  $[\text{EM}_4\text{Im}]^+$  and  $[\text{EMMIIm}]^+$ -based electrolytes in the presence of independent organic proton donor, we successfully decoupled the different contributions of imidazolium promoters to  $\text{CO}_2$  electrocatalytic reduction. Our data demonstrates that the co-planarly delocalized positive charge on imidazolium rings is the key moiety to enabling imidazolium cations to

stabilize adsorbed  $\text{CO}_2^-$ . Further, our results of [TBA]/imidazolium mixtures indicates that the ring structure of imidazolium cations enhances their surface activity, eventually promoting selective  $\text{CO}_2$  reduction even at relatively low bulk concentrations.

Further, drawing on kinetic and surface-enhanced spectroscopic studies, we illustrate that the size and identity of aromatic substituents of  $[\text{EMMIm}]^+$  enables it to densely assemble on cathode surfaces. This blocking bound ion layer appears to modify the local chemical environment to hinder the access of proton donors, which suppresses proton activity, relative to that of  $\text{CO}_2$  reduction. In particular,  $[\text{EMMIm}]^+$  exhibits uniquely high surface activity, high kinetic current density at a short time scale, and distinct enhancement of CO selectivity during  $\text{CO}_2$  reduction. The dense assembly of  $[\text{EMMIm}]^+$ , however, also compromises the steady-state current density of  $\text{CO}_2$  reduction due to suppressing proton activity to the point where there is a deficiency of active species needed to sustain proton-coupled electron transfers involved in  $\text{CO}_2$  reduction. Therefore,  $[\text{EM}_4\text{Im}]^+$ , with a bulkier structure and moderated assembly density, provides the optimum performance during steady-state  $\text{CO}_2$  reduction.

Overall, our findings yield new insights into how the imidazolium core and surrounding ring substituents influence electrochemical  $\text{CO}_2$ . Our study raises the prospect that aromatic cations have distinct interfacial assembly and intermolecular interactions with anionic intermediates via a “ $\pi^+$ -anion” interaction that appears to be an electrostatic analog of the more commonly investigated “cation- $\pi$ ” interaction.<sup>53, 54</sup> Furthermore, our study suggests new criteria for designing electrolytes that balance the suppression of  $\text{H}_2$  formation and the support of proton-coupled electron transfer, which is especially critical for facilitating selective yet fast  $\text{CO}_2$  reduction.
