Accepted Manuscript

This is an *Accepted Manuscript*, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

*Accepted Manuscripts* are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this *Accepted Manuscript* with the edited and formatted *Advance Article* as soon as it is available.

You can find more information about *Accepted Manuscripts* in the [Information for Authors](#).

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard [Terms & Conditions](#) and the [Ethical guidelines](#) still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this *Accepted Manuscript* or any consequences arising from the use of any information it contains.

5  
6 2 The absolute and relative quantitation of proteins plays a fundamental role in modern proteomics, as  
7  
8 3 it is the key to understand still unresolved biological questions in medical and pharmaceutical  
9  
10 4 applications. Highly sensitive analytical methods are required to quantify proteins in biological  
11  
12 5 samples and to correlate their concentration levels with several diseases.

13  
14 6 Enzyme-linked immunosorbent assay (ELISA) and Western blot represent specific strategies for  
15  
16 7 protein quantitation. However, these approaches are impractical for quantitative studies: the  
17  
18 8 availability of high quality ELISAs for biomarker candidates is limited, and the performance  
19  
20 9 characteristics of many commercially marketed ELISAs are poorly documented or unknown. The  
21  
22 10 development of ELISA or Western blot is also expensive and time-consuming.

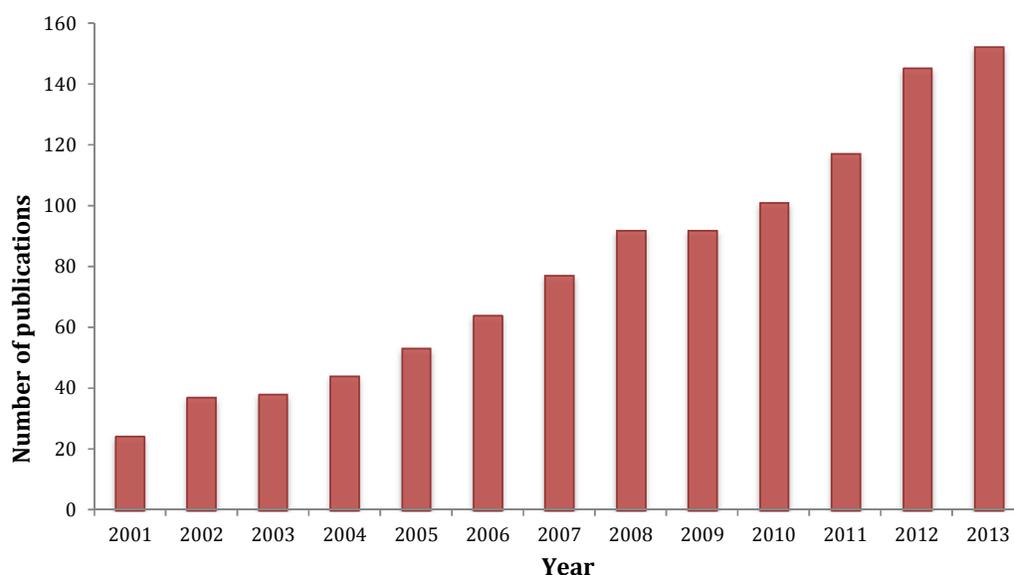

23  
24 11 The limitations of these strategies, combined with the large numbers of biomarker candidates  
25  
26 12 emerging from genomic and proteomic discovery studies, have created the need for alternative  
27  
28 13 strategies for quantitation of targeted proteins.

29  
30 14 In recent years, a widely explored approach to identify and quantify intact proteins is based on (i)  
31  
32 15 the detection of endogenous metals covalently bound to the protein structure or (ii) the labelling of  
33  
34 16 proteins with metallic probes. The development of several hyphenated analytical techniques for  
35  
36 17 metals quantitation has led to new possibilities for the quantitative analysis of proteins.

37  
38 18 In the present review, we attempt to provide a full coverage of current methodologies for proteins  
39  
40 19 quantitation based on the detection of endogenous metal(loid)s or chemical labeling with  
41  
42 20 metal(loid)s, highlighting, to the best of our knowledge, their merits and limits.

## 1 Introduction.

2 The quantitative analysis of protein mixtures is essential to understand the variations in the  
3 proteome of living organisms. Quantitative proteomics is a rapidly increasing, important research  
4 field since many specific functions in the cell are controlled by changes in protein expression levels  
5 under different physiological conditions. Thus, the quantitation of the proteome can reveal  
6 alterations of the normal biological state or even point out biological markers in important diseases.  
7 Figure 1 shows the number of published research articles in proteomics using a search query with  
8 keywords “protein\* and quantitation” in title from 2000 to 2013, and reflects the growing interest in  
9 absolute and relative protein quantitation techniques.

10  
11 **Fig. 1** Number of published research articles in proteomics using a search query with keywords  
12 “protein\* and quantitation” in title from 2000 to 2013 via Scopus excluding reviews and abstract  
13 proceedings.

14  
15 For a clinical biomarker, quantitative information is mandatory in order to use the protein/peptide  
16 routinely in clinical diagnosis.<sup>1</sup>

1  
2  
3 1 Consequently, sensitive analytical methods are needed, which allow the quantitation of individual  
4  
5 2 proteins synthesized by a cell at a given moment and under specific conditions. One of the main  
6  
7 3 goals of developing protein quantitation strategies is their clinical applications to quantify candidate  
8  
9 4 proteins in biological matrices as biomarkers or putative marker proteins associated with a variety  
10  
11 5 of diseases, for the development of new drug and personalized medicine.

12  
13  
14 6 In an analytical framework the expression “relative quantitation” refers to the quantitation of  
15  
16 7 relative ratios of proteins and/or peptides in two or more samples. In contrast, the expression  
17  
18 8 “absolute quantitation” refers to the quantitation of proteins and peptides in units of weight,  
19  
20 9 concentration or total amount of substance in one or more samples.<sup>2</sup>

21  
22  
23 10 Traditionally, the enzyme-linked immunosorbent assay (ELISA) has been the method more widely  
24  
25 11 applied for the targeted quantitation of proteins, providing good sensitivity and throughput.<sup>3</sup>

26  
27 12 When ELISA assays or high quality antibodies already exist, the process of validation of a  
28  
29 13 biomarker candidate can be relatively straightforward as, to date, it remains the “gold standard” for  
30  
31 14 targeted protein quantitation.<sup>4</sup>

32  
33  
34 15 However, for many or most of the novel protein candidates discovered in recent proteomics studies,  
35  
36 16 the ELISA approach is limited by the lack of availability of antibodies with high specificity, and the  
37  
38 17 development of a high quality ELISA assay requires a significant investment in time and resources.<sup>3</sup>

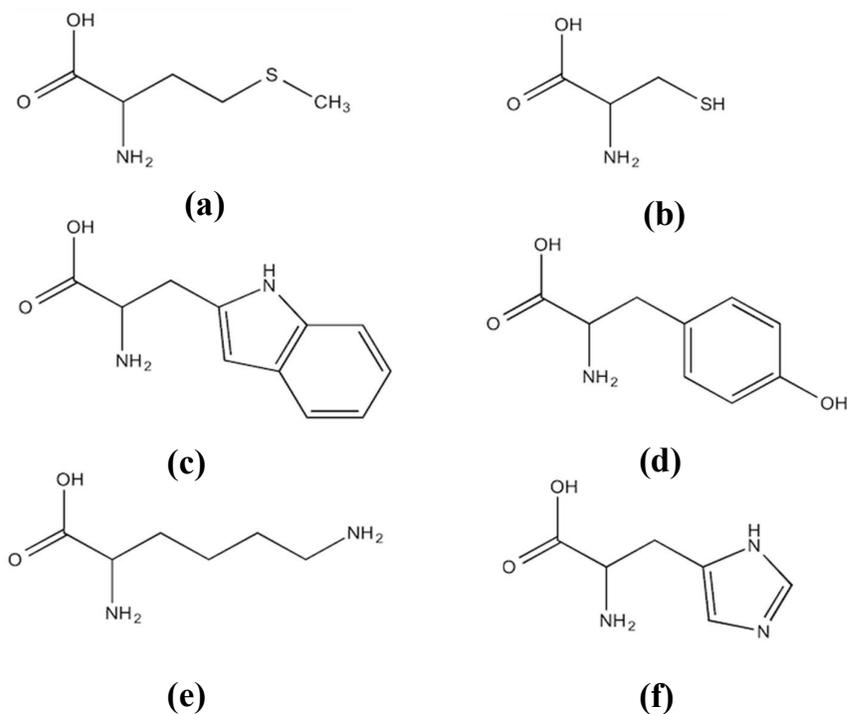

39  
40 18 Mass spectrometry (MS) with electrospray ionization (ESI) or matrix-assisted laser desorption  
41  
42 19 ionization (MALDI) are currently the major technique for protein identification.<sup>5,6</sup> Advances in the  
43  
44 20 use of mass spectrometry over the last 5 years opened the door to the identification and quantitation  
45  
46 21 of proteins with an unprecedented speed.

47  
48  
49 22 Although MS techniques are crucial in the identification of peptides and proteins, their application  
50  
51 23 to quantitative analysis presents some important drawbacks such as the differential response of  
52  
53 24 proteins and peptides depending on size, hydrophobicity, matrix, or solvents.<sup>7</sup>

54  
55  
56 25 To overcome these disadvantages and obtain better analytical results various types of tags have  
57  
58 26 been developed to label proteins for their detection and quantitation. Additionally, since standards  
59  
60

1 for most biomolecules of natural origin are unavailable, their tagging using different derivatization  
2 approaches is a valuable alternative for their quantitation.<sup>8</sup>

3 The variety of chemistry available to modify reactive groups in a typical peptide (Figure 2)  
4 combined with the numerous structures possible for a quantitative tag creates a large number of  
5 possibilities to chemically incorporate a labeling agent.

6  
7 **Fig 4.** Structures of the most-reactive amino acids used to functionalize proteins. (a): methionine;  
8 (b): cysteine; (c): tryptophan; (d): tyrosine; (e): lysine; (f): histidine.

9  
10 The so-called “global” approaches aim to target common functional groups, i.e., amino groups at  
11 the N terminus of a peptide or protein and on lysine (Lys) side-chain, or carboxyl groups at the C  
12 terminus and on aspartic (Asp) and glutamic (Glu) acid residues.<sup>9</sup> The labeling agent for a relative  
13 quantitation of proteins or peptides may be introduced in this way to ensure the highest possible  
14 coverage, so that almost every peptide will carry the tag. Global strategies have to rely on more  
15 sophisticated separation steps like multidimensional chromatography or high-resolution mass  
16 spectrometry to deal with the higher complexity of the mixtures.

1  
2  
3 1 More specific approaches are frequently directed towards peptides carrying rare amino acids.  
4  
5 2 Cysteine (Cys) is a relatively rare amino acid, with an average relative abundance ranging between  
6  
7 3 2.26% in mammals and 0.5% in bacteria.<sup>10</sup> Cys is very frequently used as probe target because its  
8  
9 4 thiolic group can be specifically modified, and many different stable-isotope labeling reagents for  
10  
11 5 Cys have been reported.<sup>11</sup> With the exclusion of the thiolic group of Cys, few other functional  
12  
13 6 groups of amino acids can be specifically modified, e.g. the specific tagging of lysine (via  
14  
15 7 amidination/guanidination) or tryptophan (modification of the indol system) has been reported.<sup>9</sup>  
16  
17 8 These methods, restricted to those proteins that have these amino acids, are advantageous because  
18  
19 9 they lead to the determination of target proteins in complex matrices.  
20  
21  
22  
23 10 In the case of Cys labeling, reduction of disulphide bonds in proteins is usually a necessary step.  
24  
25 11 This can be achieved using dithiothreitol (DTT), mercaptoethanol or 3,3',3''-  
26  
27 12 phosphanetriyltripropanoic acid (TCEP), the last preferred in order to avoid additional thiol groups  
28  
29 13 in the mixture that may react with the labeling reagent.  
30  
31  
32 14 For quantitative analysis, the ideal labeling reagent should provide high detection sensitivity,  
33  
34 15 specificity, quantitative labeling reaction and it must/should not be susceptible to major matrix  
35  
36 16 interfering reactions. The selected labeling agent should not require solvent extraction steps to  
37  
38 17 remove reagent excess prior to the separation step.  
39  
40  
41 18 Analytical methods using colorimetric labeling reagents and UV/fluorescence detection are simpler  
42  
43 19 as compared with MS technique but they have lower sensitivity. Fluorescence leads to much lower  
44  
45 20 detection limits than UV absorbance detection, and the use of lasers (mainly argon, or in some  
46  
47 21 studies mercury or krypton ion lasers) to induce fluorescence is associated with further  
48  
49 22 improvements.  
50  
51  
52 23 Many proteins have been labeled with probes that target the Cys reactive thiolic group. Typical  
53  
54 24 derivatization reagents are imidazole<sup>12</sup>, monobromobimane<sup>13</sup>, 5,5-dithio-bisnitrobenzoic acid<sup>14</sup>,  
55  
56 25 maleimide<sup>15</sup>, 3-diazole-4-sulfonate<sup>16</sup>, 3-iodoacetylaminobenzanthrone.<sup>17</sup> For example, Nygren et  
57  
58 26 al. presented a dual-labeling approach of a binding protein using N-iodoacetyl-N-(5-sulfo-1-

1  
2  
3 1 naphthyl)ethylenediamine and succinimidyl-6-(N-(7-nitrobenz-2-oxa-1,3-diazol-4-  
4  
5 2 yl)amino)hexanoate to subsequently label the –SH and the N-terminal –NH<sub>2</sub>, allowing specific  
6  
7 3 fluorescence detection of the protein.<sup>18</sup> However the application of these dyes to proteomic studies  
8  
9  
10 4 still has some limitations: organic dyes often suffer from photobleaching; they usually have a large  
11  
12 5 size (~1 nm in diameter), sometimes limiting their access to target amino acids located inside the  
13  
14 6 protein because of steric restrictions; and dye molecular rigidity might be destroyed, leading to  
15  
16 7 fluorescence signal suppression.<sup>19</sup>  
17  
18 8 Common probes include large fusion proteins such as the green fluorescent protein (GFP) or b-  
19  
20 9 lactamase.<sup>20</sup> Although their potential has been convincingly demonstrated, possible problems,  
21  
22 10 including their degradation and high background signal, might arise from the use of such large  
23  
24  
25 11 fusion proteins. In addition, large fluorescent proteins could interfere with the function of the  
26  
27 12 targeted protein.<sup>21</sup>  
28  
29 13 Recent approaches for quantitative proteomics are based on isotopically (<sup>2</sup>H, <sup>13</sup>C, <sup>15</sup>N, or <sup>18</sup>O)  
30  
31 14 labeled derivatives of proteins or peptides producing a mass shift in molecular MS between light and  
32  
33 15 heavy labeled compounds. Stable isotope labeling by amino acids in cell culture (SILAC)<sup>22</sup> or the  
34  
35 16 introduction of <sup>18</sup>O using H<sub>2</sub><sup>18</sup>O in the enzymatic digestion<sup>23</sup>, are examples of metabolic and  
36  
37 17 enzymatic labeling, respectively. The most extended methodologies are the chemical labeling with  
38  
39 18 ICAT (isotope coded affinity tag)<sup>24</sup>, CDIT (culture-derived isotope tags)<sup>25</sup>, iTRAQ (isobaric tag for  
40  
41 19 relative and absolute quantitation)<sup>26</sup>, or PROTEIN-AQUA (protein absolute quantitation)<sup>27</sup>.  
42  
43  
44 20 Although the development of these techniques for protein quantitation on a large scale is increasing,  
45  
46 21 the comparison and validation among different laboratories of the wide data obtained by different  
47  
48 22 methods is very difficult.<sup>28</sup> The quantitation needs efficient labeling of the detected peptides or  
49  
50 23 proteins and also relies on the accuracy of the mass measurement and the chromatographic  
51  
52 24 reproducibility. PROTEIN-AQUA using a synthetic isotopically labeled standard of each target  
53  
54 25 peptide is limited to a small number of analytes due to the high cost of the standard preparation.<sup>29</sup>  
55  
56  
57  
58  
59  
60

1  
2  
3 1 In the last decades, the outlook about protein quantitation has changed noticeably with the  
4  
5 2 incorporation in this field of the screening of multiple heteroatoms naturally present, or introduced  
6  
7 3 as labels in biological samples.

8  
9 4 In recent years the analysis of naturally covalently incorporated heteroelements such as sulphur or  
10  
11 5 phosphorous by inductively coupled plasma-mass spectrometry ICP-MS has an increasing  
12  
13 6 interest.<sup>28</sup> However, isobaric interferences, the high first ionization energies of these  
14  
15 7 heteroelements, and the resulting high limits of detection often lead to unsatisfactory results.<sup>30</sup>

16  
17 8 Proteins frequently contain one or more essential coordinated metal(loid) ions in their catalytic or  
18  
19 9 functional centres.<sup>31</sup> In addition, metal ions involved in allosteric regulations of proteins may be  
20  
21 10 bound to other sites. Metals are typically coordinated to histidine (N), Cys (S) or carboxyl  
22  
23 11 functions (O).<sup>32</sup> Even though trace metals play a vital role in living systems and their application as  
24  
25 12 tags for selected bio-molecules has been demonstrated in a number of papers, their use as tags is  
26  
27 13 limited since they are often only weakly associated with their ligands. This makes them susceptible  
28  
29 14 to changes in the tag stoichiometry especially during the complex sample preparation procedures,  
30  
31 15 which may result in inaccurate quantitative results.<sup>29</sup>

32  
33 16 Peptides and proteins that do not contain naturally detectable elements can be chemical derivatized  
34  
35 17 with metals, or radionuclides, in order to make them “visible” and quantifiable and to allow  
36  
37 18 sensitive and specific detection of the analytes. In order to quantify proteins on the basis of their  
38  
39 19 metal content, specific factors must be considered: (i) the metal-protein stoichiometry has to be  
40  
41 20 known, and (ii) the thermodynamic and kinetic stability of the protein has to be guaranteed.

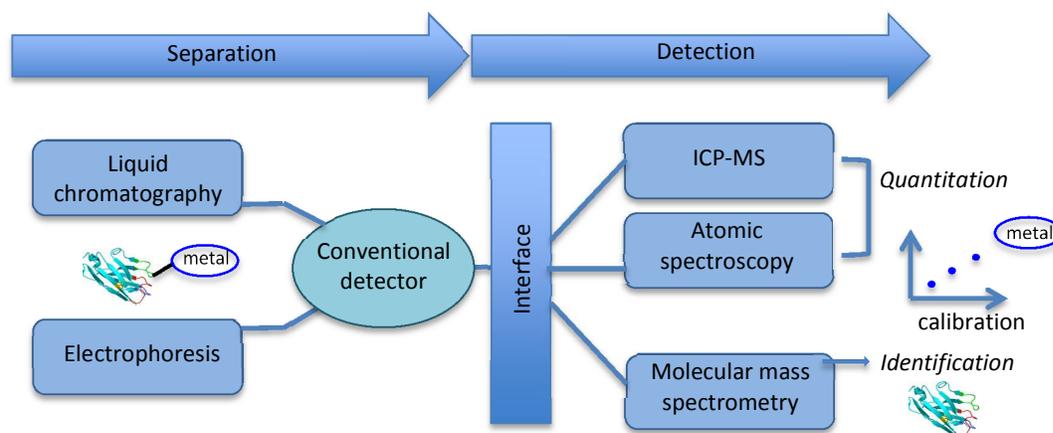

42  
43 21 The aim of this review is to focus on the determination and quantitation of proteins containing a  
44  
45 22 naturally occurring heteroelement (such as Se, Fe, etc.) or after labeling with a metal(loid)s (such as  
46  
47 23 lanthanides, Ru, Hg, I, etc.) using element-specific hyphenated techniques.

48  
49  
50  
51  
52  
53  
54 24

## 1 Hyphenated techniques for proteins / peptides quantitation.

2 Quantitation and bio-speciation studies require the separation step to distinguish each single  
3 species. Among the steps required for proteome analysis (sample preparation, separation of the  
4 proteins or the digested peptides, identification of the proteins and data processing of the huge  
5 information generated) separation is the most challenging due to the high complexity of  
6 protein/peptide samples.

7 The increasing progress in separation techniques for purification and isolation coupled to the  
8 ultrasensitive elemental detectors are the basis of hyphenated analytical methods (Figure 3).  
9

10  
11 **Fig. 3** Schematic workflow showing the information obtainable by hyphenated techniques for the  
12 analysis of heteroelement containing/tagged proteins.

13  
14 For the analysis of metalloproteins and metal-tag proteins the configuration mainly considered is  
15 the on-line hyphenation of a separation technique (high-performance liquid chromatography,  
16 HPLC, or capillary electrophoresis, CE) with an element (moiety, species)-specific detector (in  
17 general atomic spectrometry or ICP-MS).

18 Different modes of HPLC (reversed phase, ion exchange, size exclusion, affinity, hydrophobic  
19 interaction) and CE (capillary zone, isoelectric focusing, isotachopheresis, affinity, micellar) or a

1 combination of both techniques in hyphenated multidimensional formats can be used for the  
2 fractionation and/or separation of peptides. The choice of the hyphenated technique depends on the  
3 characteristic of the system under investigation and on the quantity of sample available. When the  
4 target species have similar physico-chemical properties, the separation component of the  
5 hyphenated system becomes very important. For complex biological matrices, it may even be  
6 necessary to combine in series two or more separation steps. The choice of the detector becomes  
7 crucial when the concentration of analyte species in the sample is very small and low limits of  
8 detection are required.

#### 10 *Electrophoretic techniques*

11 Electrophoresis was first introduced in 1930 by Arne Tiselius, a Swedish chemist.<sup>33</sup> Electrophoresis  
12 is generally employed to characterize a biological system and to select specific protein bands for  
13 sequencing and identification. This technique involves the separation of charged species under the  
14 influence of an applied electric field. In proteins, the charged species can be produced by  
15 dissociation of carboxylic groups or protonation of amino groups, or by uniform coating of proteins  
16 with an anionic surfactant, such as sodium dodecylsulfate (SDS). As a result, SDS imparts the  
17 same free-solution mobility to all proteins, regardless of their identity, so their separation is  
18 controlled only by molecular weight. The charged species moves in a (semi)liquid medium, which  
19 serves as a conducting medium for the generated electric current and it is supported by an inert  
20 substance (paper or a semi-solid gel), where the migration velocity is an important factor.  
21 Polyacrylamide is the most common gel support matrix and it is obtained from the polymerization  
22 of monomeric acrylamide (polyacrylamide gel electrophoresis, PAGE).  
23 Gel electrophoresis with its various formats, such as PAGE, isoelectric focusing (IEF) and  
24 immunoelectrophoresis, offers a number of attractive features for the characterization of  
25 metalloproteins. Protein separation by gel electrophoresis can be performed in one- or two-  
26 dimensions. One-dimension SDS-PAGE may not guarantee the complete dissociation of

1  
2  
3 1 multimeric proteins into their subunits and it may give rise to several labeled bands originating from  
4  
5 2 the same compound, so an orthogonal separation mechanism (2-D) is required. Two-D separations  
6  
7 3 do not require treatment with SDS to modify the sample and the analytes are separated in two stages  
8  
9 4 on the basis of different parameters (e.g. size, charge or hydrophobicity). Proteins are separated in  
10  
11 5 the gradient gel according to the mass-to-charge ratio in the first dimension. A second dimension  
12  
13 6 can be added by isoelectric focusing using pH gradients and separating proteins by their isoelectric  
14  
15 7 points.

16  
17  
18 8 The amount of proteins concentrated in the tiny gel volumes is very small and hardly accessible to  
19  
20 9 standard analytical chemical methods. The first approaches for metal detection in gel are  
21  
22 10 autoradiography, Instrumental Neutron Activation Analysis (INAA), particle induced x-ray  
23  
24 11 emission (PIXE), but currently laser ablation-ICP-MS is the most common.

25  
26  
27 12 Another important approach involving electrophoresis is capillary electrophoresis (CE), which has  
28  
29 13 been applied to protein analyses in the last two decades and has become an important separation  
30  
31 14 tool for chemists and life scientists. Capillary electrophoresis is a high speed and high-resolution  
32  
33 15 separation technique, which requires exceptionally small sample volumes (0.1–10 nL, in contrast to  
34  
35 16 gel electrophoresis, which requires samples in the  $\mu\text{L}$  range). CE can be easily hyphenated with  
36  
37 17 different detection techniques.

38  
39  
40 18 Whereas in CE the separation of small peptides often is relatively straightforward and well  
41  
42 19 understood, it appears that no single strategy is applicable for large peptides and proteins. As might  
43  
44 20 be expected, this is due largely to the wide diversity and complexity associated with these  
45  
46 21 biomolecules. Thus, different strategies often work for different protein separation problems, hence  
47  
48 22 requiring different CE separation modes.

49  
50  
51 23 Capillaries can be filled with a replaceable or fixed solid gel (capillary gel electrophoresis) or with a  
52  
53 24 replaceable running buffer (capillary zone electrophoresis, CZE).<sup>34</sup> CZE has been suggested as a  
54  
55 25 new tool for separation and quantitation of proteins from serum, urine, cerebrospinal fluid, synovial  
56  
57 26 fluid and saliva. CZE combines the separation principles of conventional electrophoresis with the  
58  
59  
60

1  
2  
3 1 advanced instrumental design of high-performance liquid chromatography and capillary  
4  
5 2 technology.<sup>34</sup> The sample is introduced using pressure into a buffer-filled fused silica capillary  
6  
7 3 (internal diameter 20 to 200  $\mu\text{m}$  and lengths of 10-100 cm), either electrokinetically or  
8  
9 4 hydrodynamically. For separation, both ends of the capillary are placed into a buffer solution that  
10  
11 5 contains the electrodes and a high voltage is applied to the system. The applied voltage induces the  
12  
13 6 migration through the capillary of the analytes and through the detector window.<sup>34</sup> The walls of  
14  
15 7 untreated fused silica capillaries are negatively charged in contact with aqueous solution due to the  
16  
17 8 ionisation of surface silanol groups ( $\text{pI}=1.5$ ). The negatively charged silica surface attracts cations  
18  
19 9 from the buffer, creating an electrical double layer. When a voltage is applied across the capillary,  
20  
21 10 cations in the diffuse portion of the double layer migrate in the direction of the cathode, carrying  
22  
23 11 water with them. The final result of the protein separation is affected by capillary length and  
24  
25 12 diameter, buffer composition and pH, sample injection mode, capillary thermostating (Joule heat),  
26  
27 13 separation temperature, electroosmotic flow, solute concentration effects, wall-solute interactions  
28  
29 14 and applied field.

30  
31  
32  
33  
34 15 CZE has been suggested as an alternative for the conventional agarose gel electrophoresis in  
35  
36 16 separating human serum proteins since it allows fast protein separation with good resolution, using  
37  
38 17 only small amounts of sample. The main problem of the protein separation in body fluids with CZE  
39  
40 18 is the effects of sample matrix composition, because the migration time of the same proteins varies  
41  
42 19 significantly depending on the nature of the matrix.<sup>35</sup> Electropherograms are consequently difficult  
43  
44 20 to compare and the peak identification is uncertain.

45  
46  
47 21 Olesik et al. designed the first interface between CZE and ICP-MS.<sup>36</sup> After this various interfaces  
48  
49 22 have been described.<sup>37,38,39</sup>

50  
51  
52 23 Although initial separations of proteomic samples have traditionally been accomplished by  
53  
54 24 electrophoretic techniques, chromatographic separations of intact proteins are becoming attractive  
55  
56 25 alternatives. Electrophoresis limitations are due to the difficulty of the automation of 2-D  
57  
58 26 electrophoresis, low sensitivity, bias against categories of proteins (e.g., membrane proteins) and  
59  
60

1  
2  
3 1 low dynamic range.<sup>40</sup> A good overview of methods and protocols for proteins gel electrophoresis  
4  
5 2 has been published in a book.<sup>41,42</sup>

9 3

#### 10 4 *High-performance liquid chromatography*

11 5 HPLC had a remarkable development in the past two decades. Liquid chromatography has been,  
12 6 traditionally, the basis of most methods for the separation of proteins. Size-exclusion (SE, ion  
13 7 exchange (IE) and reversed-phase (RP) chromatography are the principal HPLC separation  
14 8 techniques used for protein analysis. The separation mechanism of SE chromatography is based on  
15 9 differences in size and tridimensional configuration of proteins.<sup>43</sup> Differences in the global charge  
16 10 of proteins at a certain pH allow the use of ion exchange (IE) chromatography in both cationic and  
17 11 anionic modes<sup>44,45</sup>, while RP chromatography separates proteins on the basis of their different  
18 12 hydrophobicity given by the different polarity of the 20 essential amino acids.<sup>46</sup> Moreover, the  
19 13 presence of specific prosthetic groups permits the separation of protein isoforms with affinity  
20 14 chromatography.<sup>47,48</sup>  
21  
22  
23  
24  
25  
26  
27

29  
30  
31  
32  
33  
34  
35

#### 36 16 *Size-exclusion chromatography*

37 17 The application of a hyphenated technique to the analysis of metal-binding proteins requires that  
38 18 column stationary or mobile phases do not compete with ligands, displacing them from the analyte-  
39 19 metal complex. From this point of view SEC is an excellent chromatographic option for the  
40 20 separation of metal-binding proteins, because this chromatography technique operates in mild  
41 21 conditions. The most widely used types of packing materials are cross-linked dextrans (Sephadex),  
42 22 crosslinked agarose (Sephacryl), cross-linked polyacrylamide (Biogel), cross-linked allyldextran  
43 23 (Sephacryl), controlled pore glass beads and silica.

44 24 However, silica and organic polymer stationary phases tend to absorb proteins through ionic and  
45 25 hydrophobic interactions, respectively, giving non-ideal SEC behaviour.<sup>43,49</sup> So, while the choice  
46 26 of buffer does not affect resolution, salts (e.g. 25-150 mM NaCl) are usually used to reduce the  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 1 electrostatic interactions between proteins and the stationary phase, thus suppressing the residual  
4  
5 2 silanol activity of the column packing. The selected buffer conditions should also avoid  
6  
7 3 inactivation or precipitation, and maintain the stability of biomolecules and target proteins activity  
8  
9 4 and it should be compatible with the detection technique. In the particular case of metal-binding  
10  
11 5 proteins, weak alkaline eluents are recommended to avoid dissociation of metals.<sup>43</sup>

12  
13  
14 6 SE-HPLC shows a good compatibility with ICP and atomic spectrometry both in terms of flow rates  
15  
16 7 (0.7-1 mL min<sup>-1</sup>) and mobile phase composition. Up to 30 m mol L<sup>-1</sup> Tris-HCl was found to be  
17  
18 8 well tolerated ICP-MS applications whereas 20 m mol L<sup>-1</sup> formate or acetate buffer in 10%  
19  
20 9 methanol is acceptable for ESI MS.

21  
22  
23 10 SE-HPLC has the following advantages: i) good separation of proteins from small molecules with a  
24  
25 11 minimal volume of eluate, ii) the use of aqueous eluent phase (that preserves the biological activity  
26  
27 12 of proteins and is tolerated in flame atomic spectroscopy), iii) minimal interaction between proteins  
28  
29 13 and the stationary phase.<sup>50</sup>

30  
31  
32 14 However, the number of theoretical plates in SEC is small and in most cases only 6–8 peaks can be  
33  
34 15 obtained because SEC can resolve only more than a 1.5–2-fold difference in molecular weight.  
35  
36 16 Furthermore, the coupling with ICP-MS is difficult because of the presence of salt in the eluent.  
37  
38 17 The lacks of resolution of this technique is a frequently encountered problems, e.g. in the separation  
39  
40 18 of serum selenoproteins<sup>51</sup> or in the separation of human albumin and transferrin.<sup>52</sup>

41  
42  
43  
44 19

#### 20 *Ion-exchange chromatography*

45  
46  
47  
48 21 Ion-exchange chromatography is based on the reversible interaction between a charged molecule  
49  
50 22 and an oppositely charged chromatography medium. Several side-chain groups of the amino acid  
51  
52 23 residues in proteins (e.g. lysine or glutamic acid) as well as the N-terminal amino and C-terminal  
53  
54 24 carboxyl groups are involved in proteolytic equilibria. The choice of the optimal ion exchanger and  
55  
56 25 separation conditions allows the separation with high resolution of biomolecules with even small  
57  
58  
59  
60

1  
2  
3 1 differences in net surface charge. In biological field, this technique has been widely used for the  
4  
5 2 fractionation of metallothioneins and serum proteins.<sup>43</sup>  
6

7 3 Two common weak exchangers used for protein separation are carboxymethyl (that at neutral pH is  
8  
9 4 ionized as  $-\text{CH}_2\text{OCH}_2\text{COO}^-$  so it is a weak cation exchanger) and diethylaminoethyl group  
10  
11 5 (positively charged at neutral pH, so it is a weak anion exchanger). Two strong exchangers are  
12  
13 6 quarternary amine, which have a non-titratable positive charge, and the sulphonyl group ( $-\text{SO}_3^-$ ).  
14

15  
16 7 The Sepharose types are particularly useful for the separation of high molecular weight proteins.  
17

18 8 Both the immobilized charged groups and the backbone structures of the stationary phase are  
19  
20 9 important in the separation of proteins by IEC, because they may interact with proteins, giving  
21  
22 10 unspecific binding. Cellulose (carboxymethylcellulose and diethylaminoethyl-cellulose) is the most  
23  
24 11 traditional material but also dextran, agarose, silica and polymeric materials have been used as  
25  
26 12 backbone structures.  
27

28  
29 13 Elution is usually performed by increasing salt concentration or changing pH in a gradient, or  
30  
31 14 stepwise. The most common salt is NaCl, but other salts can also be used. The concentration of  
32  
33 15 buffers used in anion-exchange (AE) chromatography of proteins often exceeds  $0.1 \text{ mol L}^{-1}$ , and  
34  
35 16 their use may result in variations of ICP-MS sensitivity because of the clogging of the nebulizer,  
36  
37 17 sampler and skimmer cones, while the percentage of organic solvents usually is not problematic for  
38  
39 18 plasma stabilization. Cation exchange could be more feasible for the coupling with ICP-MS  
40  
41 19 because several millimolar pyridine-formate buffer<sup>53</sup> or citric acid is sufficient to achieve an  
42  
43 20 optimal separation.<sup>54</sup>  
44  
45  
46  
47  
48  
49

## 50 *Reverse phase chromatography*

51  
52 23 Reverse phase (RP)-HPLC is based on proteins solubility and hydrophobicity. All peptides and  
53  
54 24 proteins carry a mix of hydrophilic and hydrophobic amino acids, but those with high net  
55  
56 25 hydrophobicity are able to participate in hydrophobic interactions with the stationary phase. The  
57  
58 26 stationary phase is packed with silica containing covalently bounded silyl ethers with non-polar  
59  
60

1  
2  
3 1 alkyl groups, typically C<sub>8</sub> or C<sub>18</sub>, which create a hydrophobic stationary phase. However, as big  
4  
5 2 proteins are more hydrophobic, it is convenient to use stationary phases with short alkyl chains (C<sub>2</sub>,  
6  
7 3 C<sub>4</sub>) to avoid losses of protein due to their irreversible binding to the solid phase.<sup>49</sup>

8  
9 4 Conversely, the mobile phase contains relatively polar organic solvents such as methanol, butanol,  
10  
11 5 isopropanol or acetonitrile. The use of ion-pairing reagents in the mobile phase (ion-interaction  
12  
13 6 chromatography) permits to extend the application of RP-HPLC to ionic analytes.

14  
15 7 As polar solvents often induce protein denaturation and loss of metals eventually bounded, RPC in  
16  
17 8 general is used for the analysis of small and stable proteins.

18  
19 9 The main disadvantages of RP-HPLC are long chromatographic runs (40–60 min) and the need of  
20  
21 10 modifying the normal working configuration of ICP-MS detector. The introduction of an organic  
22  
23 11 solvent in percentages > 20–30% methanol and 10% acetonitrile at 1 ml/min into the ICP-MS  
24  
25 12 affects negatively the ICP stability, leading to a decrease in signal intensity, and to the deposition of  
26  
27 13 carbon on the cones. This issue can be solved by removing solvent vapor, using a cooled spray  
28  
29 14 chamber or a membrane desolvator accompanied by the addition of oxygen to the plasma gas and  
30  
31 15 the use of platinum cones. Moreover, as the organic solvents modify the plasma ionization  
32  
33 16 conditions, their concentration has a significant effect on the ICP-MS signal intensity. The use of  
34  
35 17 capillary HPLC (4 μl min<sup>-1</sup> flow rate) and nano HPLC (200 nL min<sup>-1</sup> flow rate) is fundamental to  
36  
37 18 control organics-rich mobile phases. The introduction of HPLC eluent at low flow rates allows the  
38  
39 19 introduction up to 100% organic solvent without cooling the spray chamber or the need of oxygen  
40  
41 20 addition.<sup>55</sup>

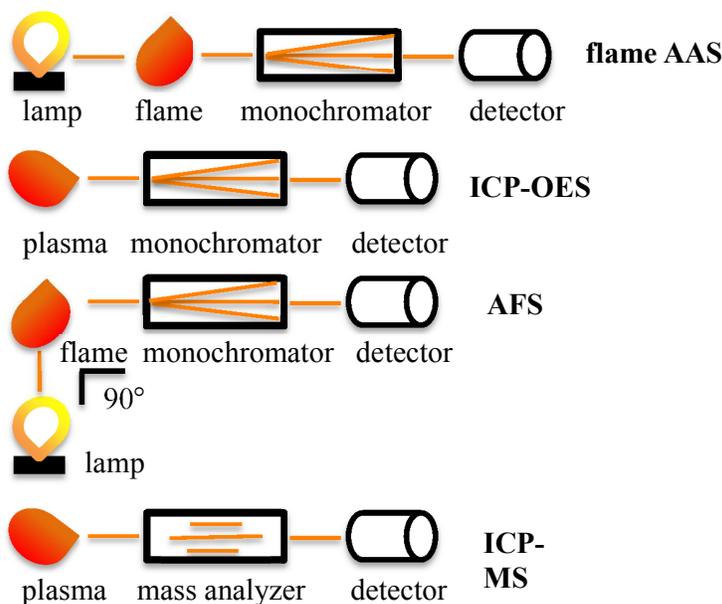

42  
43 21  
44  
45 22 Affinity and hydrophobic interaction chromatography are also employed for protein separation and  
46  
47 23 they can be hyphenated with atomic spectrometric techniques, but not with mass spectrometric  
48  
49 24 detector because of the high concentration of salts typically used in the eluent phase.

50  
51 25 An application of affinity chromatography is the immobilized metal ion affinity chromatography  
52  
53 26 (IMAC), a highly versatile separation method based on interfacial interactions between biopolymers  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 1 in solution and metal ions fixed to a solid support, usually a hydrophilic cross-linked polymer.  
4  
5 2 IMAC is commonly used for fractionation of metalloproteins dependent on their differential  
6  
7 3 binding affinities of the surface exposed amino acids (imidazole, Trp and Cys) towards  
8  
9 4 immobilized metal ion. Metal depleted samples are loaded on an IMAC column/chip saturated with  
10  
11 5 the metal of interest, and proteins with affinity to the metal are recovered and can be analyzed by  
12  
13 6 any of the classical proteomics methods. However, IMAC provides information on the presence of  
14  
15 7 metal-binding sites in proteins but it does not detect eventual endogenous metals. The other  
16  
17 8 drawback of the IMAC technique is that metalloproteins with a high metal affinity site do not  
18  
19 9 interact with column/chip stationary phase and are not detected as the metal sites are already  
20  
21 10 occupied.<sup>56</sup>  
22  
23  
24  
25  
26  
27  
28

## 29 12 *Metals specific detectors*

30  
31 13 Speciation analysis performed by hyphenated techniques is fundamental in analytical science. The  
32  
33 14 added value provided by speciation analysis compared to classical elemental analysis is not only of  
34  
35 15 academic interest, but it is the key to answer important biological questions.  
36  
37 16 Flame atomic absorption spectroscopy (AAS), atomic fluorescence spectroscopy (AFS), inductively  
38  
39 17 coupled plasma (ICP)-optical emission spectroscopy (OES) and ICP-MS are the major element-  
40  
41 18 specific detectors used in chromatography (Figure 4).  
42

57  
58  
59  
60

**Fig. 4.** Schematics of the main element-specific detectors.

The main issues related to the interfacing of a separative technique with a detector are: i) the concentrations of the mobile phase eluting from the separative system (salts and organic solvents) and ii) the efficiency of the sample transfer, which includes the optimization of flow rates, peak broadening and dead volume.

#### *AAS*

Flame atomic absorption spectrometry is the atomic spectrometric technique most widely used for trace element determination. This is due to its easy set up and low running costs, its robustness and few interference issues in the determination of trace elements. AAS is not a truly multi-element technique, but some instruments guarantee the simultaneous analysis of about four elements, which is satisfactory for a number of practical applications. Flame AAS can be straightforwardly coupled with HPLC, and it is compatible both with its flow rates and mobile phase composition (including organic solvent). The sensitivity of flame atomic absorption spectrometry measurements can be

1  
2  
3 1 improved significantly by increasing the efficiency of aerosol generation/transport and prolonging  
4  
5 2 the residence time of the free analyte atoms in optical path. For this reason, several advanced  
6  
7 3 interfaces based on thermospray have been proposed. In the thermospray interface the liquid is  
8  
9  
10 4 transported into the flame furnace by a low or high-pressure pump through a very hot and simple  
11  
12 5 ceramic capillary tip.<sup>57</sup>

13  
14 6 HPLC-AAS was the first hyphenated technique employed for the determination of metal–protein  
15  
16 7 complexes. The major fields of applications include the detection of complexes with metals that  
17  
18 8 give intense response in AAS (Cd, Zn, Cu) or of species that can be converted on-line into volatile  
19  
20 9 hydrides (As, Se, Cd)<sup>58, 59</sup>.

21  
22  
23 10

24  
25  
26 11 *AFS*

27  
28 12 Atomic fluorescence spectrometry represents a suitable alternative to the other atomic and mass  
29  
30 13 spectrometric techniques. AFS is more sensitive than AAS and has a sensitivity similar to ICP-MS  
31  
32 14 (LOD < 1 µg L<sup>-1</sup>) and dynamic linear range between mg L<sup>-1</sup> to µg L<sup>-1</sup> for arsenic, selenium and  
33  
34 15 mercury analysis.<sup>60</sup> Further advantages are its simplicity and lower acquisition and running costs.

35  
36  
37 16 AFS spectrometers are commonly based on the use of non-dispersive instruments, equipped with a  
38  
39 17 discharge hollow cathode lamps as excitation radiation source and often with chemical vapour  
40  
41 18 generation systems. Volatile species of As, Se and Hg, for example, obtained after hydride or vapor  
42  
43 19 generation, are stripped from the solution and delivered by an argon flow to a gas–liquid separator  
44  
45 20 and then atomized and detected in an argon–hydrogen diffusion flame.

46  
47  
48 21 For those chemical species that do not readily form volatile species, such as organometallic species,  
49  
50 22 additional online derivatization steps are needed (e.g. photo-oxidation, pyrolysis or microwave  
51  
52 23 digestion) before hydride or vapor generation.

53  
54  
55 24 Quenching reactions and interferences are the drawbacks of atomic fluorescence spectrometry.

56  
57 25 Quenching occurs when excited atoms collide with other molecules in the atomisation sources. An  
58  
59  
60

1  
2  
3 1 additional disadvantage of “generic” AFS is source scatter and atomizer emission that cause  
4  
5 2 spectral interferences. These are minimal when hydride or vapor generation are used.<sup>60</sup>  
6  
7  
8 3

9  
10 4 *ICP-OES*

11  
12 5 ICP-OES is a powerful analytical tool for the detection of elements. Compared to AAS techniques,  
13  
14 6 ICP-OES enjoys a higher atomization temperature, a more inert environment, and the natural ability  
15  
16 7 to provide simultaneous determinations for up to 70 elements. This makes the ICP less susceptible  
17  
18 8 to matrix interferences, and better able to correct for them when they occur.<sup>61</sup>  
19  
20 9 ICP-OES offers detection limits at the 1 ng ml<sup>-1</sup> concentration level (continuous infusion), which  
21  
22 10 translates into 10–100 ng ml<sup>-1</sup> for a transient signal of an analyte eluted from the column.<sup>62</sup>  
23  
24 11 Because of the absence of cones (in the plasma radial configuration) or for the larger orifices than  
25  
26 12 the cones used in ICP-MS, ICP-OES tolerates complex matrices in terms of salt concentration and,  
27  
28 13 because of higher rf power, organic solvents. Instruments equipped with a polychromator offer the  
29  
30 14 advantage of multi-element analysis.  
31  
32  
33  
34  
35  
36  
37

38 16 *ICP-MS*

39  
40 17 ICP-MS provides excellent analytical characteristics for elemental detection in clinical biomarkers  
41  
42 18 containing heteroatoms, including: (1) elevated sensitivity (detection limits between ng g<sup>-1</sup> and pg g<sup>-1</sup>)  
43  
44 19 and specificity to the heteroatom; (2) multielemental capabilities to simultaneously monitor  
45  
46 20 different metals and heteroatoms associated to a protein; (3) direct isotopic information and  
47  
48 21 quantitations (by isotope dilution analysis); (4) versatility and easy coupling to separation  
49  
50 22 techniques with the aim of monitoring the metal or metalloid associated to a certain protein; (5)  
51  
52 23 minimal matrix effects; (6) capability of up to 8 magnitudes of linear dynamic range.<sup>28</sup>  
53  
54  
55 24 It is not surprisingly that liquid chromatography and ICP-MS is the most common hyphenated  
56  
57 25 system employed for speciation analysis. About 1/3 of all publications are related to LC-ICP-MS.  
58  
59  
60

1  
2  
3 1 The possibility of interfacing HPLC to ICP-MS is strongly dependent on the type of nebulizer  
4  
5 2 employed as sample introduction device. In the simplest form the interface is a conventional  
6  
7 3 pneumatic nebulizer, i.e. a concentric nebulizer (using 1 ml /min for regular bore HPLC flow)  
8  
9  
10 4 connecting the outlet of the column to the liquid sample inlet using an inert polymeric or stainless  
11  
12 5 steel tubing. The length of the tubing has to be minimized to avoid peak broadening. The  
13  
14 6 concentric nebulizer is not so different from the nebulizer described by Gouy at the end of the  
15  
16 7 nineteenth century<sup>63</sup>, but, to overcome the limitations of this interface (i.e. the low transfer  
17  
18 8 efficiency ranging between 1-5%, losses in the spray chamber and, thus, lower sensitivity), a  
19  
20 9 significant number of alternative designs have been published.

21  
22  
23 10 The match of the optimum column flow with the optimum nebulizer flow is critical to achieve both  
24  
25 11 efficient separation and sample nebulization. Any nebulizer has a range of flows over which it  
26  
27 12 produces the highest proportion of fine droplets in the aerosol. This is critical since fine droplets  
28  
29 13 are more efficiently transported through the spray chamber, atomized and ionized in the plasma.  
30  
31 14 Typical HPLC flows ranging from 100  $\mu\text{L}/\text{min}$  to 1  $\text{mL}/\text{min}$  are compatible with conventional  
32  
33 15 concentric nebulizers, either in glass, quartz, or fluoropolymer. At significantly higher flows, part  
34  
35 16 of the sample has to be split off prior to the nebulizer. In general, ICP-MS requires more diluted  
36  
37 17 buffers and tolerates lower concentrations of organic solvents with respect to ICP-OES.<sup>64</sup>

38  
39  
40 18 Conventional nebulizers operate at typical sample flow rates of 0.5–2  $\text{mL min}^{-1}$ . This makes it  
41  
42 19 necessary to have a sample volume available for the analysis ranging from about 1 to 10 mL. The  
43  
44 20 simplest proposed solutions for analysis of micro-samples has been to decrease the liquid flow rate  
45  
46 21 down to 10–300  $\mu\text{L min}^{-1}$ . However, because with conventional pneumatic nebulizers working  
47  
48 22 with these conditions leads to a dramatic loss of sensitivity and an increase in the washout times,  
49  
50 23 new nebulizers have been purposely developed. The development of micro-nebulizers (e.g. direct  
51  
52 24 injection nebulizer, DIN, hydraulic high pressure nebulizers, HHPN, high efficiency nebulizer,  
53  
54 25 HEN, Micro Mist nebulizer, MMN, PFA nebulizer) has increased the use of narrow bore columns  
55  
56  
57  
58  
59  
60

1  
2  
3 1 minimizing the mobile phase introduced into the ICP-MS. So-called micronebulizers are optimized  
4  
5 2 to work at a solution delivery rate below 200–300 mL min<sup>-1</sup>, usually in the range 20–100 μL min<sup>-1</sup>.  
6  
7 3 The direct injection nebulizer (DIN) interface is a microconcentric pneumatic nebulizer without  
8  
9 4 spray chamber, which nebulizes the sample directly into the central channel of the torch. This  
10  
11 5 interface offers several advantages, such as low dead volume, minimization of post-column peak  
12  
13 6 broadening and fast sample washout with minimal memory effects.<sup>65,46</sup>  
14  
15  
16 7 In the hydraulic high pressure nebulizers (HHPN) interface the liquid to be nebulized is pressed  
17  
18 8 through a very fine nozzle of Pt/Ir (20 μm inner diameter) resulting in an aerosol jet with a diameter  
19  
20 9 of a few tenths of a millimetre, which is converted into an aerosol cloud on a converter ball. With  
21  
22 10 the HHPN interface the sensitivity is enhanced by one order of magnitude and the tolerance to high  
23  
24 11 salt concentrations is higher than the pneumatic nebulizer.<sup>66</sup>  
25  
26  
27 12 Laser ablation (LA) coupled to ICP-MS is an apparently cheap and competitive alternative  
28  
29 13 detection technique coupled to gel electrophoresis, which is attractive for the scanning of gels with  
30  
31 14 heteroatom-containing proteins. This technique pioneered by Neilsen et al.<sup>67</sup> consists of the  
32  
33 15 ablation of the analyte with a laser beam guided over the gel within an electrophoretic lane. The  
34  
35 16 ablated analytes are swept into the ICP by a continuous stream of argon, and MS analyses the ions.  
36  
37 17 As a result, an electropherogram is obtained in which the quantity of a given element is a function  
38  
39 18 of its position in the gel. Quantitation by LA-ICP-MS is a fast and robust technology, since the  
40  
41 19 signal is theoretically directly proportional to the quantity of the analyte element in the gel and  
42  
43 20 eliminates the quantitation problems related to the recovery of the protein from the gel.  
44  
45  
46 21 Although imaging LA-ICP-MS methods have been established for the distribution of metals and  
47  
48 22 non-metals in sections of biological tissue, quantitative measurements that use LA are not enough  
49  
50 23 accurate so far as much the hyphenation of HPLC with ICP-MS. The technique is prone to  
51  
52 24 elemental fractionation and other matrix effects so that accurate quantitation still remains difficult.  
53  
54  
55 25 Several approaches for quantitation have been proposed in several works in recent years.<sup>68</sup>  
56  
57  
58  
59  
60

1  
2  
3 1 In his pioneering work Neilsen <sup>67</sup> proposed the use of element-doped gels as standards for external  
4  
5 2 calibration, but, despite a good calibration precision (6% RSD), this approach did not take into  
6  
7 3 account the possibility of inhomogeneous distribution of the analytes within the gel.

8  
9  
10 4 Also, the use of liquid standards has been suggested, but the different characteristics of a nebulised  
11  
12 5 solution and the laser-generated aerosol in ICP leads to another significant source of uncertainty.

13  
14 6 Another approach frequently used in LA is to use the ion signal of a matrix element as internal  
15  
16 7 standard. However, the internal standard and the analyte have to enter the ICP in the same form,  
17  
18 8 which might be unknown.

19  
20 9 For those elements that have at least two or more stable isotopes, accuracy and precision of the  
21  
22 10 quantitation can be considerably improved by isotope dilution analysis (IDA) coupled with ICP-  
23  
24 11 MS. The two principal approaches of IDA include speciated IDA (in which a species-specific spike  
25  
26 12 is used) and non-speciated IDA (when the isotopic spike ignores the speciation of the analyte  
27  
28 13 compounds).<sup>69</sup>

29  
30  
31 14 In the speciated IDA an isotopically labeled analyte species is added to the sample before any  
32  
33 15 sample treatments and/or chromatographic separations incomplete recoveries and matrix effects can  
34  
35 16 be corrected. The use of this approach is limited by the availability of labeled analyte molecules  
36  
37 17 and the equilibration of the spike with the analyte species.

38  
39  
40 18 For most of biomolecules, the isotopically labeled calibration standards are unavailable and the only  
41  
42 19 possibility allowing the improvement of precision and accuracy is the continuous introduction of an  
43  
44 20 isotopically enriched, species-unspecific spike solution after treatment and/or separation step.  
45  
46 21 However, quantitation by this external calibration gives rise to problems as a result of matrix-  
47  
48 22 induced differences in detector sensitivity between standards and samples.

49  
50  
51 23 Species-specific isotope dilution analysis (SS-IDA), that allows the correction of multiple matrix  
52  
53 24 effects, has been proposed for the first time by Kingston in 1990s <sup>70</sup> and has been applied to  
54  
55 25 proteomic studies by Deitrich et al.. They use this approach for the absolute quantitation of  
56  
57 26 superoxide dismutase (SOD) by GE-LA-ICP-MS using <sup>65</sup>Cu and <sup>68</sup>Zn isotopically enriched SOD as  
58  
59  
60

1 a spike. Although unsatisfactory LOD and recoveries were achieved, this work demonstrated the  
2 potentiality of the method for protein quantitation and pointed out some important issues such as the  
3 cross contamination in 1D-PAGE gels or the stability of the metal– protein interactions, two factors  
4 that make the isotope dilution unusable.<sup>71</sup>

5 The use of ICP-MS with IDA as a quantitation methodology has been successfully applied for the  
6 accurate determination of other metalloproteins such as transferrin <sup>72</sup> and haemoglobin <sup>73</sup> in  
7 biological fluids. In all these cases, the concentration calculations are based on the determination of  
8 the metal associated to the protein by IDA after chromatographic separation and assessing the  
9 preservation of the metal: protein stoichiometry during the sample handling and chromatography.

10 A thorough discussion of the IDA method is beyond the scope of this article. Further details are  
11 reported in the review of Bettmer.<sup>74</sup>

12 Table 1 shows the principal advantages and disadvantages of the techniques described here for the  
13 quantitation of metals.

**Table 1.** Typical features for the major metal detection techniques.

<b>Metal detection technique</b>	<b>Advantages</b>	<b>Drawbacks</b>	<b>Sensitivity</b>	<b>Dynamic range</b>
FAAS	Easy to use Fast Cheap Very compact instrument Good performance Robust interface	Moderate detection limits Element limitations 1-10 elements per determination No screening ability Burner-nebulizer system is a relatively inefficient sampling device	100 – 1 $\mu\text{g L}^{-1}$	10 <sup>3</sup>
ICP-OES	Easy to use Multi-element Few chemical interferences Robust interface Good screening abilities Solid and organic samples	Moderate/low detection limits Possible spectral interferences Some element limitations	100 – 0.1 $\mu\text{g L}^{-1}$ (radial) 10 – 0.01 $\mu\text{g L}^{-1}$ (axial)	10 <sup>6</sup>
AFS	High degree of element specificity Relatively free from interferences Separation and pre-concentration of the analytes with vapor/hydride generation Lower acquisition and running costs	Quenching Interferences Source scatter Atomizer emission	0.1 – 0.01 $\mu\text{g L}^{-1}$	10 <sup>3</sup> – 10 <sup>7</sup> depending on the source
ICP-MS	Excellent detection limits Multi-element Wide dynamic range Isotopic measurements Fast semiquantitative screening LA-ICP-MS hyphenation (solids)	Some method development skill required Expensive Some spectral interferences Limited to <0.2% dissolved solids	1 – 0.0001 $\mu\text{g L}^{-1}$	10 <sup>8</sup>

1  
2  
3 1 Although ICP-MS detection is used for quantitation of biological analytes characterized by the  
4  
5 2 presence of natural or added metal-containing fractions, molecular mass spectrometry (MS) is still  
6  
7 3 the main analytical tool used in proteomics for the large-scale identification of proteins. The  
8  
9 4 coupling of chromatographic separation with molecular mass spectrometry has opened the  
10  
11 5 possibility of high-throughput peptide mapping, protein sequencing, and the determination of post-  
12  
13 6 translational modifications of proteins. The availability of different fragmentation approach in  
14  
15 7 MS/MS experiments, such as CID (collision-induced dissociation), ECD (electron capture  
16  
17 8 dissociation) or ETD (electron transfer dissociation), provided highly specific structural  
18  
19 9 information.<sup>75</sup>

20  
21  
22  
23 10 ESI-MS is the most popular method for protein identification because of its powerful MS/MS  
24  
25 11 ability and the easy coupling with liquid chromatography. On the other hand, MALDI mass  
26  
27 12 spectrometry offers higher tolerance toward sample contaminants (such as buffers, salts and  
28  
29 13 surfactants), higher speed of analysis and lower sample consumption for each analysis. On-line  
30  
31 14 coupling of MALDI with liquid separations is relatively challenging as this system requires the  
32  
33 15 continuous delivery of separation effluent to the MALDI interface and the simultaneous co-  
34  
35 16 crystallization of the analyte and matrix. The off-line coupling of MALDI to LC is easier and  
36  
37 17 involves the collection of the eluted fractions from the separation column and their deposition on  
38  
39 18 the MALDI target.<sup>76</sup>

40  
41  
42  
43 19 In the case of labeled proteins, it must be taken into accounts that the labeling may affect the mass  
44  
45 20 and the charge of the proteins. As a consequence, smaller peptides might appear at higher  $m/z$   
46  
47 21 values in ESI-MS, while larger peptides, especially with multiple labels, become too heavy and less  
48  
49 22 suitable for protonation, falling out of the measuring range.<sup>77</sup> On the other hand, labeled protein  
50  
51 23 with metals that have three or more isotopes leads to very characteristic cluster that allow,  
52  
53 24 especially with high resolution mass spectrometry, to identify with high accuracy the  
54  
55 25 protein/peptide.  
56  
57  
58  
59  
60

1  
2  
3 1 Molecular mass spectrometry techniques for proteome analysis has been reviewed in an excellent  
4  
5 2 work by Aebersold and Mann.<sup>78</sup>  
6

7 3  
8 4  
9 5  
10 6 **Proteins quantitation by detection of endogenous metal(loid)s.**

11  
12  
13  
14 7 Approximately one-half of all known protein crystal structures in the protein data bank (PDB,  
15  
16 8 <http://www.rcsb.org>) contains metal ion cofactors, which play vital roles in charge balance,  
17  
18 9 structure, and function.<sup>79</sup> Examination of the PDB shows that Zn is the most abundant, while Fe,  
19  
20 Mg and Ca are also frequently observed, associated with proteins as ferritin (Fe, Cu, Zn),  $\beta$ -amylase  
21  
22 (Cu), alcohol dehydrogenase (Zn), carbonic anhydrase (Cu, Zn) and others.<sup>80</sup>  
23

24  
25 12 Proteins contain several functional groups in the side-chains of amino acids that are particularly  
26  
27 13 well suited for metal coordination. They include cysteine ( $-\text{CH}_2\text{SH}$ ) and methionine ( $-\text{CH}_2\text{CH}_2\text{SCH}_3$ )  
28  
29 14 that bind metals with sulphur affinity (Cd, Cu, Zn), and histidine, whose nitrogen  
30  
31 15 atoms is available for coordination after deprotonation (e.g., Cu, Zn in superoxide dismutase).  
32  
33 16 Peptide-complexed metal ions are known to perform a wide variety of essential specific functions  
34  
35 17 (regulatory, storage, catalytic, transport) associated with life processes.<sup>81</sup>  
36  
37  
38  
39  
40

41 19 **Selenium.**

42  
43  
44 20 Although selenium is not a metal, it is a heteroatom and the quantitation of selenoproteins is an  
45  
46 21 important challenge in the bioanalytical field.

47  
48 22 The human selenoproteome consists of 17 selenoprotein families, some with multiple genes with  
49  
50 23 similar functions. The major Se-containing proteins are selenoprotein P (SeP), sometimes used as  
51  
52 24 a biochemical marker of selenium status, selenoenzymes such as several glutathione peroxidases  
53  
54 (GPx), selenalbumin (SeAlb), thioredoxin reductases (TrxR) and iodothyronine deiodinases  
55  
56 25 (DIO).<sup>82</sup>  
57  
58  
59  
60

1  
2  
3 1 The quantitative concentrations of specific selenium-tagged proteins provide significant information  
4  
5 2 concerning physiological changes, and the relationship between the level of specific selenium-  
6  
7 3 tagged proteins and diseases (as hypertension, coronary heart disease, cancer, asthma and diabetes  
8  
9 4 <sup>83</sup>) has been widely recognized.<sup>84</sup>

10  
11 5 For this reason it is imperative to establish robust, accurate and straightforward analytical  
12  
13 6 approaches suitable for the routine speciation analysis and quantitation of selenoproteins in human  
14  
15 7 serum and plasma. This topic still remains a challenge in physiological research and clinical  
16  
17 8 diagnosis.<sup>85</sup>

18  
19  
20 9 The principal analytical approach developed for the identification and determination of  
21  
22 10 selenoproteins is based on affinity and size exclusion chromatography.<sup>43</sup>

23  
24 11 The main column packing materials for affinity chromatography are based on a heparin–Sepharose  
25  
26 12 or Blue 2-Sepharose, a group of specific adsorbents widely used for serum proteins. Akesson and  
27  
28 13 Martensson showed that heparin interacts with some Se-containing proteins<sup>86</sup> and, after this, they  
29  
30 14 separated plasma selenoproteins into heparin-binding and non-heparin binding fractions.<sup>87</sup>  
31  
32 15 Following this, Deagen et al. succeeded in separating plasma Se-containing proteins into three  
33  
34 16 components using in tandem two affinity columns, a heparin-Sepharose and a reactive blue 2-  
35  
36 17 Sepharose column.<sup>88</sup>

37  
38 18 The main drawback of affinity-HPLC coupled with ICP-MS arise from the poor retention of GPx  
39  
40 19 and hence its co-elution with not retained species, such as Cl<sup>-</sup> and Br<sup>-</sup> (present at high levels in  
41  
42 20 serum), which lead to serious spectral interferences, such as <sup>40</sup>Ar<sup>37</sup>Cl on <sup>77</sup>Se, <sup>79</sup>Br<sup>1</sup>H on <sup>80</sup>Se and  
43  
44 21 <sup>81</sup>Br<sup>1</sup>H on <sup>82</sup>Se. The control of these interferences can be performed offline by serum clean-up  
45  
46 22 using anion exchange solid phase extraction (SPE) and multi-affinity media, or on-line by resolving  
47  
48 23 selenoproteins from Br/Cl by two dimensional HPLC separation employing anion exchange –  
49  
50 24 affinity HPLC (AE-AF-HPLC) before ICP-MS detection.<sup>89</sup> However, these approaches introduce  
51  
52 25 additional steps in the analytical process hence increasing the time of analysis and the uncertainty  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 1 sources, and would be preferable to eliminate the polyatomic interferences with instruments  
4  
5 2 equipped with a reaction cell or using a high-resolution ICP-MS.  
6

7 3 Size exclusion-HPLC is also employed for the analysis of selenoproteins. However, it lacks of an  
8  
9 4 adequate resolution, it cannot allow the separation of the major serum selenoproteins, and the large  
10  
11 5 dilution factor limits the sensitivity of this technique.  
12

13  
14 6 Jitaru et al.<sup>89</sup> quantified selenoproteins in human serum using microbore affinity-HPLC hyphenated  
15  
16 7 to ICP-sector field-MS coupled with on-line (post column) isotope dilution. They compared the  
17  
18 8 method with external calibration by using Se-L-cystine (SeCys) standards and assessed the method  
19  
20 9 accuracy for the determination of total Se-protein by the analysis of a human serum reference  
21  
22 10 material certified for total Se content. This method enables the determination of selenoproteins in 5  
23  
24 11  $\mu$ L of human serum.  
25  
26

27 12 Shigeta et al.<sup>90</sup> reported a method based on micro-affinity chromatography coupled with low flow  
28  
29 13 ICP-MS, which enabled the separation and analysis of selenoproteins in sub- $\mu$ l samples.  
30  
31

32 14 Table 2 shows the most recent chromatographic and detection conditions proposed for the  
33  
34 15 separation of the main Se-containing proteins in plasma.

## 1 **Iron.**

2 Iron is an essential element for life, playing a vital catalytic and structural role in numerous  
3 metalloproteins. Iron is also toxic to cells in its free form and in excessive amounts.<sup>106</sup> Under  
4 physiological conditions, indeed, ferrous ion is highly insoluble and rapidly auto-oxidizes to ferric  
5 iron, catalyzing the formation of highly damaging oxygen radicals able to attack cellular  
6 membranes, proteins and DNA.<sup>107</sup>

7 Under physiological conditions the majority of iron is bound to proteins. The main iron proteins in  
8 humans are globins, hemoglobin and myoglobin, followed by ferritins, and then by a variety of  
9 heme and iron-sulfur proteins where iron cofactors are directly bound to protein, e.g., in  
10 ribonucleotide reductases.

11 The ICP-MS allows a very sensitive and isotope-specific analysis of Fe-proteins, without using  
12 radioactive tracers. It is known that accuracy and precision for the determination of the four  
13 isotopes of iron (<sup>54</sup>Fe 5.8%, <sup>56</sup>Fe 91.7%, <sup>57</sup>Fe 2.14%, <sup>58</sup>Fe 0.31%) by ICP-MS with a conventional  
14 quadrupole analyzer is limited by polyatomic interferences coming from the argon, the atmospheric  
15 gases and the biological material.<sup>108</sup> However, the use of double focusing sector field, ICP-(SF)-  
16 MS, multicollector, MC-ICP-MS, or collision/reaction cell, ICP-(ORS)-MS makes easier the  
17 elimination of such interferences and provides robust, high sensitivity and specific iron detection.<sup>106</sup>

18 Quantitation of Fe-proteins is mainly conducted using post-column isotope dilution – ICP-MS after  
19 their separation by ion exchange or size exclusion HPLC.

20 Table 3 shows the most recent chromatographic and detection conditions proposed for the  
21 quantitation of the main Fe-containing proteins in various types of samples.

**Table 3.** Analytical methods for the species-selective analysis of iron-containing proteins by hyphenated techniques with element-selective detection.

Analyte	Sample type	Separation technique	Detector	Ref.
Myoglobin Ferritin	Raw and cooked beef steak	Size exclusion HPLC	ICP-double-focusing sector field-MS	109
Transferrin	Serum samples from human and harbour seals	Anion exchange HPLC	ICP-octapole reaction cell-MS	110
Transferrin isoforms	Human serum from healthy individuals and alcoholic patients	Anion exchange HPLC	ICP-octapole reaction cell-MS ESI-quadrupole/time of flight-MS	72
Nine transferrin glycoforms	Blood samples of harbour seals	Anion exchange HPLC	ICP-octapole reaction cell-MS	111
Five transferrin isoforms	Human serum	Capillary zone electrophoresis or anion exchange HPLC	UV ICP-octapole reaction cell-MS	112
Myoglobin Holo-transferrin	Proteins standard solutions	Size exclusion HPLC Reversed phase HPLC	ICP-OES Particle beam/hollow cathode-OES	113
$\beta_2$ -transferrin	Cerebrospinal fluid	Anion exchange HPLC	ICP-octapole reaction cell-MS ESI-quadrupole/time of flight-MS	114
Cytochrome C Haemoglobin Transferrin Ferritin	Proteins standard solutions	SDS-PAGE Anodal native PAGE Cathodal native PAGE	ICP-MS	115
Ferritin	Edible plant seeds	Anion exchange HPLC	Sector field-MS	116
Glycated and non-glycated haemoglobin	Human blood from healthy individuals and diabetic patients	Cation exchange HPLC	ICP-octapole reaction cell-MS ESI-quadrupole/time of flight-MS	117

1  
2  
3 **1 Copper.**  
4

5  
6 2 The determination of the free/protein-bound copper ratio is an important subject of research. The  
7  
8 3 knowledge of the copper distribution in biological samples helps understanding the copper  
9  
10 4 metabolism and this contributes to the diagnosis and follow up of the copper related diseases  
11  
12 5 (Wilson and Menkes disease).<sup>118</sup> In Wilson disease, a mutation in the gene ATP7B leads to a  
13  
14 6 dysfunction of ceruloplasmin (Cp), which is the major Cu binding protein.<sup>119</sup> Clinically, serum Cp  
15  
16 7 concentration diminishes and the so-called “free Cu” increases becoming toxic due to Cu deposits  
17  
18 8 in target organs (liver, brain, kidney, and eyes). If not treated, irreversible damages can occur.  
19  
20 9 Quantitation of ceruloplasmin, transcuprein and superoxide dismutase is mainly conducted using  
21  
22 10 ICP-MS after separation in size exclusion columns packed with Sephadex or silica TSKGel.  
23  
24  
25

**Table 4.** Analytical methods for the species-selective analysis of copper-containing proteins by hyphenated techniques with element-selective detection.

Analyte	Sample type	Separation technique	Detector	Ref.
Superoxide dismutase	Tissue samples from bovine liver	Non denaturing 1-D PAGE	LA-ICP-MS	<sup>71</sup>
Four native and recombinant copper proteins	Cell extracts from <i>Escherichia. coli</i> and <i>Synechocystis</i>	Capillary reversed phase HPLC Size exclusion HPLC Anion exchange HPLC	ICP-dynamic reaction cell-MS ESI-time of flight-MS	120
Ceruloplasmin	Human serum from four different diseases and a set of normal controls	Size exclusion HPLC Reversed phase HPLC	ICP-octapole reaction cell-MS ESI-ion trap-MS	121
Transcuprein Ceruloplasmin	Human plasma from healthy subjects and an untreated Wilson disease patient	Size exclusion HPLC	ICP-dynamic reaction cell-MS	122
Albumin-copper Ceruloplasmin	Human serum	Size exclusion HPLC	ICP-quadrupole-MS	123

## 1 **Metallothioneins.**

2 Metallothioneins (MTs) are a group of non-enzymatic low molecular mass (6–7 kDa), cysteine-rich  
3 metal-binding proteins. The interest in the determination and characterization of MT-isoforms  
4 derive from their multifunctional physiological role in homeostatic control, storage, transport and  
5 detoxification of a number of essential (Zn, Cu) and toxic (Cd, Hg) trace metals.<sup>124</sup> Furthermore,  
6 the characterization of MT-isoforms is important in the study of metal-mediated gene expression  
7 mechanism, because they are the product of genetic polymorphism characteristic of MT genes in  
8 animals and humans.<sup>125</sup>

9 Conventional methods used by biochemists for the analysis of MTs include metal-saturation assays,  
10 immunochemical methods such as radio immunoassays or ELISAs and electrochemical techniques  
11 such as differential pulse polarography (DPP).<sup>126</sup> However, these techniques lack in selectivity for  
12 the different MT isoforms, may suffer of interferences, and are unable to provide information on  
13 metal compositions.<sup>127</sup> As a result of genetic polymorphism, indeed, a number of isoforms and sub-  
14 isoforms of MTs, similar in hydrophobicity but slightly different in total electric charge, can be  
15 isolated.

16 HPLC and CE are capable to separate different MT isoforms; however when these techniques are  
17 coupled with UV detection, they suffer of a relatively poor sensitivity and they do not offer  
18 elemental specificity for unequivocal indication of the different forms of the protein bound to a  
19 given metal. Thus, in the last decades, the detection of MTs has been addressed using the coupling  
20 of HPLC and CE with element-specific detectors like atomic spectroscopy and ICP-MS.<sup>128-130</sup>

21 MT isoforms may differ only in few amino acids and therefore their separation requires a high-  
22 resolution technique that is able to separate compounds with very small differences in charge or  
23 hydrophobicity.<sup>131</sup> CE has a great potential in the separation of MT isoforms and sub-isoforms.  
24 Moreover, the small sample volume required (20–30  $\mu$ L) makes CE an ideal technique to analyse  
25 biological material.

1  
2  
3 1 The critical point of CE-ICP-MS coupling is the interface, for two main reasons: the different MT  
4  
5 2 isoforms and sub-isoforms appear very close to each other in the time scale (so a minimum  
6  
7 3 “suction” effect in the nebulizer would degrade the separation achieved), and the metal content  
8  
9 4 present in the different forms of MTs in living organisms is extremely low, so the interface should  
10  
11 5 not compromise the high sensitivity required.<sup>132</sup>  
12

13  
14 6 In their work, Wolf et al. quantified MT-3 in complex biological samples (tissue cytosol) reducing  
15  
16 7 the amount of sample matrix prior to the CZE-separation step with a precipitation step in  
17  
18 8 acetonitrile of the high molecular weight proteins. The remaining matrix material caused a shift in  
19  
20 9 the migration time of the different components, but it was possible to obtain comparable  
21  
22 10 electropherograms by correcting the migration times mathematically using several internal  
23  
24 11 standards.<sup>35</sup>  
25  
26

27 12 An advantage of HPLC compared to CE is its higher sensitivity due to the larger injection volume:  
28  
29 13 a few  $\mu\text{L}$  up to 1 mL in HPLC vs. a few nL in CE.  
30

31  
32 14 In their work, Alvarez-Llamas et al. tested two different interfaces for CE-ICP-MS coupling, based  
33  
34 15 on two commercially available microflow nebulizers (HEN and MicroMist). They found that the  
35  
36 16 interface design was critical in order to keep the separation profile as obtained with UV detection.  
37  
38 17 However, comparing both interfaces, similar performances in terms of sensitivity, linearity of  
39  
40 18 response and resolution were observed.<sup>132</sup>  
41  
42

43 19 In another work, Alvarez-Llamas et al. developed an alternative CE-ICP-MS interface based on  
44  
45 20 chemical volatile species generation (VSG) for the specific detection of Cd bound to MTs, as an  
46  
47 21 alternative to conventional sample introduction systems via nebulisation. They observed an eight  
48  
49 22 times improvement in peak height for Cd detection by VSG as compared to a classic microflow  
50  
51 23 nebulizer. However, in order to make on-line VSG a suitable alternative interface, further studies  
52  
53 24 are necessary to improve the analytical performance of the method (such as to decrease the high  
54  
55 25 background noise derived from the VSG interface).<sup>133</sup>  
56  
57  
58  
59  
60

1  
2  
3 1 Size-exclusion HPLC coupled to ICP-MS or atomic spectroscopy is a valuable tool for the detection  
4  
5 2 of MTs in real matrices. SE-HPLC advantages are the good separation of proteins from small  
6  
7 3 molecules with a minimal volume of eluate, the use of aqueous eluent phase (that preserve the  
8  
9 4 biological activity of proteins) and the minimal interaction between proteins and the stationary  
10  
11 5 phase.<sup>50</sup> However, the coupling with ICP-MS is disadvantageous because of the presence of salt  
12  
13 6 eluent and SE-HPLC has poor resolution: MT-1 and MT-2 isoforms cannot be separated by SE-  
14  
15 7 HPLC whereas the MT-1 peak is clearly resolved from the MT-2 peak with ion-exchange-HPLC  
16  
17 8 and RP-HPLC in modified silica columns (typically C<sub>4</sub>, C<sub>8</sub>, or C<sub>18</sub>).<sup>127</sup> In anion-exchange HPLC  
18  
19 9 MT isoforms can be separated because of their negative charge. MT-1 and MT-2 can be separated,  
20  
21 10 but the sub-isoforms of each class cannot be distinguished because the differences in electric charge  
22  
23 11 are too small.<sup>127</sup>  
24  
25  
26  
27 12 Table 5 summarizes the most recent separation and detection conditions proposed for the  
28  
29 13 quantitation of MTs isoforms in biological samples.

1  
2  
3 1 Some authors compared the separation capability of capillary LC and CE for MTs separation and  
4  
5 2 quantitation, coupling both separative techniques with ICP-MS detectors. The results of these  
6  
7 3 studies, although very similar, supported the use of capillary LC instead of CE<sup>150</sup> but different  
8  
9 4 opinions have been expressed.<sup>151</sup>  
10  
11

### 12 5 13 6 14 7 **Current strategies for proteins and peptides quantitation by metal labeling.**

15  
16  
17 8 Most peptides and proteins are invisible to metal-specific detectors, and, in order to make them  
18  
19 9 detectable by ICP-MS, ICP-OES, AAS or AFS, a proper elemental tag must be employed.<sup>152</sup>  
20

21  
22 10 The quantitation of proteins and peptides using a tag requires:

- 23  
24 11 - the formation of a stable bond between the tag and proteins;
- 25  
26 12 - a quantitative, reproducible and specific reaction;
- 27  
28 13 - mild reaction conditions if the biological activity of the protein must be retained;
- 29  
30 14 - the knowledge of the stoichiometry of the complex.

31  
32  
33 15 In the present review we report four types of common labeling agents: inorganic and organic  
34  
35 16 mercury, iodination tags, metallocene-based reagents and lanthanide-based reagents. The  
36  
37 17 advantages and drawbacks of the various labeling agent described in the subsequent paragraphs are  
38  
39 18 reported in Table 6.

Labeling element	Advantages	Drawbacks	Target sites
Mercury	Highly stable complexes Low blank levels Relatively fast reaction	Toxicity High ionization potential Persistent memory effects	Cysteine
Iodine	Fast labeling reactions Cheap and simple reagent	Not specific labeling Possible oxidative side reactions High background Low sensitivity in ICP-MS	Tyrosine Histidine
Ferrocene	Turn highly polar analytes into less polar Low ppt detection limits Cheap	Isobaric interferences in normal ICP-MS	Cysteine Amino groups
Lanthanides	Low ionization potential Limited interferences Low blank levels	High polarity of protein-complexes Two-step reaction	Cysteine Amino groups

1

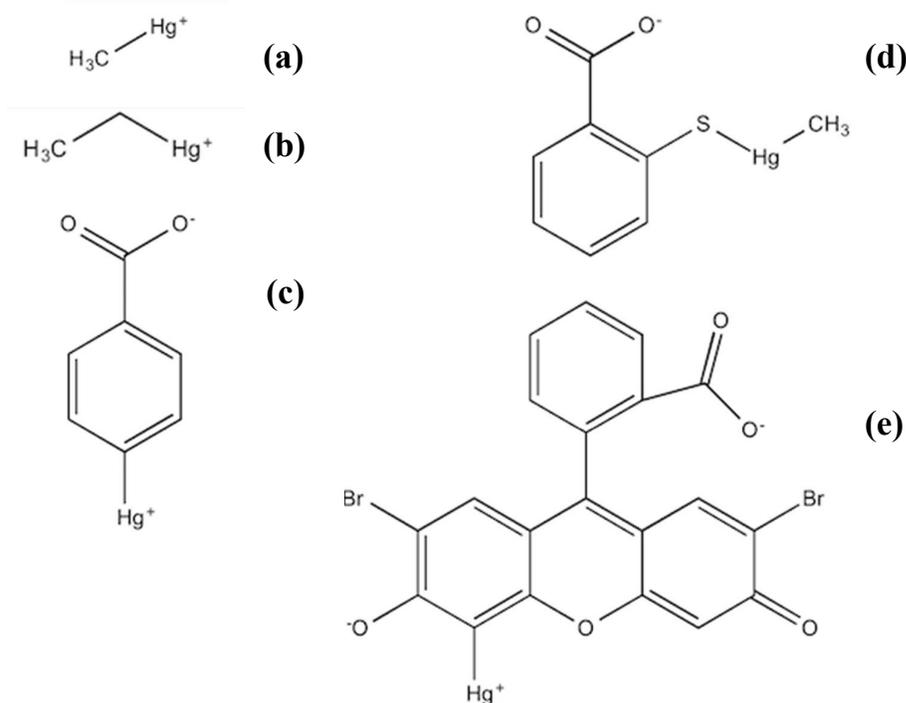

## 2 Inorganic and organic mercury.

3 The interaction between mercury and biological thiols (low molecular thiols, i.e. cysteine or  
4 glutathione, and proteins) have been extensively studied since the 90s,<sup>153</sup> but only in the last decade  
5 the quantitation of proteins and peptides has become significant.

6 The combination of the high affinity of inorganic and organic mercury ( $\text{Hg}^{\text{II}}$  and  $\text{RHg}^+$ ) for the  
7 sulfhydryl group (-SH) in the 1–13 pH range and the presence of cysteine in about 70% of proteins  
8 of proteome<sup>154</sup> makes possible the use of mercury for analytical purposes.<sup>155</sup>

9 The reaction of mercury with –SH group has been extensively investigated: it belongs to the soft–  
10 soft interactions, it is exothermic and thermodynamically favorable, with average bond energy of  
11  $217 \text{ kJ mol}^{-1}$  for Hg-S.<sup>153,156,157,158</sup> In the protein labeled with organic mercurial probe, Hg is  
12 associated to C atom (in the organic moiety) at an average distance of  $2.03 \pm 0.02 \text{ \AA}$  and to S atom  
13 (in the –SH) at an average distance of  $2.34 \pm 0.03 \text{ \AA}$ , clearly indicating the formation of a Hg–S  
14 covalent bond.<sup>159, 160</sup> The standard entropy change is also very favorable for the labeled protein and  
15 the final complex is characterized by a large stability constant (e.g. for ethylmercury the stability

1  
2  
3 1 constant varies from  $10^{16.3}$  to  $10^{16.7}$ ).<sup>161</sup> This makes the labeled proteins stable adducts during  
4  
5 2 chromatographic separations.<sup>162</sup>  
6  
7 3 Bramanti et al.<sup>163</sup> employed  $\text{HgCl}_2$  to study the behavior of  $\text{Hg(II)}$  and  $\text{Hg(II)}$ -thiol complexes with  
8  
9 4 chemical vapor generation (CVG)-AFS detector in different reducing media.  $\text{HgCl}_2$  is highly  
10  
11 5 soluble in aqueous solution under physiological conditions and is highly specific for -SH groups,  
12  
13 6 reacting readily without requiring any incubation time or excess reagent and interfering with the  
14  
15 7 protein molecular structures less than larger hydrophobic compounds (organic compounds of  
16  
17 8 mercury, fluorescent labels, etc.).<sup>163</sup> However, inorganic mercury has the drawback of adsorbing to  
18  
19 9 many chromatographic stationary phases<sup>164</sup> and of forming several mercury-thiol complexes with  
20  
21 10 different stoichiometry, where  $\text{Hg(SR)}_2$  and  $\text{Hg}_2(\text{SR})_2$  are the most commonly observed.<sup>155</sup>  
22  
23 11 Mono-functional organic mercurial probes ( $\text{MFOHg}^+$ ) like alkyl and phenylmercury compounds of  
24  
25 12 the type  $\text{RHg}^+$  do not present the latter inconvenient and they specifically react at room temperature  
26  
27 13 with active sulfhydryl groups forming stable, soluble and covalently bounded complexes of defined  
28  
29 14 1:1 stoichiometry ( $-\text{S-Hg-R}$ ).<sup>157</sup>  
30  
31  
32  
33  
34 15 Several studies show the advantages of using organic mercurial compounds, such as methylmercury  
35  
36 16 ( $\text{MeHg}^+$ ), ethylmercury ( $\text{EtHg}^+$ ) and 4(hydroxymercuric)benzoic acid (*p*HMB) (Figure 5).<sup>157,164</sup>

1

2 **Fig 5.** Structures of the organic mercurial probe used to tag cysteine-containing proteins. (a)  
 3 methylmercury; (b) ethylmercury; (c) *p*HMB; (d) methylmercurithiosalicylate; (e) 2,7-dibromo-  
 4 4hydroxymercurifluoresceine disodium.

5

6 Over the last 10 years Bramanti et al., extensively studied the interaction between *p*HMB and  $-\text{SH}$   
 7 groups for analytical and diagnostic purposes in proteins,<sup>163-167</sup> low molecular weight thiols,<sup>168-170</sup>  
 8 mercaptans,<sup>170</sup> metallothioneins<sup>165</sup> and nitrosothiols<sup>168, 169, 171</sup> by means of liquid chromatography  
 9 coupled to CVG-AFS, a sensitive, selective and relatively inexpensive technique for mercury  
 10 determination.

11 Xu et al.<sup>162</sup> using size exclusion HPLC-ICP-MS studied the size-dependent effects of  
 12 monofunctional organic Hg ions ( $\text{MFOHg}^+$ ), including  $\text{MeHg}^+\text{Cl}^-$  (4.84 Å),  $\text{EtHg}^+\text{Cl}^-$  (6.06 Å),  
 13 *p*HMB (9.65 Å), and 2,7-dibromo-4hydroxymercurifluoresceine disodium (Merbromin, 12.03 Å)  
 14 on the labeling efficiency toward the sulfhydryl in intact proteins taking  $\beta$ -lactoglobulin as a model.  
 15 Kinetic studies showed that the labeling reaction rate constants of  $\text{MFOHg}^+$  are in the order

1  
2  
3 1  $\text{CH}_3\text{Hg}^+ > \text{CH}_3\text{CH}_2\text{Hg}^+ > p\text{HMB} > \text{Merbromin}$ , which is in agreement with the increased trend in  
4  
5 2 their size, suggesting that the smallest  $\text{CH}_3\text{Hg}^+$  is the most effective agent for  $\beta$ -lactoglobulin  
6  
7 3 labeling.

8  
9  
10 4 Considering the toxicity of  $\text{CH}_3\text{Hg}^+$ , Xu et al. searched for a  $\text{CH}_3\text{Hg}^+$ -equivalent tag, and  
11  
12 5 synthesized methylmercurithiosalicylate ( $\text{CH}_3\text{Hg-THI}$ ) and  $^{204}\text{Hg}$ -enriched  
13  
14 6 methylmercurithiosalicylate ( $\text{CH}_3^{204}\text{Hg-THI}$ ) for protein labeling.<sup>172</sup> The labeling strategies have  
15  
16 7 been applied to the separation and detection of glutathione,  $\beta$ -lactoglobulin and ovalbumin as model  
17  
18 8 peptide/proteins by SEC-ICP-MS and the absolute quantitation was conducted with isotope labeling  
19  
20 9 strategies.

21  
22  
23 10 Kutscher and Bettmer<sup>173</sup> developed a procedure for the absolute and relative quantitation of insulin  
24  
25 11 as a model protein based on the synthesis of  $^{199}\text{Hg}$ -enriched  $p\text{HMB}$ . Their approach was divided  
26  
27 12 into two different steps: the first was based on the differential isotope labeling to compare two  
28  
29 13 different samples for their relative quantitation using MALDI-MS followed by the deconvolution of  
30  
31 14 the isotope pattern. The approach was extended to the absolute protein quantitation, by  
32  
33 15 characterizing isotopically labeled insulin by ICP-MS and by adding it to the sample as an internal  
34  
35 16 standard. Proteins labeled with either  $[^{199}\text{Hg}]p\text{HMB}$  or  $[^{\text{nat}}\text{Hg}]p\text{HMB}$ , can be easily distinguished  
36  
37 17 by the observed isotope pattern provided by MALDI-MS. The main advantage of this approach is  
38  
39 18 that the isotopically labeled protein used as internal standard can be independently quantified by  
40  
41 19 ICP-MS on the basis of the reverse isotope dilution analysis of mercury (a common and accurate  
42  
43 20 quantitation method for isotopically labeled species), whereas molecular mass spectrometry allows  
44  
45 21 the detection and quantitation of  $[^{\text{nat}}\text{Hg}]p\text{HMB}$  labeled protein.

46  
47  
48  
49 22 Cold vapour generation coupled with atomic spectrometry is traditionally the technique most  
50  
51 23 widely used for mercury determination.<sup>174, 175, 176</sup>

52  
53  
54 24 Among the atomic spectrometric techniques, CVG-AFS is the most sensitive, selective, and low-  
55  
56 25 cost technique for mercury detection reaching detection limits (LOD)  $\leq 0.1 \text{ ng/L}$ .<sup>177</sup> Cold vapor-  
57  
58 26 AFS has also the advantage of being free of interference from any other vapor or hydride forming  
59  
60

1  
2  
3 1 elements. However, the direct introduction of organic mercury into the detector lowers the CVG-  
4  
5 2 AFS performance, so this technique usually requires the use of decomposition systems for the  
6  
7 3 conversion of organomercury species to  $\text{Hg}^{\text{II}}$ , before their introduction into the AFS detector. Thus,  
8  
9 4 online decomposition systems are mandatory to obtain higher sensitivity and reproducible results  
10  
11 5 using atomic spectrometric detectors. Decomposition systems include (i) chemical oxidants (the  
12  
13 6 more common include  $\text{KBr}/\text{KBrO}_3$ <sup>178,179</sup>,  $\text{K}_2\text{S}_2\text{O}_8$  in presence of copper sulphate<sup>180</sup> and  $\text{K}_2\text{Cr}_2\text{O}_7$ <sup>181</sup>)  
14  
15 7 and (ii) UV irradiation assisted<sup>182</sup> or not<sup>183,184</sup> by microwaves (MW).

16  
17  
18 8 The latter has introduced a novel “green strategy” in the analytical determination of mercury,  
19  
20 9 leading to the digestion of mercury species without the use of toxic and carcinogenic chemicals.

21  
22  
23 10 The mixture  $\text{Br}^-/\text{BrO}_3^-$ , for example, has the advantage of being performed at room temperature but  
24  
25 11  $\text{BrO}_3^-$  is a reagent classified as carcinogenic. Furthermore, bromine is a fluorescence quencher and  
26  
27 12 the generated excess has to be reduced into bromide during the subsequent reducing step by  
28  
29 13 hydrazine, a compound classified as carcinogenic, flammable, toxic by inhalation, in contact with  
30  
31 14 skin and if swallowed, and very toxic to aquatic organisms.<sup>185</sup> Falter and co-workers adopted UV  
32  
33 15 irradiation to decompose organic mercury.<sup>186</sup> Bendicho et al. have reviewed in an excellent work  
34  
35 16 the photo-oxidation and photoreduction of mercury and other elements.<sup>187</sup>

36  
37  
38 17 Tang et al.<sup>188</sup> proposed UV/ $\text{HCOOH}$ -induced Hg CVG as an effective interface between HPLC and  
39  
40 18 CVG, instead of  $\text{K}_2\text{SO}_8\text{-KBH}_4/\text{NaOH-HCl}$  and/or  $\text{KBrO}_3/\text{KBr-KBH}_4/\text{NaOH-HCl}$  systems as  
41  
42 19 oxidizing/reducing system for the simultaneous determination of low molecular mass thiols tagged  
43  
44 20 with *p*HMB. Other authors proposed acidic  $\text{K}_2\text{S}_2\text{O}_8$  solution combined with microwave (MW)  
45  
46 21 digestion<sup>189</sup> or MW digestion in acidic conditions.<sup>190</sup>

47  
48  
49 22 Recently, Angeli et al.<sup>185</sup> have proposed a novel HPLC-MW/UV combined reactor coupled to  
50  
51 23 CVG-AFS detection system for the determination of *p*HMB-tagged thiols. The use of a fully  
52  
53 24 integrated MW-UV photochemical reactor<sup>190,191</sup> allowed to obtain the on-line digestion of *p*HMB  
54  
55 25 and thiols- *p*HMB complexes to  $\text{Hg}(\text{II})$ .  $\text{Hg}(\text{II})$  was reduced to  $\text{Hg}^0$  in a knitted reaction coil with  
56  
57 26  $\text{NaBH}_4$  solution, and detected by AFS. The integrated photochemical reactor is able to measure and  
58  
59  
60

1  
2  
3 1 control the MW power working on the sample during experiments and overcome the large amount  
4  
5 2 of drawbacks given by reactors placed in a microwave oven, or in a waveguide applicator working  
6  
7 3 at 2450 MHz <sup>191 192</sup>, or by an immersed electrodeless MW/UV lamp.<sup>185</sup>  
8

9  
10 4 In the last years ICP-MS has become an attractive tool for the determination of mercury, as shown  
11  
12 5 by the growing number of papers that use this technique as detector for mercury. Unfortunately, the  
13  
14 6 relatively high ionization potential of mercury and persistent memory effects seriously limit the  
15  
16 7 attractiveness of mercury compounds for routine analysis with ICP-MS.

17  
18 8 Table 7 summarizes the most recent separation and detection conditions proposed for the  
19  
20 9 quantitation of mercury-tagged proteins in biological samples

## 1 Iodination tags.

2 Among the ICP-MS-detectable halogens, only iodine has been used as labeling agent for protein  
3 derivatization, because the determination of other halogens is affected by low ionization  
4 efficiency.<sup>198</sup> Iodination proceeds with electrophilic substitution of iodine to the aromatic side  
5 chains of histidine and tyrosine (about 50%) (Figure 6), so this labeling it is not specific for only  
6 one functional group in a protein. Nevertheless, a recent work that uses the more complex  
7 iodination-reagent bis(pyridine)iodonium tetrafluoroborate demonstrated the complete and  
8 specific derivatization only of tyrosine residues in standard peptides.<sup>199</sup>

9 Iodination is a long known method and has been applied in particular for the incorporation of  
10 radioactive <sup>125</sup>I or <sup>127</sup>I and detection by ICP-MS. This type of labeling offers some advantages,  
11 such as fast labeling reactions (2–15 min) and the use of a cheap and simple reagent like sodium  
12 iodide after its oxidation to I<sup>+</sup>.<sup>200</sup> The reaction is possible at two different sites: at the orthoposition  
13 of tyrosine and at the 2, 5 positions of the imidazole-ring of histidine.<sup>201</sup>

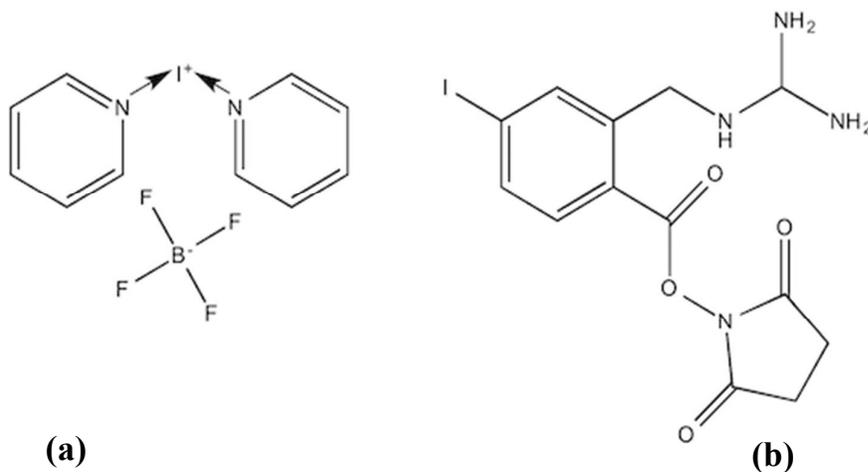

14  
15 **Fig 6.** Schematic protein chain with tyrosine and histidine derivatized with iodine.

16  
17 The iodination process should provide both labelling efficiency and, when required, the  
18 preservation of the protein activity. A possible drawback is the occurrence of oxidative side  
19 reactions such as the oxidation of methionine and tryptophan residues during the iodination

1  
2  
3 1 process.<sup>202</sup> For this reason, specific reagents and procedures have been designed with the aim of  
4  
5 2 minimizing these negative side effects on protein function and structure. For example, iodination  
6  
7 3 by means of chloramine T (N-chloro 4-methylbenzenesulfonamide, sodium salt) and in particular of  
8  
9 4 immobilized chloramine T has been claimed to be a protein structure preserving method.<sup>203</sup>  
10  
11 5 An alternative approach to label proteins with iodine is indirect labelling using iodine-containing  
12  
13 6 compounds that can be coupled to proteins *via* their functional groups, thus avoiding the direct  
14  
15 7 contact of proteins with iodine species. For this purpose, iodinated Bolton-Hunter reagent, N-  
16  
17 8 succinimidyl-3-(4-hydroxyphenyl)- propionate, is used, which binds to the amino group of lysine  
18  
19 9 side chains (Figure 7).<sup>204</sup> Besides this, the well known reagent N-succinimidyl-3-iodobenzoate as  
20  
21 10 well as N-succinimidyl 4-guanidinomethyl-3-iodobenzoate were successfully applied.<sup>205,206</sup>  
22  
23 11 Pereira Navaza and his co-workers <sup>199</sup> reported the labelling of tyrosine residues by  
24  
25 12 bis(pyridine)iodonium tetrafluoroborate (IPy<sub>2</sub>BF<sub>4</sub>) (Figure 7) for quantitative detection of  
26  
27 13 polypeptides using  $\beta$ -casein, a well-characterized protein, as a model. Two iodine atoms are  
28  
29 14 specifically bioconjugated to the meta-positions of the aromatic ring of every tyrosine residue.  
30  
31 15 Characterization studies performed by capillary HPLC with parallel ICP-MS and ESI-MS/MS  
32  
33 16 detection clearly demonstrated that the tyrosine residues present in the peptide are completely  
34  
35 17 diiodinated. They optimized the proposed method for tyrosine labeling and then they performed the  
36  
37 18 validation by applying the method to the absolute quantitation of  $\beta$ -casein after tryptic digestion  
38  
39 19 and of three standard peptides present in a reference material.  
40  
41 20 Jakubowski et al. explored the use of immobilized chloramine T (IODO-Beads<sup>TM</sup>) to label intact  
42  
43 21 proteins with the iodine isotope <sup>127</sup>I, followed by protein electrophoresis and electro-blotting and  
44  
45 22 detection by LA-ICP-MS.<sup>207</sup> Unfortunately, laser ablation requires harsh conditions and the results  
46  
47 23 obtained demonstrated that the labeling process on the separated spotted proteins was neither  
48  
49 24 quantitative nor site-specific. Additionally, oxidation of methionine residues were observed, which  
50  
51 25 implies the risk of affecting the functionality of proteins.  
52  
53  
54  
55  
56  
57  
58  
59  
60

1 Waeting et al. in their work compared a mild protein iodination by  $KI_3$  with the IODO-Beads  
2 method, demonstrating, by labeling single proteins, whole proteome and antibodies, that the  
3 labeling with  $KI_3$  is fast, cheap and efficient for ICP-MS based analytics.<sup>208</sup>

5 **Fig 7.** Structures of two iodination tags. (a):  $IPy_2BF_4$ <sup>199</sup>; (b): N-succinimidyl 4-guanidinomethyl-3-  
6 iodobenzoate<sup>204</sup>.

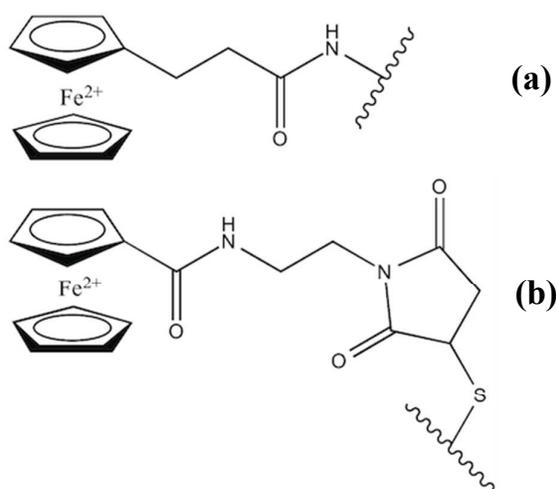

7  
8  
9 The sensitivity of iodine in ICP-MS detection and a considerable background of natural iodine  
10 contained in some biological samples are general drawbacks of iodine labelling.<sup>209</sup> The sensitivity  
11 (100–1000 ng/L) is 3–4 orders of magnitude lower than that observed for lanthanides because of  
12 iodine high ionization energy (10.45 eV). The energy transferred by the plasma is sufficient to  
13 excite only a minor fraction of halogens atoms and ions, which leads to only about 29% of ionized  
14 iodine in argon plasma,<sup>209</sup> and consequently higher LODs are typically reached.

### 15 **Metalocene-based reagents.**

16  
17 Metalloenes are compound with general formula  $M(C_5H_5)_2$ , containing two cyclopentadienyl  
18 anions bound to a transition-metal center (M) usually in the +2 oxidation state.

1  
2  
3 1 Ferrocene, an iron(II) complex of low polarity, is the best known and representative metallocene  
4  
5 2 compound.<sup>210,211</sup> A unique property of metallocenes is the possibility of introducing substituents on  
6  
7 3 one or both the cyclopentadienyl rings, although it retains the properties of a simple one-electron  
8  
9 4 redox couple.<sup>212</sup>  
10  
11 5 Their detection by ICP-MS under normal conditions suffers the formation of the isobaric [<sup>40</sup>ArO]<sup>+</sup>  
12  
13 6 ion (m/z 56 cannot be discriminated from the respective main isotope of iron <sup>56</sup>Fe at low resolution),  
14  
15 7 which leads to moderate LODs.<sup>213</sup> Hence, a resolution over 2500 would be needed to separate <sup>56</sup>Fe  
16  
17 8 from [<sup>40</sup>ArO]<sup>+</sup>, which is achievable by sector-field (SF) instrument. On the other hand quadrupole  
18  
19 9 instruments equipped with a hexapole or octapole reaction or collision cell can almost entirely  
20  
21 10 eliminate the argon interferences. Combined with a reaction or collision cell, the ICP-quadrupole  
22  
23 11 MS can give low ppt detection limits for iron in bulk analysis, which are about the same or slightly  
24  
25 12 higher than those obtained with ICP-SF-MS instrument.<sup>214</sup> Works based on reversed phase/size  
26  
27 13 exclusion-HPLC-ICP-MS measurements have been published for the analysis of ferrocene-  
28  
29 14 derivatized lysozyme,  $\beta$ -lactoglobulin A and insulin.<sup>215</sup>  
30  
31  
32 15 The ability of different metallocenes to react with amino acid side chains of proteins was mentioned  
33  
34 16 for the first time in 1972 by Giese et al.<sup>216</sup> However, the derivatization of functional groups in  
35  
36 17 proteins with metallocene derivatives was published for the first time by Peterlik, who analysed the  
37  
38 18 reaction of ferrocenesulfonyl chloride with ovalbumin using the X-ray structure analysis. In that  
39  
40 19 work an average of 8.6 out of the total 20 lysines in the protein structure were derivatized.<sup>217</sup>  
41  
42 20 Many ferrocene-based derivatizing agents have been proposed and used in combination with liquid  
43  
44 21 chromatography and electrochemical detection (i.e. amperometry or voltammetry). Eckert and  
45  
46 22 Koller synthesised several ferrocenes for the derivatization of the N-terminus and lysine residues in  
47  
48 23 peptides and proteins and tested them in the reaction with bovine serum albumin followed by LC-  
49  
50 24 electrochemical detection analysis.<sup>218</sup> AAS as well as ICP-OES or ICP-MS were also proposed as  
51  
52 25 detection techniques for ferrocene derivatives.<sup>212</sup>  
53  
54  
55  
56  
57  
58  
59  
60

1 Bomke et al. <sup>215</sup> applied for the first time the ferrocene-based reagent succinimidylferrocenyl  
2 propionate (SFP) as dual labelling reagent for amino and thiolic groups present in peptides and  
3 proteins. The previously reduced thiolic groups were functionalised with ferrocenecarboxylic  
4 acid(2-maleimidoyl)ethylamide (FMEA) at pH 7, and subsequently the amino groups were  
5 derivatized with SFP at pH 9 (Figure 8). The derivatized biomolecules were analysed using  
6 reversed phase HPLC coupled with ESI-MS and ICP-MS.

7  
8 **Fig 8.** Amino (a) and thiolic (b) groups derivatized respectively with SFP and FMEA.

9  
10 All 6 lysine residues and the N-terminus present in the basic protein lysozyme were quantitatively  
11 derivatized by SFP. However, as the reaction proceeded, also the basic side chain of histidine and  
12 arginine reacted with the ferrocene-based reagent. With acidic proteins, as insulin and  $\beta$ -  
13 lactoglobulin A, a distribution of different labelling degrees was achieved but in both cases no  
14 underivatized proteins remained.

15 They subsequently applied the dual labeling approach to the tripeptide glutathione and insulin. This  
16 new approach of the multiple labelling leads to a strong increase of quantifiable information and,  
17 independently on the reagents used for the labelling process, it is a promising tool for bioanalysis in

1  
2  
3 1 the future. Using this strategy the discrimination between amino and thiol groups on the same  
4  
5 2 peptide by ICP-MS is not possible.

6  
7 3 The FMEA reagent has also been employed by Braütigam et al. to derivatize several phytochelatins  
8  
9 4 and thiolic species (PC<sub>2-4</sub>, CysGSH, CysPC<sub>2-4</sub>, CysPC<sub>2</sub>desGly, CysPC<sub>2</sub>Glu and CysPC<sub>2</sub>Ala) from  
10  
11 5 algal extracts. PCs are peptides with the general structure (GluCys)<sub>n</sub>Gly, and their identification  
12  
13 6 and quantification is essential for physiological studies. After the derivatization, the phytochelatins  
14  
15 7 have been identified with HPLC-MS/MS and quantify by ICP-MS. However, they did not observe  
16  
17 8 a constant Fe signal in ICP-MS by gradient elution and they did not obtain a baseline separation of  
18  
19 9 the derivatized PC by isocratic separation. Thus, a species independent Fe determination by  
20  
21 10 LC/ICP-MS was not possible and the quantification was performed with the help of standard  
22  
23 11 compounds. Besides the identification of canonic phytochelatins, they confirmed the presence of  
24  
25 12 PC<sub>3</sub>desGly, which was only proposed before.<sup>219</sup>

26  
27 13 Tanaka et al.<sup>220</sup> developed an on-chip type cation-exchange chromatography system with  
28  
29 14 electrochemical detection of HbA<sub>1c</sub>, which is one of the most important marker protein in diabetes,  
30  
31 15 using ferrocene-conjugated antihuman hemoglobin (Hb) monoclonal antibody (FcAb). Ferrocene-  
32  
33 16 conjugated anti-human haemoglobin monoclonal antibody, which can react with all Hbs, was used  
34  
35 17 as an electrochemical probe, and an optimized 15 minutes procedure allowed the separation of  
36  
37 18 HbA<sub>1c</sub> from other Hbs in blood samples.

38  
39 19 Table 8 summarizes the analytical methods for the species-selective analysis of proteins tagged with

1  
2  
3 1 **Metal-coded affinity tag.**  
4 2

5 3 Other interesting labeling strategies use bi-functional chelating agents loaded with different  
6  
7 4 lanthanide ( $\text{Me}^{3+}$ ) ions and a second functional group for specific covalent interaction with the  
8  
9 5 target biomolecule (cysteine residues or amino groups in the case of NHS-ester derivatives). The  
10  
11 6 lanthanide series ranges from Ce to Lu (where La and Y are often included because of their similar  
12  
13 7 chemistry) and they differ primarily in their ionic radii, which show a decrease along the series  
14  
15 8 (lanthanide contraction).<sup>223</sup> By using different lanthanides within the chelate complex, different  
16  
17 9 proteomic states or samples can be assessed.  
18  
19

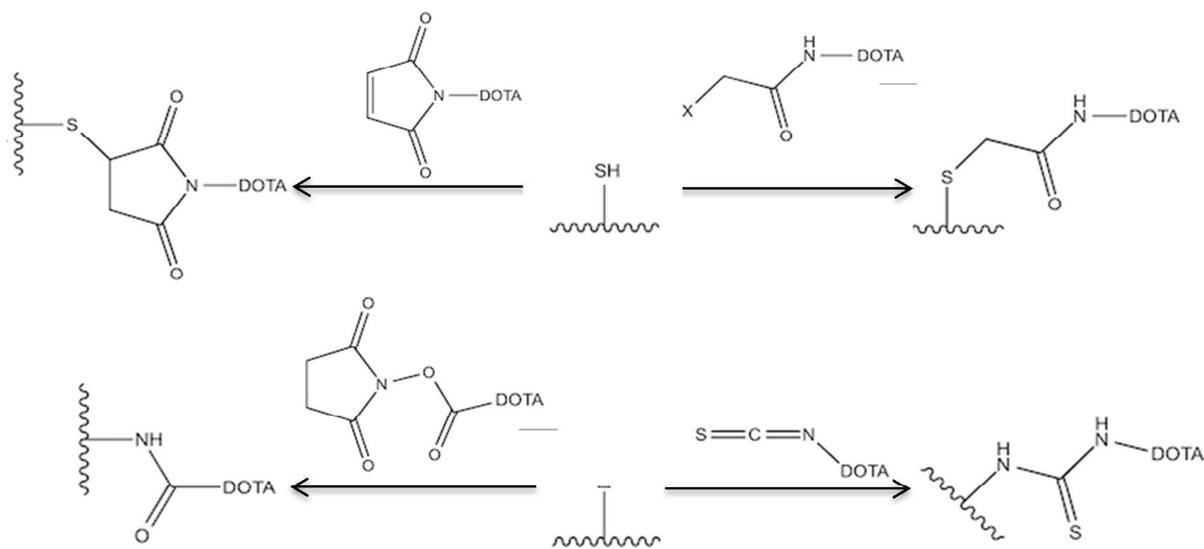

20 10 The strategy of protein labeling based on rare earth metal is an excellent method for protein  
21  
22 11 quantitation because of its unique advantages. First, the elemental labeling for protein quantitation  
23  
24 12 can be applied not only for biological mass spectrometry, but also combined with ICP-MS, enabling  
25  
26 13 the absolute determination of proteins and peptides via the measurement of the incorporated  
27  
28 14 lanthanide ion without the need for a structurally related standard. Second, the rare earth metal  
29  
30 15 chelated tags are inexpensive and can be easily obtained, compared with the stable isotope-labeling  
31  
32 16 agents.<sup>224</sup>  
33  
34  
35

36 17 As detector for rare-earth elements, ICP-MS has major detection capabilities due to (i) the low  
37  
38 18 ionization potential of these elements, (ii) their high mass, so doubly charged species of other  
39  
40 19 elements does not interfere with them and (iii) the low blank values due to their low natural  
41  
42 20 abundance in biological samples.<sup>225</sup> Absolute quantitation of rare earth labeled peptides and  
43  
44 21 proteins can be achieved by external calibration using salt standards, as element signals in ICP-MS  
45  
46 22 are largely matrix independent and they have up to 12 decades of linear dynamic range.<sup>226</sup>  
47  
48

49 23 Derivatives of the diethylenetriaminepentaacetate (DTPA) and tetraazacyclododecane (DOTA)  
50  
51 24 macrocycles have been extensively used as chelating agents to label proteins, peptides, and  
52  
53 25 antibodies. A common derivatizing agent is the commercial available bifunctional chelating agent  
54  
55 26 maleimido-mono-amide-DOTA (or MMA-DOTA), which forms an extremely stable complex with  
56  
57  
58  
59  
60

lanthanide ions, while the functional maleimide group binds covalently to the –SH group in the proteins with high specificity and efficiency under mild conditions.<sup>227</sup>

In addition to the MMA group for specific thiol labelling,<sup>7,228</sup> other commonly reactive groups used as chelating agents are the isothiocyanates (SCN) for the labeling of amino groups.<sup>207</sup>

**Fig 9.** The reactions involving thiolic (a) and amino (b) group with different MeCAT reagents.

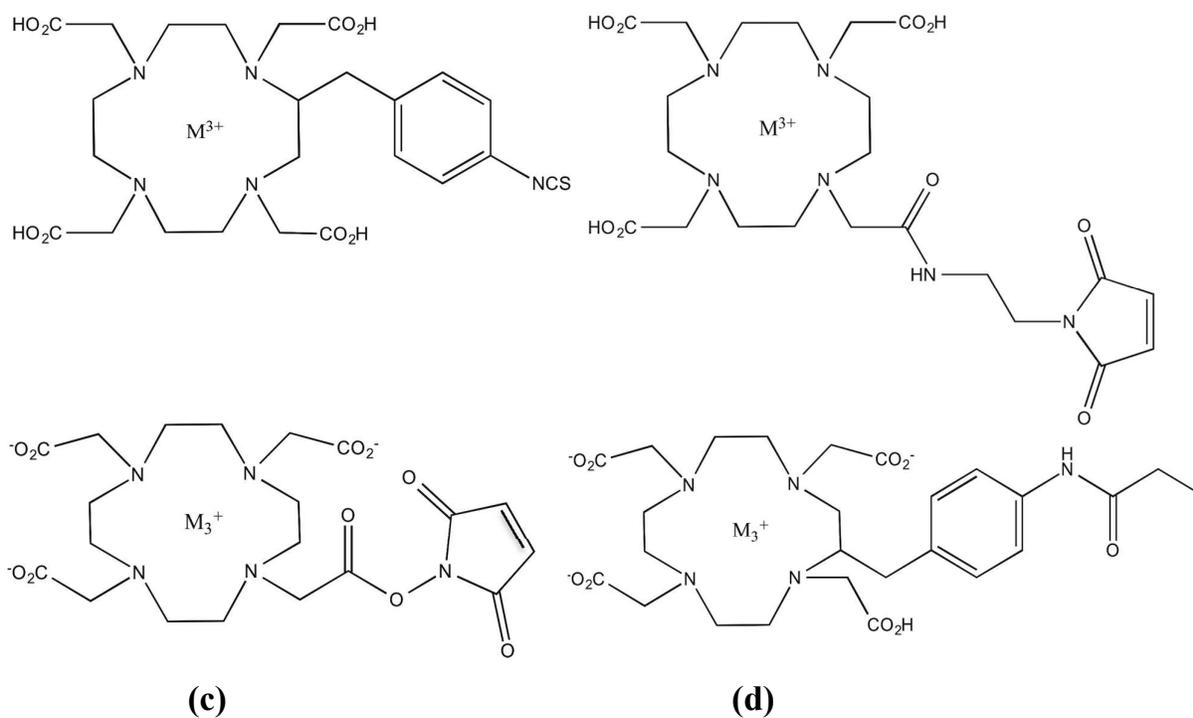

Thiolic groups react with maleinimides and halogen acetamides, while amino groups react with NHS and isothiocyanate functionalities.

In the case of DOTA and 1,4,7-triazacyclononane-*N,N',N''*-triacetic acid (NOTA), the complex coordination is maintained via free electron pairs of heteroelements as well as via carboxylate groups and is mainly influenced by pH, temperature and concentration.<sup>229</sup>

DOTA-rare earth chelates have exceptional properties if used as affinity tags. Unlike biotin, they have no natural analogues that might interfere with affinity purification. They are highly polar and water-soluble. Many of the rare earth elements are naturally monoisotopic, providing a variety of simple choices for preparing mass tags.<sup>230</sup> The polydentate macrocyclic DOTA and the noncyclic

1 open form DTPA generate extremely stable metal complexes with stability constants ( $\log k$ ) up to  
 2 25.4.<sup>231</sup>

3 In 2004 Meares and his colleagues,<sup>230</sup> based on DOTA labeling, developed a method for the relative  
 4 and absolute quantitation of peptides and proteins called metals-coded affinity tag (MeCAT) based  
 5 on the cysteine-specific chemical labels by tags containing different element-coded metal chelates  
 6 with similar chemical nature. The MeCAT approach together with flow injection analysis-ICP-MS  
 7 was applied for eye lens proteomics quantitation.<sup>228</sup>

**Fig 10.** Structures of some of the MeCAT reagents used in the articles cited by the present review. MeCAT reagents consist of three parts: a macrocycle for metal chelating, a spacer with connects the macrocycle, and a functional group for specific labeling of amino acid side chains. (a): isothiocyanate-DOTA; (b) and (c): MMA-DOTA; (d): iodoacetamide-DOTA.

With respect to DOTA, the bicyclic anhydride of DTPA used to introduce the lanthanides is an inexpensive and easily obtained labeling agent that reacts with primary amines (amino terminus and

1  
2  
3 1 internal Lys) present in the proteins.<sup>232</sup> DTPA-based tags allow the choice of different metals and  
4  
5 2 can be bound to amino groups for peptide and protein labeling with two-step reactions: once the  
6  
7 3 protein is derivatized with DTPA, the complex with rare earth metal of interest is obtained by  
8  
9 4 adding the metal to the solution.<sup>233</sup>  
10  
11 5 Liu et al.<sup>224</sup> demonstrated the labeling of peptides by using yttrium and terbium–DTPA complexes.  
12  
13 6 Furthermore, lanthanide ions such as Eu, Tb, and Ho were implemented in a DOTA-acid  
14  
15 7 succinimide ester (SCN–DOTA) complex to label bovine serum albumin and hen egg white  
16  
17 8 lysozyme.<sup>224</sup>  
18  
19 9 Commercially available fluorescent probes (DELFIATM) containing the lanthanides Eu, Tb, and Sm  
20  
21 10 were employed for DOTA labeling of different antibodies with a specific metal and detection by  
22  
23 11 ICP-MS.<sup>234</sup> Recently, the first ICP-MS-based multiplex profiling of glycoproteins was published,  
24  
25 12 in which lectins conjugated to lanthanide-chelating compounds were used.<sup>235</sup>  
26  
27 13 The integration of elemental labeling in quantitative bio-analysis requires fundamental experiments  
28  
29 14 concerning the yield of complexation stability of protein-metal complexes during the analysis.  
30  
31 15 McDevitt et al.<sup>236</sup> had compared the yield of binding of actinium (<sup>225</sup>Ac) in chelates based on  
32  
33 16 DTPA, 1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid (TETA), DOTA, 1,4,7,10-  
34  
35 17 tetraazacyclododecane-1,4,7,10-tetra-propionic acid (DOTPA), 1,4,8,11-tetra-azacyclotetradecane-  
36  
37 18 1,4,8,11-tetrapropionic acid (TETPA), 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetra-  
38  
39 19 methylenephosphonic acid (DOTMP), a-(5-isothiocyanato-2-methoxyphenyl)-1,4,7,10-  
40  
41 20 tetraazacyclodo-decane-1,4,7,10-tetraacetic acid (MeO-DOTA-NCS) and 2-(4-  
42  
43 21 isothiocyanatobenzyl)-1,4,7,10-tetraazacyclo-dodecane-1,4,7,10-tetraacetic acid (p-SCNBn-  
44  
45 22 DOTA). In a second step, they assessed also the yield in the binding of the chelate to an antibody  
46  
47 23 (IgG). Among the chelates investigated, only the compounds based on DOTA showed the highest  
48  
49 24 labelling yield of the antibody and the best recovery during sample preparation.  
50  
51 25 Lewis et al. described the use of a sulfo-SHN (N-hydroxysuccinimide) linker attached to DOTA.<sup>237</sup>  
52  
53 26 This group used a 100-fold excess of sulfo-NHS-DOTA with respect to the protein of interest and  
54  
55  
56  
57  
58  
59  
60

1 performed the labelling with radioactive isotopes ( $^{111}\text{In}$  and  $^{90}\text{Y}$ ). After the optimisation of the  
2 labelling procedure, the maximal number of labels detected per protein molecule was not more than  
3 3.8 for an antibody and about 9 for cytochrome c, demonstrating that this value strongly depends on  
4 the protein structure. In all cases this value was by far below the theoretical number of binding  
5 sites.<sup>207</sup>

6 Kretschy et al.<sup>229</sup> investigated the complex stability of the chelating moieties DOTA, NOTA and  
7 DTPA in combination with 11 different lanthanides under typical chromatographic conditions.  
8 Measurements were carried out via LC-ICP-quadrupole-MS using a novel mixed mode separation  
9 method. The influence of chromatographic separation, pH and temperature on complex stability  
10 constants was assessed, and they found that, for all investigated complexes, the stability was  
11 significantly decreased by the chromatographic conditions.  $\text{Ln}^{3+}$ -DOTA and  $\text{Ln}^{3+}$ -NOTA  
12 complexes provided high stability at 5 °C and 37 °C over a time of 12 hours, whereas  $\text{Ln}^{3+}$ -DTPA  
13 complexes showed significant degradation at 37 °C. Moreover, although  $\text{Ln}^{3+}$ -DOTA complexes  
14 exhibited the highest stability constant values, during the chromatographic separation they show an  
15 additional signal suggesting a positively charged intermediate product.

16 Zhang et al. developed a strategy for dual labelling of peptides based on an elemental tag and a  
17 fluorescent tag.<sup>238</sup> MMA-DOTA loaded with Eu was used to conjugate the peptide *via* the specific  
18 reaction between -SH and MMA, and with a typical fluorescent tag (fluorescein isothiocyanate,  
19 FITC) for the subsequent conjugation of the peptide *via* the reaction between  $-\text{N}=\text{C}=\text{S}$  and  $-\text{NH}_2$ .  
20 The peptide is determined using both  $^{153}\text{Eu}$  isotope dilution ICP-MS and capillary electrophoresis-  
21 laser induced fluorescence (CE-LIF). The LODs of the three tested model peptides obtained using  
22 HPLC-IDA-ICP-MS were two orders of magnitude lower than those found using (CE-LIF),  
23 suggesting that HPLC-IDA-ICP-MS is the election platform for the quantitation of peptides.

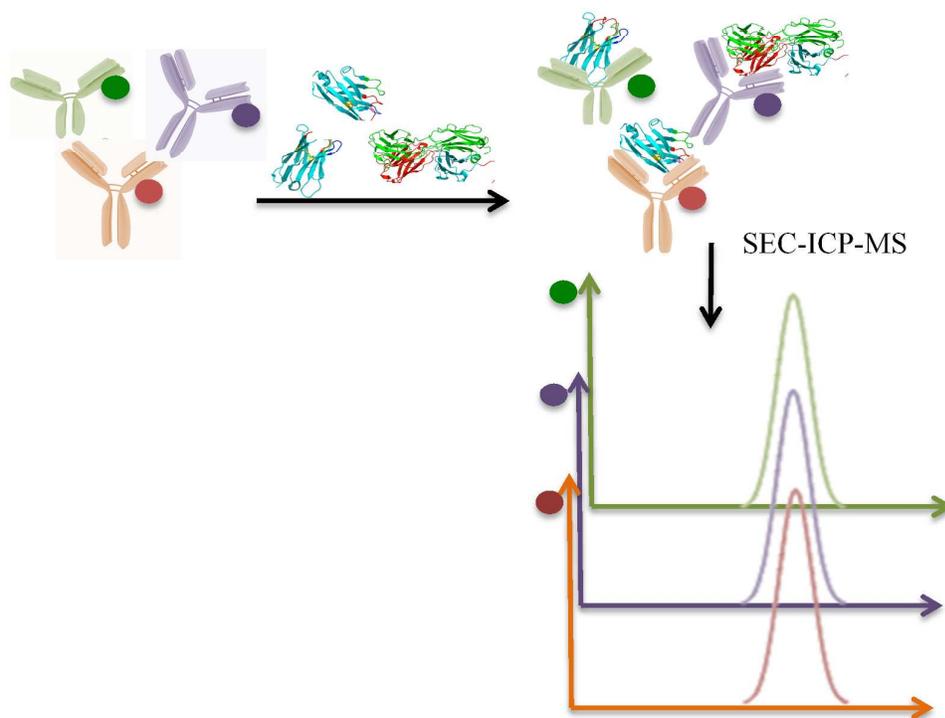

24 El-Khatib et al. recently developed a strategy in which thiolic and amino groups in peptides were  
25 targeted with different reagents. Amino groups were labeled with DOTA-NHS and thiolic groups  
26 using DOTA with iodoacetamide functionality. They showed that both labeling sites could be

1  
2  
3 1 addressed quantitatively using different metals and thereby could be distinguished in ICP-MS.  
4  
5 2 Alternatively, an increase in sensitivity *per* protein or peptide can be achieved when the same metal  
6  
7 3 for the different reagents is used.<sup>239</sup>  
8

9  
10 4 An alternative approach is based on the tagging of antibodies with rare earth elements-chelates,  
11  
12 5 which react with antigens with an extremely high degree of specificity even in complex matrices.  
13  
14 6 Once the labeling procedure is optimized, the activity of the metal-tagged antibodies can be  
15  
16 7 preserved.  
17

18 8 Terenghi and his co-workers<sup>240</sup> developed a method for the multiplexed determination of five  
19  
20 9 protein cancer biomarkers as complexes with antibodies tagged with different rare earth elements,  
21  
22 10 separated in size exclusion-HPLC and detected by ICP-MS (Figure 10). Their aim was to optimize  
23  
24 11 the conditions to determine simultaneously target proteins directly in the sample matrix without any  
25  
26 12 sample pretreatment. Size exclusion-HPLC allowed the online separation of the protein-antibody  
27  
28 13 complexes from the unreacted antibodies and the degradation products of the labeling reagent.  
29  
30 14 Despite the coelution of the immunocomplexes of different proteins, as well of the free antibodies,  
31  
32 15 the detection and determination of each protein-antibody complex occurs on the basis of each  
33  
34 16 metal-specific chromatogram.

**Fig. 11.** Schematic workflow showing the antibody-labeling strategies for protein quantitation. Different antibodies are labeled with different MeCAT reagents and react with the respective antigens. The labeled proteins are subsequently analyzed *via* SEC-ICP-MS.<sup>240</sup>

Muller et al.<sup>241</sup> investigated the maleimide-based modification procedure via size exclusion-HPLC coupled with ICP-MS and LC-time-of-flight-MS, by analyzing the antibody structure after modification with MeCATs. The maleimide-based tagging of antibodies is a procedure quite complex. The drawback of this linking chemistry is, indeed, the pretreatment of the antibody, which needs to be reduced to generate free sulfhydryl groups to react with the maleimide linker of the metal tag. As the tagged antibody usually still shows antigen selectivity in the immune reaction, the assumption is that the hinge region of the antibody is preferentially reduced, leading to two identical parts of the antibody with intact antigen-binding sides.<sup>242</sup> They found that maleimide-modified antibodies show an excellent specificity and sensitivity during the immune reaction. The functional efficiency of the maleimide-tagged antibodies even after the reduction of the interchain

1  
2  
3 1 disulfide bridges with TCEP, can be explained by the fact that the antibody structure is preserved by  
4  
5 2 its hydrophobic interactions. Nevertheless, each antibody needs to be validated after tagging to  
6  
7 3 prove its specificity against the target antigen. The complexity of the metal-tagged antibody  
8  
9 4 prevents the development of a quantitation concept, because a calculation of an exact tagging  
10  
11 5 degree, which is the prerequisite for calculating the amount of antibody molecules in the sample, is  
12  
13 6 not possible. Thus, the absolute quantitation of element-tagged antibodies by ICP-MS requires the  
14  
15 7 development of new strategies.<sup>241</sup>

16  
17  
18 8 The validation of the analytical methods based on MeCAT is an important topic because peptide  
19  
20 9 quantitation is an upcoming issue in in pre-clinical studies of drug development, as many peptides  
21  
22 10 are recognized as promising drugs. Koellensperger et al.<sup>243</sup> loading DOTA not with a lanthanide  
23  
24 11 but with indium, compared the quantitation of labeled peptides by LC-ICP-MS with the results  
25  
26 12 obtained using LC-ESI-MS measurement without labeling, in the same chromatographic conditions.

27  
28  
29 13 The analysis of aqueous standards using the two methods showed comparable results in terms of  
30  
31 14 sensitivity and limit of detection, whereas in cell culture experiments the measurement of the  
32  
33 15 cytoplasm samples revealed severe matrix effects in the case of LC-ESI-MS, which made  
34  
35 16 impossible quantitative measurements. On the contrary, LC-ICP-MS quantitation of peptides in  
36  
37 17 combination with elemental labeling showed the advantage of a matrix-independent signal  
38  
39 18 intensity.

40  
41  
42  
43 19 The work of Tanner and Nolan about the development of ICP-MS-linked metal-tagged  
44  
45 20 immunophenotyping deserves some mention. This is a rather hot topic in medical research, as it  
46  
47 21 has great potential for highly multiplexed proteomic analysis.<sup>244,245,246</sup> They found that the  
48  
49 22 sensitivity of ICP-MS linked immunophenotyping employing commercially available tags is  
50  
51 23 comparable with that of fluorescence activated flow cytometry analysis. However flow cytometry,  
52  
53 24 the common optical methods for detection of intracellular and extracellular proteins within single  
54  
55 25 cells, is not suitable for multiplex analysis. In a work of Tanner et al.<sup>247</sup>, the data obtained provide  
56  
57 26 that lanthanides labeling coupled with ICP-MS detection can be used in the multiplexed molecular  
58  
59  
60

1  
2  
3 1 analysis of human leukemia cell lines, detecting proteins on the cell surface as well as  
4  
5 2 intracellularly in permeabilized cells. A critical further application of ICP-MS to cell biology  
6  
7 3 would be to combine this detection methodology with single cell analysis in a novel flow-based  
8  
9 4 ICP-MS instrument.

10  
11 5 Despite the excellent detectability of lanthanide ions by ICP-MS and the high stability of the  
12  
13 6 reagents avoiding metal loss or metal exchange, the high polarity of complexes and their derivatives  
14  
15 7 makes their separation on reversed-phase (RP) columns impossible.<sup>30</sup> Unfortunately, without a  
16  
17 8 satisfactory separation of the derivatized biomolecules, an absolute quantitation cannot be expected.  
18  
19 9 Moreover, the rare earth element labeling needs a two-step reaction and the reaction efficiency of  
20  
21 10 each step would affect the quantitative results.

22  
23  
24

2  
3 **1 Concluding remarks.**  
4

5  
6 2 The necessity to understand fundamental biological processes in living organism has led to an  
7  
8 3 accelerated development of accurate, relative or absolute methods for quantitation of peptides and  
9  
10 4 proteins related to the metabolism or to certain pathological conditions (e.g. HbA1c as a marker of  
11  
12 5 diabetes, or transferrin glycosylation in the recognition of alcoholism). The detection of  
13  
14 6 endogenous metal(loid)s or metal-tag covalently bound to proteins has been recognized as a  
15  
16 7 powerful complementary approach to modern techniques as ESI or MALDI MS (which misses the  
17  
18 8 comparability of different analytes due to different ionization behaviour) or the classical ELISA and  
19  
20 9 Western blot test.  
21

22  
23  
24 10 The absolute quantitation of proteins is also fundamental especially for the pharmaceutical industry.  
25  
26 11 As a matter of fact, the yield of a purification procedure obtained with the common enzymatic  
27  
28 12 assays measures activities rather than actual amounts, and immunological assays rely on antibodies,  
29  
30 13 which are difficult to assess for specificity and activity. Thus, metal coded tagging may open an  
31  
32 14 alternative approach to protein quantitation when antibody-based approaches reach their limits.  
33

34  
35 15 The relative quantitation with respect to a comparative proteome analysis has recognized to be  
36  
37 16 important, but the challenge for the future is the ability to perform absolute protein quantitation for  
38  
39 17 a large numbers of proteins. It is also necessary to validate the proposed methods to demonstrate  
40  
41 18 their applicability and robustness for their application to real samples.  
42

43  
44 19 Hyphenated techniques are an attractive tool for a rapid, sensitive and comprehensive  
45  
46 20 characterization and quantitative determination of metal-protein complexes in biological samples.  
47

48  
49 21 The development and improvement of ICP-MS based methods, free of interferences will be  
50  
51 22 fundamental for the absolute protein quantitation based on endogenous elements, such as  
52  
53 23 phosphorous and sulphur.  
54

55  
56 24 The development of quantitative MS-based proteomics strategies is still a great challenge due to  
57  
58 25 various limitations, as the low concentration level of the biomarkers, the lack of available standards  
59  
60

1 and instrumental limitations. Moreover, a disadvantage of absolute metal-binding proteins  
2 quantitation is frequently the lack of internationally recognized certified reference materials of  
3 known purity and international conventional measurement procedures. The acceptance of  
4 elemental labels for biological studies and their entry into biochemical and clinical laboratories will  
5 strongly depend on these two key points, i.e. the development of reliable procedures and the  
6 commercial availability of standards and certified reference materials that would permit the  
7 validation of hyphenated techniques against the classical methods.
