Accepted Manuscript

This is an *Accepted Manuscript*, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

*Accepted Manuscripts* are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this *Accepted Manuscript* with the edited and formatted *Advance Article* as soon as it is available.

You can find more information about *Accepted Manuscripts* in the [Information for Authors](#).

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard [Terms & Conditions](#) and the [Ethical guidelines](#) still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this *Accepted Manuscript* or any consequences arising from the use of any information it contains.

# *Ab initio* and Metadynamics Studies on the Role of Essential Functional Groups in Biomineralization of Calcium Carbonate and Environmental Situations

Moumita Saharay,<sup>\*a</sup> R. James Kirkpatrick<sup>b</sup>

First published on the web Xth XXXXXXXXXXXX 200X

DOI: 10.1039/b000000x

The interactions of proteins, polysaccharides and other biomolecules with  $\text{Ca}^{2+}$ ,  $\text{CO}_3^{2-}$ , and water are central to the understanding of biomineralization and crystallization of calcium carbonate ( $\text{CaCO}_3$ ), and their association with the natural organic matter (NOM) in the environment. A molecular-level investigation of how such interactions and thermodynamic forces drive the nucleation and growth of crystalline  $\text{CaCO}_3$  in living organisms remains elusive. This paper presents *ab initio* and metadynamics studies of the interactions of  $\text{Ca}^{2+}$ ,  $\text{CO}_3^{2-}$ , and water with the essential amino acids/functional groups, *e.g.* arginine/ $\text{NH}_2^+$ , aspartate or glutamate/ $\text{COO}^-$ , aspartic or glutamic acid/ $\text{COOH}$ , and serine/ $\text{OH}$ , of protein/organic molecules that are likely to be critical to the biomineralization of  $\text{CaCO}_3$ . These functional groups were modeled as guanidinium ( $\text{Gdm}^+$ ), acetate ( $\text{AcO}^-$ ), acetic acid ( $\text{AcOH}$ ), and ethanol ( $\text{EtOH}$ ) molecules, respectively. The  $\text{Gdm}^+$ - $\text{Ca}^{2+}$ - $\text{CO}_3^{2-}$  and  $\text{AcO}^-$ - $\text{Ca}^{2+}$ - $\text{CO}_3^{2-}$  systems were found to form stable ion-complexes irrespective of the presence of near neighbor water molecules. The strong electrostatic interactions of these functional groups with their counterions significantly affect the fundamental vibrational frequencies of the functional groups, mainly the  $\text{NH}_2$  stretching (str.) and degenerate (deg.) scissors modes of  $\text{Gdm}^+$  and  $\text{-C=OO}$ , CC, and CO str. modes of  $\text{AcO}^-$ . The free-energy calculations reveal that  $\text{EtOH}$  forms weakly bound molecular complexes with the  $\text{Ca}^{2+}$ - $\text{CO}_3^{2-}$  ion pairs in water. However, the interaction strength of  $\text{EtOH}$  with crystalline  $\text{CaCO}_3$  can increase significantly due to combined effect of H-bond and electron donor acceptor (EDA) type of interactions. These results indicate that  $\text{-NH}_2^+$  and  $\text{-COO}^-$  bearing molecules serve as potential nucleation sites promoting crystallization of  $\text{CaCO}_3$  phases while  $\text{-OH}$  bearing molecules are likely to control the morphology of the crystalline phases by attaching to the growing crystal surfaces.

The interactions of proteins, polysaccharides and other biomolecules with  $\text{Ca}^{2+}$ ,  $\text{CO}_3^{2-}$ , and water molecules are central to understanding the biomineralization of  $\text{CaCO}_3$  and are also fundamental to the interactions among naturally occurring organic matter, mineral surfaces, groundwater, and minerals<sup>1–5</sup>.  $\text{CaCO}_3$  biomineralization is an essential process in the formation of the exoskeletons and other structural components of many living organisms, including crustaceans, algae, sea urchins, and avian eggshells. Crystalline  $\text{CaCO}_3$  formed both biogenically and inorganically occurs as one of the three polymorphs, calcite, aragonite, and less commonly vaterite. The crystallization pathway for these phases depends greatly on the physical and chemical conditions<sup>6–11</sup>. The biologically produced phases have a wide range of morphologies and physical properties due to the influence of the proteins and enzymes present<sup>12–15</sup> and these properties can be utilized to develop ‘smart’ materials<sup>7,16</sup>. Proteins generally carry a net non-zero surface charge that facilitates interaction and binding with either positively charged  $\text{Ca}^{2+}$  or negatively charged  $\text{CO}_3^{2-}$ . Although it is not yet known how the binding of proteins to these ions controls nucleation, it has been speculated that the calcium-binding proteins delay nucleation and reduce the rate of crystal growth<sup>17</sup> by increasing the activation energy of the process.

polymorphs, calcite, aragonite, and less commonly vaterite. The crystallization pathway for these phases depends greatly on the physical and chemical conditions<sup>6–11</sup>. The biologically produced phases have a wide range of morphologies and physical properties due to the influence of the proteins and enzymes present<sup>12–15</sup> and these properties can be utilized to develop ‘smart’ materials<sup>7,16</sup>. Proteins generally carry a net non-zero surface charge that facilitates interaction and binding with either positively charged  $\text{Ca}^{2+}$  or negatively charged  $\text{CO}_3^{2-}$ . Although it is not yet known how the binding of proteins to these ions controls nucleation, it has been speculated that the calcium-binding proteins delay nucleation and reduce the rate of crystal growth<sup>17</sup> by increasing the activation energy of the process.

Calcite is formed in systems with proteins that contain principally aspartic acid/aspartate<sup>18,19</sup> or have negatively charged regions on their surface<sup>11</sup>. The interaction of individual amino acid residues with  $\text{Ca}^{2+}$ - $\text{CO}_3^{2-}$  ion pairs are also important in biomimetics, where additives with selective charged functional groups are used to control the crystallization pathway<sup>20</sup> and crystal morphologies<sup>21</sup>. For example, poly(aspartic acid) and poly(acrylic acid), both contain COOH functional groups and stabilize a polymer-induced liquid phase (PILP) prior to the formation of amorphous calcium carbonate (ACC)<sup>22</sup>. In contrast, positively charged additives<sup>21</sup> with amine ( $\text{NH}_2^+$ ) groups induce phase separation driven by the interaction with negatively charged carbonate ions forming hydrated charge-separated ( $\text{Ca}^{2+}$ /additive/ $\text{CO}_3^{2-}$ ) droplets. This phase separation induces dramatic changes in the crystal morphologies of  $\text{CaCO}_3$ . In all these processes, charge-dipole and dipole-dipole interactions play a major role in the association and dissociation of ions from the protein surface, synthetic polymers, or liquid organic additives. Thus, understanding the binding affinities and interaction strengths of amino acid residues with  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  is an important step in understanding and predicting the crystallization behavior of biogenic  $\text{CaCO}_3$  phases.

Despite great progress in experimental studies of the nucleation and growth of biogenic and natural  $\text{CaCO}_3$ , molecular scale understanding of the influence of biomolecules on the crystallization pathways has remained elusive. Computational modeling studies have the potential to provide significant insight into this question. Recent studies using classical simulation methods have focused principally on the interaction and adsorption of proteins<sup>23</sup>, polysaccharides<sup>15</sup>, and synthetic peptides<sup>24</sup> on the surfaces of crystalline  $\text{CaCO}_3$  phases. Peter et al.,<sup>24</sup> for instance, studied the adsorption of polystyrene sulfonate (PSS) on calcite using classical molecular dynamics (MD) simulations. PSS is an additive to control crystal growth in vitro. They observed that the binding of the acidic sulfonate group on the polar (001) calcite surface is much stronger than on the non-polar (104) surface due to the dominant interaction between sulfonate functional groups and the positively

charged  $\text{Ca}^{2+}$  on the (001) surface. In addition to this charge-dipole interaction, solvent-mediated interaction between the acidic functional groups and  $\text{Ca}^{2+}$  is also crucial in this surface binding, with free energy calculations showing that the binding energies for direct and solvent-mediated adsorption on (001) surfaces are essentially the same. In contrast, on the non-polar (104) surface, solvent separated acidic groups form strong hydrogen bonds with the ordered water molecules on the surface.

Freeman *et al.*<sup>23</sup> studied the binding of the eggshell protein Ovocleidin-17 on calcite surfaces. This protein has a net +7 charge at neutral pH. These results show that the residues alanine (functional group:  $\text{CH}_3$ ), arginine (functional group:  $\text{NH}_2^+$ ), aspartic acid (functional group: COOH), and serine (functional group:  $\text{OH}^-$ ) are able to help bind the protein on the non-polar (104) calcite surface and that the interaction of arginine is dominant. The strong interaction between the calcite surface and water molecules results in the formation of an ordered water layer on the surface, and the most favorable binding of the protein is achieved by solvent-mediated interactions that minimize displacement of water molecules from the surface layer.

In natural and anthropogenic environments, aqueous fluids rich in  $\text{Ca}^{2+}$  and carbonate species are common in near surface environments and deeper in the earth’s crust. These fluids are the medium from which  $\text{CaCO}_3$  minerals crystallize, and as in biomineralization, bio- and organic- molecules appear to play a significant role.  $\text{Ca}^{2+}$  binding is also thought to be central to the structure and behavior of NOM, its interaction with mineral surfaces, and even fouling of water purification membranes<sup>25–27</sup>. The relevant functional groups<sup>2,28</sup> are often the same as in biomineralization, and the molecular scale interactions are also incompletely understood.

Modeling results concerning calcium carbonate biomineralization published to date have focused on the interaction of macromolecules and preexisting calcite surfaces, but to understand the effects of these molecules on  $\text{CaCO}_3$  nucleation and growth it is also necessary to study the interaction of the important amino acid residues with  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  in aqueous solution.  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  form strong ion pairs in solution<sup>29–31</sup>, and it is thus also important to understand these interactions not just with the individual ions but also with both ions present. Similarly, the published computational studies of the role of  $\text{Ca}^{2+}$  in NOM structure and binding have not included  $\text{CO}_3^{2-}$  or  $\text{HCO}_3^-$ , despite the near ubiquitous presence of carbonate species in natural waters.

We present here a computational study of the interaction of  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  with functional groups relevant to  $\text{CaCO}_3$  biomineralization and NOM using DFT, classical molecular dynamics (MD) and metadynamics methods to evaluate the structural environments, energetics of these interactions in small molecular clusters, changes in the vibrational frequen-

cies due to ion-association, and the effects of solvation of the clusters in bulk water. The results illustrate quantitatively the role of solvating H<sub>2</sub>O molecules in changing the structural arrangements of the gas phase clusters.

There have been several previously published computational studies relevant to our results. Hamm *et al.*<sup>32</sup> performed classical MD simulations of hydrated Ca<sup>2+</sup> in the presence of negatively charged aspartate (Asp) using CHARMM<sup>33</sup> force field parameters. They showed that the strong interaction between these species triggers dehydration of Ca<sup>2+</sup> by reducing the energy barrier of Ca<sup>2+</sup> dehydration. Nielsen *et al.*<sup>34</sup> considers this to be the rate-limiting step for the calcium carbonate nucleation and growth. Gale *et al.*<sup>35</sup> used modified CHARMM parameters to perform similar calculations to study the free energy landscape for the binding of Asp/Aspartic acid to the surfaces of amorphous and crystalline CaCO<sub>3</sub>. Freeman *et al.*<sup>23,36</sup> used AMBER<sup>37</sup> parameter set in their study of Ovocleidin-17 on calcite surfaces, although this parameter set underestimates the hydration free energies of Ca<sup>2+</sup> and CO<sub>3</sub><sup>2-</sup>.

For the classical MD and metadynamics calculations here, we use CHARMM parameters for Ca<sup>2+</sup>, CO<sub>3</sub><sup>2-</sup>, and the organic molecules and TIP3P<sup>38</sup> for water molecules. The functional groups modeled are NH<sub>2</sub><sup>+</sup> (guanidinium, CN<sub>3</sub>H<sub>6</sub>, Gdm<sup>+</sup>), COO<sup>-</sup> (acetate, AcO<sup>-</sup>), COOH (acetic acid, AcOH) and OH (ethanol, EtOH). These groups are relevant models for arginine, aspartate/glutamate, aspartic acid/glutamic acid, and serine, respectively and are common functional groups in NOM.

## 1 Simulation Details

To study amino acid-CaCO<sub>3</sub>-water interactions in the gas phase, we performed quantum-chemical calculations using the Gaussian09<sup>39</sup> suite of programs at the B3LYP/6-311+G(d,p) level. The C<sub>α</sub> atoms of alanine, aspartic/glutamic acid, and serine were modeled as methyl groups. We will refer to these residues as ethanol (EtOH), acetate (AcO<sup>-</sup>) and acetic acid (AcOH). The arginine side chain was modeled as a positively charged guanidinium ion (Gdm<sup>+</sup>). Vibrational analysis of the optimized geometries do not show any imaginary modes that represent a stable geometry.

Classical MD simulations of aqueous solutions containing a formula unit of CaCO<sub>3</sub> and a model residue, Re (Re = EtOH, AcO<sup>-</sup>, AcOH, Gdm<sup>+</sup>), were carried out using the NAMD software<sup>40</sup> package, the CHARMM 27 all-atom force-field<sup>33</sup> parameters, and the TIP3P water model<sup>38</sup>. The simulations were performed in the NPT ensemble at 310 K and 1 atm pressure. The system pressure was controlled using a Langevin piston with a period of 100 fs. The temperature was controlled by a Langevin thermostat. The cubic box dimensions of the EtOH-, AcO<sup>-</sup>-, AcOH-, and Gdm<sup>+</sup>-CaCO<sub>3</sub> systems

were 29.1, 22.8, 22.3, and 19.1 Å<sup>3</sup>, respectively. The AcO<sup>-</sup> and Gdm<sup>+</sup> systems were neutralized by one Na<sup>+</sup> and one Cl<sup>-</sup>, respectively. The number of water molecules in these systems were 826, 400, 285, and 233, respectively. The non-bonded interactions were smoothed using a switching function between 10 and 12 Å. Electrostatic interactions were calculated using the particle mesh Ewald (PME) method with a distance cutoff of 12 Å. Each system was run for total 4 ns including 2 ns of initial equilibration.

The metadynamics methods implemented in the NAMD software package were used to study the free energy profiles for the association of the ion pairs in bulk solution using collective variable (CV) module. Each CV is the measure of distance between a particular pair of atoms. The CVs for each system are described in the respective sections of this paper. For these calculations, each system was run for total 22 ns including 2 ns of initial equilibration. During the simulation, Gaussian hills of width 2<sup>o</sup> were added at a regular interval of 100 fs.

## 2 Validation of Force Field Parameters

The applicability of MD models involving organic and inorganic species depends greatly on the quality of the force field parameters. To validate the suitability of the CHARMM force field parameters to study the interactions between organic molecules and CaCO<sub>3</sub> we calculated the hydration free energies of the Ca<sup>2+</sup> and CO<sub>3</sub><sup>2-</sup> and the local hydration shell around Ca<sup>2+</sup> using the NAMD software package. These values were compared with the existing theoretical and experimental values. The hydration free energy of a particular ion was calculated by the Free-Energy-perturbation (FEP) method, implemented in NAMD package, where the interaction strength of the ion with the was gradually increased or decreased. For example, if the interaction strength ( $\lambda$ ) is 0 then the ion is considered to be non interacting and is placed infinitely far apart from the solvent molecules. In contrast,  $\lambda = 1$  indicates favorable interaction between the ion and the solvent. Thus, the potential energy of a system containing solute (here, the ion) and solvent is given by

$$E_{Total} = E_{solute-solute} + E_{solvent-solvent} + \lambda E_{solute-solvent} \quad (1)$$

The change in free energy between two  $\lambda$  states ( $i, i+1$ ) is

$$\Delta G_i = -\frac{1}{\beta} \ln \langle \exp[-\beta(E_{\lambda_{i+1}} - E_{\lambda_i})] \rangle \quad (2)$$

and the hydration free energy is

$$\Delta G_{hyd} = \sum_{i=1}^N \Delta G_i \quad (3)$$

where  $N$ =total number of  $\lambda$  points,  $\lambda_1 = 0$  and  $\lambda_N = 1$ . During the FEP calculations, the  $\lambda$  value was varied in steps of 0.5 for both the forward ( $\lambda=0 \rightarrow 1$ ) and reverse ( $\lambda=1 \rightarrow 0$ ) processes. Each model system was generated by solvating an ion ( $\text{Ca}^{2+}$  or  $\text{CO}_3^{2-}$ ) in a cubic water box of dimension  $30\text{\AA}$  and was equilibrated for 1 ns before initializing the FEP calculations. At each  $\lambda$  value, the equilibrium run length was 60 ps and the production run length was 1.4 ns. To overcome the singularity issue at the terminal windows,  $\lambda=0$  and 1, a soft-core potential was used.

Table 1 lists the hydration free energies of the ions from the existing literature and the results from our calculations. The  $\Delta G_{\text{hyd}}$  of  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  calculated using the CHARMM

**Table 1** Hydration free energies ( $\text{kJ mol}^{-1}$ ) of  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$

Ion type	Theoretical	Experimental
$\text{Ca}^{2+}$	-1384. (this work)	-1446.4 <sup>41</sup>
	-1333. <sup>36,42</sup>	
	-1447. <sup>42</sup>	
$\text{CO}_3^{2-}$	-1247.34 (this work)	-1314. <sup>43</sup>
	-1175. <sup>36,42</sup>	
	-1301. <sup>42</sup>	

parameter set are  $-1384 \text{ kJ/mol}$  and  $-1247.34 \text{ kJ/mol}$ , respectively. Compared to the experimental values, our simulation results yield a slightly lower  $\Delta G_{\text{hyd}}$ . Previous simulation studies of calcium carbonate biomineralization using the AMBER<sup>37</sup> force field parameters for the biomolecules and Pavese *et al.*'s parameters<sup>44</sup> for  $\text{CaCO}_3$  show much lower values of the  $\Delta G_{\text{hyd}}$  and underestimate the solubilities of both  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$ . In a recent publication<sup>42</sup>, Gale *et al.* provided a new set of force field parameters for  $\text{CaCO}_3$  that yield better agreement with the experimental  $\Delta G_{\text{hyd}}$  values. However, the compatibility of these parameters with the existing force field parameters for biomolecules are not yet verified. Moreover, mixing two different types of force fields may lead to systematic errors in the calculations. Thus, we chose to use CHARMM parameters for both organic and inorganic species.

To further test the applicability of the CHARMM parameters, we also studied the near neighbor hydration shell around  $\text{Ca}^{2+}$ . The radial distribution function of atom pair  $\text{Ca}, \text{O}_{\text{water}}$  ( $g_{\text{Ca-O}_w}$ , Figure 1) shows a nearest neighbor peak at  $2.26\text{\AA}$ , a minimum at  $2.56\text{\AA}$ , a second neighbor peak at  $4.5\text{\AA}$ , and a second minimum at  $5.5\text{\AA}$ . The running coordination number at the first minimum is 6.8. These values compare well with the X-ray diffraction studies<sup>45</sup> which show the position of the first minimum is at  $\sim 2.5 \text{\AA}$  and a corresponding running coordination number of  $\sim 7$ . Based on the agreement between the calculated and experimental hydration free-energies and near-neighbor distance and coordination number, we conclude

**Fig. 1** Radial distribution function (solid line) and running coordination number (dashed line) for the atom pair  $\text{Ca}^{2+}$  and oxygen of water ( $\text{O}_w$ ) molecules.

that the force field parameters used here are suitable for our purposes.

### 3 Results and Discussion

For each model residue, we first discuss the ground state properties of the gas-phase systems with and without neighboring water molecules. Then we discuss the solvation effects on these systems from the MD and metadynamics results.

#### 3.1 Gdm<sup>+</sup>

##### 3.1.1 Gas-phase

The optimized gas phase structures of the  $\text{Gdm}^+$  clusters show that  $\text{H}_2\text{O}$  has a significant effect on the equilibrium structural relationships among the  $\text{Gdm}^+$ ,  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  (Figure 2). For the system without  $\text{H}_2\text{O}$ , two  $\text{NH}_2$  groups of the  $\text{Gdm}^+$  are located directly perpendicular to the  $\text{CO}_3^{2-}$  ion forming two hydrogen bonds with two oxygens of  $\text{CO}_3^{2-}$  ( $\text{O}_{\text{CO}_3}$ ) forming a 'twin nitrogen-twin oxygen' (TNTO) geometry<sup>46-48</sup> (Figure 2A). This is a common structural arrangement for  $\text{Gdm}^+$  and  $\text{COO}^-$  containing residues. The  $\text{Ca}^{2+}$  is in bidentate coordination with two  $\text{O}_{\text{CO}_3}$  and is not directly coordinated to the  $\text{Gdm}^+$ . In general, this geometric relationship between  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  is the most stable gas phase structure<sup>29</sup>, and all the  $\text{Gdm}^+$ -containing clusters here have this geometry, irrespective of the number of near-neighbor water molecules. The strong interaction between  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  results in changes in the lengths of the C-O bonds in  $\text{CO}_3^{2-}$  relative to the bare  $\text{CO}_3^{2-}$ . In isolated  $\text{CO}_3^{2-}$ , the C-O bond length is  $1.31\text{\AA}$ . This value increases to  $1.32$  and  $1.36\text{\AA}$  for the two  $\text{O}_{\text{CO}_3}$  coordinated to  $\text{Ca}^{2+}$  and decreases to  $1.23\text{\AA}$  for the  $\text{O}_{\text{CO}_3}$  not coordinated to  $\text{Ca}^{2+}$ . The presence of the  $\text{Ca}^{2+}$  also causes the

**Fig. 2** Geometry optimized structures of  $\text{Gdm}^+$  containing clusters with (A)  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$ , (B,C,D)  $\text{Ca}^{2+}$ ,  $\text{CO}_3^{2-}$  and one  $\text{H}_2\text{O}$ , (E,F)  $\text{Ca}^{2+}$ ,  $\text{CO}_3^{2-}$  and two  $\text{H}_2\text{O}$ . Color scheme: carbon (cyan), nitrogen (green), oxygen (red), calcium (blue), hydrogen (gray).

H-bonds donated to the  $\text{O}_{\text{CO}_3}$  by the  $\text{Gdm}^+$  to have different lengths.

In systems with one water molecule, the  $\text{Gdm}^+$  and  $\text{CO}_3^{2-}$  are coplanar, and the TNTO geometry between them remains present. There are three optimized structures with one water molecule in which the  $\text{H}_2\text{O}$  interacts with, (i)  $\text{Gdm}^+$  and  $\text{CO}_3^{2-}$  (Figure 2B), (ii)  $\text{Ca}^{2+}$  (Figure 2C), and (iii)  $\text{Gdm}^+$  (Figure 2D). The energetically most stable arrangement (Figure 2C, Table 2) is the one in which  $\text{H}_2\text{O}$  is coordinated to a  $\text{Ca}^{2+}$ . The positions of the water molecule in these clusters are very different from that in an isolated  $\text{Gdm}^+$ -water complex<sup>49</sup>, in which the oxygen of water ( $\text{O}_W$ ) lies in the plane of  $\text{Gdm}^+$  and forms two hydrogen bonds with the hydrogens of two adjacent  $\text{NH}_2^+$  groups. Moreover, the distance between the  $\text{Gdm}^+$  and  $\text{CO}_3^{2-}$  is significantly changed by the presence of a water molecule that interacts with both of these ions (Figure 2B) and in the situation where it interacts with one of them (Figure 2C,D). The closest distances between  $\text{O}_{\text{CO}_3}$  and  $\text{H}_{\text{Gdm}}$  in structure B increase by  $\sim 0.12\text{\AA}$  than the structure in Figure 2C. The strong H-bond interaction between  $\text{Gdm}^+$  and  $\text{H}_2\text{O}$  in the structure in Figure 2D increases these distances even more by pulling the  $\text{Gdm}^+$  away from  $\text{CO}_3^{2-}$ .

For systems with two water molecules, the minimum energy structure (Figure 2E) has one water that interacts with both  $\text{CO}_3^{2-}$  and  $\text{Gdm}^+$  at essentially the same position as in the minimum energy one-water (Figure 2B) system and a sec-

**Table 2** Binding energies of the optimized ion-complexes.

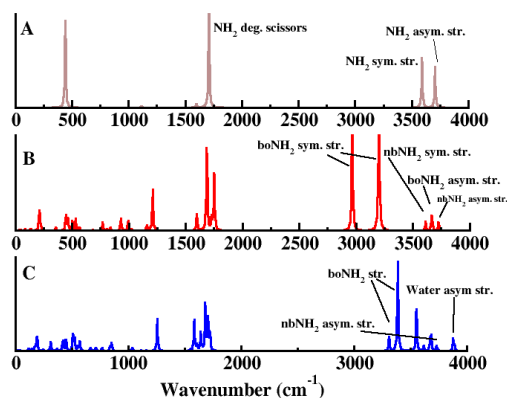

Superscript on left indicates the corresponding Figure number for the optimized geometry of the complex. The energy difference,  $\Delta E$ , for  $\text{CaCO}_3$  containing complex ( $\text{Re}[\text{CaCO}_3][\text{H}_2\text{O}]_n$ ) is  $\Delta E = E(\text{complex}) - E(\text{Re}) - E(\text{CaCO}_3) - nE(\text{H}_2\text{O})$  and that of  $\text{Ca}^{2+} / \text{CO}_3^{2-}$  containing complex is  $\Delta E = E(\text{complex}) - E(\text{Re}) - E(\text{Ca}^{2+}/\text{CO}_3^{2-}) - nE(\text{H}_2\text{O})$ , where Re and n are the model functional group and number of water molecules, respectively.

ond water molecule that donates an H-bond to the  $\text{CO}_3^{2-}$ . This structure does not show the TNTO geometry. Rather, the  $\text{CO}_3^{2-}$  is coordinated to the  $\text{Gdm}^+$  by two H-bonds donated to a single  $\text{O}_{\text{CO}_3}$  from two different  $\text{NH}_2$  groups. We will refer this arrangement as ‘twin-nitrogen-single-oxygen’ (TNSO). In the less stable complex with two water molecules (Figure 2F),  $\text{Gdm}^+$  is in TNTO geometry with  $\text{CO}_3^{2-}$  and the second water molecule interacts only with  $\text{Gdm}^+$  and forms two H-bonds with the  $\text{NH}_2$  group. Thus, the position of the nearest neighbor water molecule significantly affects the strength of H-bond interaction between  $\text{Gdm}^+$  and  $\text{CO}_3^{2-}$ . Systems with more water molecules could not be optimized. Our MD simulation of the bulk system shows that the association of more than two water molecules with the ion-complex requires an H-bond network among the neighboring water molecules.

### 3.1.2 Vibrational Spectra

The presence of near-neighbor water molecules has a significant effect on the vibrational modes of  $\text{Gdm}^+$  (Figure 3). The NH stretching modes at  $3592\text{ cm}^{-1}$  (symmetric str.) and  $3714\text{ cm}^{-1}$  (asymmetric str.) and the  $\text{NH}_2$  degenerate scissors modes at  $1713\text{ cm}^{-1}$  are most sensitive to the presence of  $\text{CO}_3^{2-}$  in the TNTO geometry. The establishment of strong H-bonds shifts the str. modes of the participating NH bonds

**Fig. 3** Power spectra of (A)  $\text{Gdm}^+$ , (B)  $\text{Gdm-CaCO}_3$ , and (C)  $\text{Gdm-CaCO}_3\text{-2H}_2\text{O}$  clusters.

to much lower frequencies that appear at 2965 and 3200  $\text{cm}^{-1}$  for N-H...O-C distances of 1.64 and 1.8 Å, respectively. However, this effect is less prominent for the non-donating  $\text{NH}$  bond. This restricted motion also splits the  $\text{NH}_2$  deg. scissors modes into lower frequency modes. *Ab initio* studies<sup>50</sup> of solvated and isolated  $\text{Gdm}^+$  show that the presence of the first hydration shell has a negligible effect on the vibrational modes of the ion. One of the reasons for this could be that the N-H (in  $\text{Gdm}^+$ ) and O-H (in water) stretching frequencies are almost the same, and it is difficult to identify the effect of water that is H-bonded with the ion and with other water molecules. In the two- $\text{H}_2\text{O}$  complex here, the transformation from TNTO geometry in the dry complex to TNSO geometry with two waters relaxes the NH vibration modes of the  $\text{NH}_2$  groups that are bonded to the  $\text{CO}_3^{2-}$  and shifts them towards higher frequencies, although these modes are still at lower frequencies than the non-bonded  $\text{NH}_2$  (Figure 3C). The deprotonated state of the arginine side chain is also important in this context. Braiman *et al.*<sup>51</sup> show that deprotonation of the arginine side chains will red-shift the CN stretching mode by  $\sim 50\text{-}100\text{ cm}^{-1}$  relative to the protonated state. In a hydrophobic environment, the association of an arginine side chain with a counter-ion depends on the position and characteristics of the counter-ion and the strength of the H-bond<sup>51</sup>.

### 3.1.3 Free Energies

The free energy profile ( $F_{\text{guano}}(r_{\text{col}})$ ) of the  $\text{Gdm}^+\text{-Ca-CO}_3$  ion-complex solvated in bulk water as a function of the distance between carbon atoms of  $\text{Gdm}^+$  and  $\text{CO}_3^{2-}$  ( $r_{\text{col}}$ ) contains a global minimum at 3.83 Å that is 4 kcal/mol more stable than the non-interacting, dissociated state at 8 Å and a secondary minimum at 4.5 Å that is 3 kcal/mol more sta-

**Fig. 4** Potential of mean force for the binding of  $\text{Gdm}^+$  to  $\text{CaCO}_3$  ion-pair.

**Fig. 5** Radial distribution functions for (a) nitrogen ( $N_{\text{Gdm}}$ ) of  $\text{Gdm}^+$  and carbon ( $C_{\text{CO}_3}$ ) of  $\text{CO}_3$ , (b)  $N_{\text{Gdm}}$  and oxygen of water ( $\text{O}_W$ ), (c) carbon ( $C_{\text{Gdm}}$ ) of  $\text{Gdm}^+$  and  $\text{O}_W$ , (d)  $\text{CO}_3^{2-}$  and  $\text{Ca}^{2+}$ .

ble than the dissociated state (Figure 4). The arrangement of the  $\text{Gdm}^+$ ,  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  at the global energy minimum is generally similar to that of gas phase complex without water molecules (TNTO) except that the  $\text{Gdm}^+$  and  $\text{CO}_3^{2-}$  are not coplanar. At this minimum, the  $\text{CO}_3^{2-}$  receives two H-bonds from the  $\text{Gdm}^+$ , and the  $\text{Ca}^{2+}$  is in bidentate coordination with the  $\text{CO}_3^{2-}$  throughout the simulation due to strong electrostatic interaction with a binding energy of nearly 8.84 kcal/mol<sup>52</sup>. At the secondary minimum, the  $\text{CO}_3^{2-}$  is almost perpendicular to the  $\text{Gdm}^+$  and this twist in the  $\theta$  angle leads to the formation of only one H-bond while maintaining the same  $H_{\text{Gdm-O}CO_3}$  distance as at the global minimum.

### 3.1.4 Bulk Solution

The intermolecular radial distribution functions (RDFs) obtained from the classical MD simulations of  $\text{Gdm}^+$ ,  $\text{Ca}^{2+}$ , and

$\text{CO}_3^{2-}$  solvated in bulk water show that the  $\text{Gdm}^+$  and  $\text{CO}_3^{2-}$  retain the TNTO structural arrangement (Figure 5a) and that the  $\text{Ca}^{2+}$  is mostly in bidentate coordination with  $\text{CO}_3^{2-}$  (Figure 5d). Previous MD calculations<sup>53</sup> of  $\text{Gdm}^+$ s and  $\text{CO}_3^{2-}$ s solvated in bulk water show that even at high concentration of  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$ , TNTO is the preferred geometry. As observed in our free-energy calculations, the strong H-bond interactions between  $\text{Gdm}^+$  and  $\text{CO}_3^{2-}$  inhibits the dissociation of the  $\text{Gdm-CO}_3$  ion-complex. This result indicates that guanidinium groups or, in general, arginine residues on protein surfaces and amine groups in NOM help bio- and organic-molecules recognize and bind to the  $\text{CO}_3^{2-}$  groups on calcium carbonate surfaces or  $\text{CO}_3^{2-}$  in solution. The RDF for the  $\text{N}_{\text{Gdm-CO}_3}$  atom pair (Figure 5a) shows two isolated peaks at 3.4 and 5.1 Å, where the first peak corresponds to the nitrogen atoms H-bonded to  $\text{CO}_3^{2-}$  and the second peak corresponds to the unpaired nitrogen atoms. Compared to the gas-phase clusters, the shortest N-C distance is increased by  $\sim 0.7$  Å in solution. This increase is due to the presence of the hydration shell around both  $\text{Gdm}^+$  and  $\text{CO}_3^{2-}$  which weakens the H-bond strength. The RDF for the  $\text{N}_{\text{Gdm-O}_W}$  atom pair (Figure 5b) shows three prominent peaks at 2.8, 3.5, and 5.0 Å. The running coordination numbers at each of these distances are 1.0, 3.6, and 15, respectively. This result shows that even in the bulk solution, the  $\text{Gdm}^+-\text{CaCO}_3$  ion-complex can accommodate a maximum of one water molecule in the first hydration shell. The RDF for the  $\text{C}_{\text{Gdm-O}_W}$  atom pair (Figure 5c) shows a peak at 3.7 Å and a broad peak at 6.9 Å. Analysis of the arrangements related to these peaks indicate that there are two types of hydration waters around  $\text{Gdm}$ : (1) in-plane water molecules that receive H-bonds from  $\text{Gdm}^+$ , and (2) out-of-plane water molecules in the plane parallel to the plane of  $\text{Gdm}^+$  interacting with the lone-electron pair of the  $\text{N}_{\text{Gdm}}$  atoms.

Classical MD study of the hydration of  $\text{Gdm}^+$ , Soetens *et al.*<sup>49</sup> used both polarizable and non-polarizable water molecules and found no dramatic differences in the solvent structure around the ions except that the number of nearest neighbor water molecules is more with the polarizable model. The structural properties extracted from our results match well with those of Soetens *et al.* using a polarizable water model. Thus, we believe that our results with the non-polarizable TIP3P water model are useful in understanding biomineralization.

## 3.2 $\text{AcO}^-$

### 3.2.1 Gas phase

The geometry optimized structures of gas phase systems containing  $\text{AcO}^-$ ,  $\text{Ca}^{2+}$ ,  $\text{CO}_3^{2-}$ , and  $\text{H}_2\text{O}$  show that in all cases coordination to the  $\text{COO}^-$  group occurs through the  $\text{Ca}^{2+}$  and

**Fig. 6** Geometry optimized structures of (A,B,C,D)  $\text{AcO}^-$  and (E,F)  $\text{AcOH}$  containing clusters. Front and top views of the  $\text{AcO}^--\text{Ca}^{2+}-\text{CO}_3^{2-}$  complexes are shown in panels B and C, respectively. Color scheme: Carbon (cyan), Oxygen (red), Calcium (blue), hydrogen (gray).

that the presence of one water molecule changes the structure significantly (Figure 6). For the  $\text{AcO}^--\text{Ca}^{2+}$  ion complex (Figure 6A),  $\text{Ca}^{2+}$  is coplanar with the  $\text{COO}^-$  group and is equidistant from the two carboxyl oxygens at 2.17 Å. The binding energies of the ion complexes are listed in Table 2. For the  $\text{AcO}^--\text{Ca}^{2+}-\text{CO}_3^{2-}$  complex (Figure 6B)  $\text{Ca}^{2+}$  bridges the two anions via coulombic interaction, with the  $\text{Ca}^{2+}-\text{O}_{\text{CO}_3}$  bond distances 0.23 Å shorter than for  $\text{Ca}^{2+}-\text{O}_{\text{AcO}}$ . The  $\text{COO}$  planes of the  $\text{AcO}^-$  and  $\text{CO}_3^{2-}$  are perpendicular to each other (Figure 6C). The  $\text{Ca}^{2+}-\text{O}_{\text{AcO}}$  distances are larger than for the  $\text{AcO}^--\text{Ca}^{2+}$  complex (2.41 Å vs. 2.17 Å) due to strong interaction between  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$ .

As for the  $\text{Gdm}^+$  clusters, in the  $\text{AcO}^--\text{Ca}^{2+}-\text{CO}_3^{2-}$  complex with one  $\text{H}_2\text{O}$ , the water molecule is coordinated to the  $\text{Ca}^{2+}$ . It donates an H-bond to  $\text{O}_{\text{CO}_3}$  and is not coordinated to the  $\text{AcO}^-$ , demonstrating the more hydrophilic nature of  $\text{CO}_3^{2-}$  (Figure 6D) relative to  $\text{COO}^-$  of  $\text{AcO}^-$ . The  $\text{Ca}^{2+}$  in this complex is coordinated by a total of 5 oxygen atoms. We modelled several initial structures of the  $\text{AcO}^--\text{Ca}^{2+}-\text{CO}_3^{2-}$  complex with more than one water molecules but could never achieve a stable geometry-optimized structure other than the one in Figure 6D. This observation is in line with our MD results which show that in bulk water, the  $\text{Ca}^{2+}$  is in bidentate coordination by  $\text{AcO}^-$  and there is a maximum of one water molecule in the first hydration shell. Recent infrared spec-

**Fig. 7** Power spectra of (a)  $\text{AcO}^-$ , (b)  $\text{AcO}^-$ - $\text{Ca}^{2+}$ , (c)  $\text{AcO}^-$ - $\text{CaCO}_3$ , (d)  $\text{AcO}^-$ - $\text{CaCO}_3$ - $\text{H}_2\text{O}$

trosopy experiments<sup>54</sup> show that even when the counter ion is  $\text{Na}^+$  rather than  $\text{Ca}^{2+}$ , the hydration number per  $-\text{COO}^-$  is 1.0. Thus, in comparison to solvated  $\text{AcO}^-$  without any counter ion<sup>55</sup> where the  $\text{O}_{\text{AcO}}$  is coordinated by 3.4  $\text{O}_{\text{W}}$  (oxygen of water), the presence of  $\text{Ca}^{2+}$  reduces the water coordination around the carboxyl group significantly. This inner sphere bridging of the carboxylic group and the  $\text{CO}_3^{2-}$  by  $\text{Ca}^{2+}$  is likely to play an important role in adsorption of bio- and organic molecules on the  $\text{CaCO}_3$  surfaces at neutral and basic pHs and in helping these molecules structure the ions in solution during nucleation.

### 3.2.2 Vibrational Spectra

The calculated power spectra of isolated  $\text{AcO}^-$  and the  $\text{AcO}^-$ - $\text{Ca}^{2+}$ ,  $\text{AcO}^-$ - $\text{Ca}^{2+}$ - $\text{CO}_3^{2-}$ , and  $\text{AcO}^-$ - $\text{Ca}^{2+}$ - $\text{CO}_3$ - $\text{H}_2\text{O}$  complexes are significantly different (Figure 7). The  $-\text{C}=\text{OO}$  stretching mode at  $1652\text{ cm}^{-1}$  and CC, CO stretching modes at  $856\text{ cm}^{-1}$  are most sensitive to the presence of  $\text{Ca}^{2+}$  in the  $\text{AcO}^-$ - $\text{Ca}^{2+}$  complex (Figure 7b). The strong interaction in the ion pair splits and shifts the  $-\text{C}=\text{OO}$  stretching modes to  $1477$  and  $1428\text{ cm}^{-1}$ , which are much lower frequencies than for isolated  $\text{AcO}^-$  ( $1664\text{ cm}^{-1}$ ) (Figure 7a). There are similar changes<sup>54</sup> in a comparable system containing  $\text{Na}^+$ . This effect is however less prominent in the presence of  $\text{CO}_3^{2-}$ , because the carbonate significantly weakens the  $\text{AcO}^-$ - $\text{Ca}^{2+}$  binding. In the  $\text{AcO}^-$ - $\text{CaCO}_3$ - $\text{H}_2\text{O}$  complex, the formation of strong H-bond between  $\text{H}_2\text{O}$  and  $\text{CO}_3^{2-}$  red shifts the OH stretching mode of the bonded OH (Figure 7d). Because the  $\text{H}_2\text{O}$  does not directly interact with  $\text{AcO}^-$ , the effect on the  $\text{AcO}^-$  modes is small. Previous IR spectroscopic<sup>56,57</sup> and theoretical<sup>57</sup> studies have shown that in bulk  $\text{AcO}^-/\text{AcOH}$  solution, there can be at least three types of hydrated species con-

**Fig. 8** Potential of mean force for the binding of  $\text{AcO}^-$  with  $\text{Ca,CO}_3$  ion-pair. The most probable geometries of these ions at each energy minima are shown with ball-and-stick representation. Color scheme: Carbon (cyan), Oxygen (red), Calcium (blue).

taining acetic acid with one or two nearest neighbor (NN)  $\text{H}_2\text{O}$  molecules and an acetate ion with two NN  $\text{H}_2\text{O}$ . In systems with protonated  $\text{AcOH}$  the mode at  $\sim 1700\text{ cm}^{-1}$  appears due to a Fermi resonance between the CO stretching mode and the first overtone of the CC stretching ( $885\text{ cm}^{-1}$ ) mode<sup>58</sup>. The splitting of this mode in our  $\text{AcO}^-$ - $\text{Ca}^{2+}$  complex may be due to the absence of the Fermi resonance.

### 3.2.3 Free-energy Calculations

The free energy profile for the solvated  $\text{AcO}^-$ - $\text{Ca}^{2+}$ - $\text{CO}_3^{2-}$  complex as a function of distance between  $\text{C}_{\text{COO}^-}$  of  $\text{AcO}^-$  and  $\text{Ca}^{2+}$  ( $r_{\text{col}}$ ) obtained from the metadynamics calculations shows a global energy minimum at  $r_{\text{col}}=2.62\text{ \AA}$ , a secondary minimum at  $3.32\text{ \AA}$  that is  $1.9\text{ kcal/mol}$  less stable, a transition state at  $3.8\text{ \AA}$ , and a total energy barrier from the global minimum to the dissociated state of  $9\text{ kcal/mol}$  (Figure 8). The energy barrier between the two minima is  $3.9\text{ kcal/mol}$ . In the global minimum energy configuration,  $\text{Ca}^{2+}$  is in bidentate coordination with both anions, as in the gas phase structure. At the secondary energy minimum,  $\text{Ca}^{2+}$  is in monodentate coordination by the  $\text{AcO}^-$  and in bidentate coordination by  $\text{O}_{\text{CO}_3}$ . The high affinity of COO groups for  $\text{Ca}^{2+}$  and their selective binding is in agreement with the observation that acetate binding sites are in general  $\text{Ca}^{2+}$  philic. A recent study<sup>28</sup> of the complexation of  $\text{Ca}^{2+}$  with the carboxylic groups of a model molecule of NOM in the absence of  $\text{CO}_3^{2-}$  showed a similar free energy profile. This study also showed only small differences in the free energy profiles for carboxylic side chains and an isolated acetate group, confirming that the interactions between  $-\text{COO}^-$  groups and  $\text{Ca}^{2+}$  are strong irrespective of their end groups and the presence of other ions.

For a more detailed structural analysis of the  $\text{AcO}^-$ - $\text{Ca}^{2+}$ - $\text{CO}_3^{2-}$  complex in solution, we define two angles,  $\theta$  and  $\phi$

**Fig. 9** Variation of  $\theta$  and  $\phi$  angles in metadynamics simulations at  $r_{col}=2.62$  (the global energy minimum; black dots),  $3.32$  (secondary energy minimum; red dots), and  $3.8\text{\AA}$  (transition state; blue dots). Scheme: Definition of  $\theta$  and  $\phi$  angles. These two angles are between the C-Ca vector and the normal ( $n1$  and  $n2$  vectors) to the COO plane (shaded regions) for the  $\text{CO}_3^{2-}$  and  $\text{AcO}^-$  groups, respectively.

(Figure 9), and investigate their variation in the metadynamics simulations at  $r_{col}=2.62$  (the global energy minimum),  $3.32$  (the secondary energy minimum), and  $3.8\text{\AA}$  (the transition state) of distance between  $\text{C}_{\text{COO}^-}$  of  $\text{AcO}^-$  and  $\text{Ca}^{2+}$  ( $r_{col}$ ) obtained from the metadynamics calculations shows a global energy minimum at  $r_{col}=2.62\text{\AA}$ , a secondary minimum at  $3.32\text{\AA}$  that is  $1.9$  kcal/mol less stable, a transition state at  $3.8\text{\AA}$ , and a total energy barrier from the global minimum to the dissociated state of  $9$  kcal/mol (Figure 8). The energy barrier between the two minima is  $3.9$  kcal/mol. In the global minimum energy configuration,  $\text{Ca}^{2+}$  is in bidentate coordination with both anions, as in the gas phase structure. At the secondary energy minimum,  $\text{Ca}^{2+}$  is in monodentate coordination by the  $\text{AcO}^-$  and in bidentate coordination by  $\text{O}_{\text{CO}_3}$ . The high affinity of COO groups for  $\text{Ca}^{2+}$  and their selective binding is in agreement with the observation that acetate binding sites are in general  $\text{Ca}^{2+}$  philic. A recent study<sup>28</sup> of the complexation of  $\text{Ca}^{2+}$  with the carboxylic groups of a model molecule of NOM in the absence of  $\text{CO}_3^{2-}$  showed a similar free energy profile. This study also showed only small differences in the free energy profiles for carboxylic side chains and an isolated acetate group, confirming that the interactions between  $-\text{COO}^-$  groups and  $\text{Ca}^{2+}$  are strong irrespective of their end groups and the presence of other ions.

For a more detailed structural analysis of the  $\text{AcO}^-$ - $\text{Ca}^{2+}$ - $\text{CO}_3^{2-}$  complex in solution, we define two angles,  $\theta$  and  $\phi$  (Figure 9), and investigate their variation in the metadynamics simulations at  $r_{col}=2.62$  (the global energy minimum),  $3.32$  (the secondary energy minimum), and  $3.8\text{\AA}$  (the transition

**Fig. 10** Distribution of  $\theta$  and  $\phi$  angles (upper panel) and the corresponding  $\text{O}_{\text{AcO}}-\text{Ca}$  distances (lower panel) at the transition state of the free-energy profile. Atom-numbering is shown in Figure 6.

state). These two angles are between the C-Ca vector and the normal to the COO plane for the  $\text{CO}_3^{2-}$  and  $\text{AcO}^-$  groups, respectively. At the global and secondary energy minima, both the  $\theta$ ,  $\phi$  distributions have maxima at  $90^\circ$  with a distribution between  $60$  and  $120^\circ$ . This geometry indicates that on average  $\text{Ca}^{2+}$  is co-planar with both  $\text{AcO}^-$  and  $\text{CO}_3^{2-}$ . These structures are similar to that of the gas phase complex. In the transition state configuration (Figure 9), the average  $\phi$  value is  $90^\circ$ , but there is a broad distribution of  $\theta$  angles with maxima near  $90$  and  $15^\circ$ . The distribution of distances between the carboxylic oxygens of  $\text{AcO}^-$  ( $\text{O}_{\text{AcO}}$ ) and  $\text{Ca}^{2+}$  (Figure 10) shows that the transition state is composed of two structural arrangements. One is an in-plane monodentate structure in which the shortest  $\text{O}_{\text{AcO}}-\text{Ca}^{2+}$  distance is  $2.5\text{\AA}$  and  $\theta=90^\circ$ . The other is an out-of-plane bidentate structure in which  $\text{Ca}^{2+}$  is equidistant from the  $\text{O}_{\text{AcO}}$  at  $\sim 4\text{\AA}$  and  $\theta=15^\circ$  (Figure 10). At the transition state, the structural arrangement of the ions oscillates rapidly between these bidentate and monodentate geometries.

Throughout the metadynamics simulation,  $\text{Ca}^{2+}$  remains in in-plane bidentate coordination with the  $\text{CO}_3^{2-}$ . The  $9$  kcal/mol energy penalty for the transition from in-plane (at the global minima) to out-of-plane (at the transition state) geometry is much higher than the thermal energy at  $310\text{K}$  ( $0.6$  kcal/mol). Thus, the dissociation of this ion-complex at ambient temperature is highly unlikely. These two angles are between the C-Ca vector and the normal to the COO plane for the  $\text{CO}_3^{2-}$  and  $\text{AcO}^-$  groups, respectively. At the global and secondary energy minima, both the  $\theta$ ,  $\phi$  distributions have maxima at  $90^\circ$  with a distribution between  $60$  and  $120^\circ$ . This geometry indicates that on average  $\text{Ca}^{2+}$  is co-planar with both  $\text{AcO}^-$  and  $\text{CO}_3^{2-}$ . These

**Fig. 11** Radial distribution functions for (a) carbon ( $C_{COO^-}$ ) of  $AcO^-$  and  $Ca^{2+}$ , (b) oxygen ( $O_{COO^-}$ ) of  $AcO^-$  and oxygen of water ( $O_W$ ), (c)  $O_{COO^-}$  and  $H_W$ , (d)  $CO_3^{2-}$  and  $O_W$ .

structures are similar to that of the gas phase complex. In the transition state configuration (Figure 9), the average  $\phi$  value is  $90^\circ$ , but there is a broad distribution of  $\theta$  angles with maxima near  $90$  and  $15^\circ$ . The distribution of distances between the carboxylic oxygens of  $AcO^-$  ( $O_{AcO}$ ) and  $Ca^{2+}$  (Figure 10) shows that the transition state is composed of two structural arrangements. One is an in-plane monodentate structure in which the shortest  $O_{AcO}-Ca^{2+}$  distance is  $2.5\text{\AA}$  and  $\theta=90^\circ$ . The other is an out-of-plane bidentate structure in which  $Ca^{2+}$  is equidistant from the  $O_{AcO}$  at  $\sim 4\text{\AA}$  and  $\theta=15^\circ$  (Figure 10). At the transition state, the structural arrangement of the ions oscillates rapidly between these bidentate and monodentate geometries.

Throughout the metadynamics simulation,  $Ca^{2+}$  remains in in-plane bidentate coordination with the  $CO_3^{2-}$ . The 9 kcal/mol energy penalty for the transition from in-plane (at the global minima) to out-of-plane (at the transition state) geometry is much higher than the thermal energy at 310K (0.6 kcal/mol). Thus, the dissociation of this ion-complex at ambient temperature is a rare event, and binding of  $Ca^{2+}$ ,  $CO_3^{2-}$  ion pairs to carboxylic groups may play an important role in facilitating calcium carbonate nucleation and growth.

### 3.2.4 Bulk Solution

The RDFs obtained from the classical MD simulations of the bulk solution of  $AcO^-$  show features that correspond to the global and secondary energy minima in the metadynamics calculations (Figure 11). The RDF for the  $C_{COO^-}$  and  $Ca^{2+}$  pairs (Figure 11a) shows two peaks at  $2.55$  and  $3.3$  Å that correspond to the global and secondary energy minima in the free-energy profile, respectively (Figure 8). The non-zero probability of the RDF in the range of  $2.4$  and  $3.6$  Å indicates the presence of a strongly bound undissociated ion complex

throughout the molecular dynamics trajectory. The  $O_{COO^-}-O_W$  RDF (Figure 11b) shows a well-defined first hydration shell around  $AcO^-$  with a nearest neighbor coordination of 5 water molecules. However, analysis of the  $O_{AcO}-H_W$  RDF (Figure 11c) indicates the formation of only one H-bond between  $AcO^-$  and solvent water, in agreement with our gas-phase calculations in which the geometry optimized cluster of  $AcO^- - CaCO_3 - H_2O$  has only one water molecule H-bonded with  $AcO^-$ .

## 3.3 AcOH

### 3.3.1 Gas phase

For AcOH, protonation of the carboxylic group causes the interactions between  $Ca^{2+}$  and  $CO_3^{2-}$  to be drastically different than for deprotonated  $AcO^-$ . For the AcOH- $Ca^{2+}$  cluster (Figure 6E), the geometry optimized structure has  $Ca^{2+}$  in monodentate coordination by the  $O_{AcOH}$  and colinear with the C=O bond at  $2.09\text{\AA}$  from the oxygen. The binding energy for this ion-complex is  $-83.38$  kcal/mol. For the AcOH- $Ca^{2+}-H_2O$  system, the only stable structure has the  $Ca^{2+}$  in monodentate coordination with the O-atom and the  $H_2O$  receiving an H-bond from the OH group (Figure 6F). The  $H_2O$  molecule does not coordinate the  $Ca^{2+}$ . The binding energy of this complex is  $-109.87$  kcal/mol. For the AcOH- $Ca^{2+}-CO_3^{2-}$  system there is no stable, energy minimized structure. Instead, the proton from the hydroxyl group of AcOH readily migrates to the carbonate forming a bicarbonate ion. Several initial structures were modeled by placing carbonate ion at different positions around the optimized structure of the AcOH- $Ca^{2+}$  complex, but in all cases the proton migrates to the  $CO_3^{2-}$ . This result is expected, since the pKa of carboxylic groups are typically near 4, and  $H_2CO_3$  is the stable carbonate species under these conditions. This result is also in line with experimental results that show rapid decomposition of  $CaCO_3$  particles that are interacting with acetic acid<sup>59-62</sup>.

Our results, thus, show that at low pHs or in a water-deficient region on a protein surface, aspartic or glutamic acids are likely to associate principally with  $Ca^{2+}$  rather than  $CO_3^{2-}$ <sup>63</sup>. Consequently, a large number of protonated side chains on a protein surface may help the protein adsorb onto the positively charged calcite (001) surface through direct interaction, whereas its adsorption on the neutral surface (104) may be due to solvent mediated interactions.

### 3.3.2 Free Energy

The free energy for the AcOH- $Ca^{2+}-CO_3^{2-}$  system as a function of distance between the C $\alpha$  atom of AcOH and  $C_{CO_3}$  rises sharply for low values of  $r_{col}$  where the planes of AcOH and  $CO_3^{2-}$  are almost parallel and the carbon and oxygen atoms of these species are perpendicular to the like atoms (Figure 12).

**Fig. 12** Potential of mean force for the binding of AcOH with CaCO<sub>3</sub> ion-pair. The most probable geometries of these ions and molecule at each energy minima are shown with ball-and-stick representation. Color scheme: Carbon (cyan), Oxygen (red), Calcium (blue).

There is a weak global energy minimum at  $r_{col}=4.25\text{\AA}$  where the hydroxyl group of AcOH points towards the oxygen of CO<sub>3</sub><sup>2-</sup> forming a strong hydrogen bonded interaction. The free energy landscape is quite flat between 5 and 8 Å and the activation barrier for dissociation of the Ca<sup>2+</sup>-CO<sub>3</sub><sup>2-</sup> ion pair from the AcOH is only 1.2 kcal/mol, of the order of the thermal energy at ambient conditions.

As AcOH in presence of Ca<sup>2+</sup>, CO<sub>3</sub><sup>2-</sup> ion-pair dissociates readily in a water-rich environment, we did not perform classical MD simulations of bulk solution containing these species.

### 3.4 EtOH

#### 3.4.1 Gas phase

For the EtOH-CaCO<sub>3</sub> cluster (Figure 13A), the geometry optimized structure has the OH- group of EtOH donating an H-bond to one of the O<sub>CO<sub>3</sub></sub> and the Ca<sup>2+</sup> in in-plane bidentate coordination with CO<sub>3</sub><sup>2-</sup>. The OH bond of EtOH is almost parallel to the CO<sub>3</sub><sup>2-</sup> plane. The binding energy for this ion-complex is -8.61 kcal/mol. This geometry is different from that of the system containing EtOH and a neutral CO<sub>2</sub> molecule in which the most stable configuration is achieved through an electron donor-acceptor (EDA) type of interaction between the oxygen of CO<sub>2</sub> (O<sub>CO<sub>2</sub></sub>) and the hydroxyl group of EtOH<sup>64</sup>. An EDA type of arrangement dominates even in a dense supercritical CO<sub>2</sub>-EtOH mixture<sup>64</sup>.

For the EtOH-CaCO<sub>3</sub>-3H<sub>2</sub>O system (Figure 13B), the presence of NN water molecules significantly affect the arrangement of EtOH, Ca<sup>2+</sup>, and CO<sub>3</sub><sup>2-</sup> relative to the anhydrous system. Here, EtOH donates an H-bond to O<sub>CO<sub>3</sub></sub> where

**Fig. 13** Geometry optimized structures of EtOH containing clusters. Color scheme: Carbon (cyan), Oxygen (red), Calcium (blue). Blue line represents H-bond.

the OH bond is at 90° to the CO<sub>3</sub><sup>2-</sup> plane. The oxygen of EtOH (O<sub>EtOH</sub>) receives an H-bond from the neighboring H<sub>2</sub>O molecule, which is also in the first coordination shell of Ca<sup>2+</sup>. The H-bond distances are 1.72 and 1.56 Å, respectively. Ca<sup>2+</sup> is in out-of-plane bidentate coordination by the CO<sub>3</sub><sup>2-</sup> with all three water molecules coordinated to it at distances of about 2.3 Å. Based on these results, in a wet system, protein side chains containing serine will form H-bonds with both water and CO<sub>3</sub><sup>2-</sup>. Due to the hydrophilic nature of EtOH, or in general the hydroxyl group, the dominant interaction between these amino acids and oxy-anions could be through both solvent mediated and direct interactions, whereas interaction with cations should be through solvent or anion mediated interactions. The binding affinity of the alcohols also depends on the CH<sub>2</sub> chain length, with the affinity increasing with increasing chain length<sup>65</sup>. Proton transfer from the EtOH to the CO<sub>3</sub><sup>2-</sup> did not occur in our calculations.

#### 3.4.2 Free energy

The free energy profile as a function of separation ( $r_{col}$ ) between O<sub>EtOH</sub> and C<sub>CO<sub>3</sub></sub> obtained from the metadynamics calculations (Figure 14) shows that the stable configuration is the dissociation of the EtOH and the Ca<sup>2+</sup>-CO<sub>3</sub><sup>2-</sup> ion pair. The free energy increases at low values of  $r_{col}$  up to  $r_{col}=4\text{\AA}$ , and there is a metastable association of EtOH and the ions at  $r_{col}=3.45\text{\AA}$  with an activation energy for dissociation of 0.5 kcal/mol. This energy minimum is composed of two types of complexes. In one of these, EtOH is H-bonded to the CO<sub>3</sub><sup>2-</sup> as in the gas phase calculations, and in the other the electron lone pair of O<sub>EtOH</sub> interacts with the C<sub>CO<sub>3</sub></sub> forming an EDA complex. During the entire metadynamics simulation, the H-bonded structure is much more abundant than the EDA com-

**Fig. 14** Potential of mean force for the binding of EtOH with  $\text{Ca}^{2+}$ - $\text{CO}_3^{2-}$  ion-pair. The most probable geometries of these ions and molecule at the local minimum at  $r_{\text{col}} = 3.45 \text{ \AA}$  are shown with ball-and-stick representation. Color scheme: Carbon (cyan), Oxygen (red), Calcium (blue), Hydrogen (gray).

plex, supporting the results of our gas phase calculations. In comparison to the AcOH, EtOH shows higher binding affinity towards  $\text{CO}_3^{2-}$ . Experimental studies<sup>65</sup> show that the strong interaction with OH- containing groups can displace water molecules from a calcium carbonate surface facilitating direct interaction with the biomolecules that can control the crystal morphology and growth<sup>66</sup>.

### 3.4.3 Bulk Solution

The RDFs between EtOH and the  $\text{Ca}^{2+}$ - $\text{CO}_3^{2-}$  ion pair obtained from our classical MD calculations show that in a water-rich environment the H-bond interaction between EtOH

**Fig. 15** Radial distribution functions for (a) oxygen ( $\text{O}_{\text{EtOH}}$ ) of EtOH and  $\text{Ca}^{2+}$ , (b)  $\text{O}_{\text{EtOH}}$  and oxygen ( $\text{O}_{\text{CO}_3}$ ) of  $\text{CO}_3^{2-}$ , (c) hydroxyl hydrogen ( $\text{H}_{\text{EtOH}}$ ) of EtOH and  $\text{O}_{\text{CO}_3}$ .

and  $\text{CO}_3^{2-}$  is predominant and that the direct interaction with  $\text{Ca}^{2+}$  is rare (Figure 15). The minimum distance between the  $\text{O}_{\text{EtOH}}$  and  $\text{Ca}^{2+}$  is  $\sim 3.5 \text{ \AA}$  and the first and second maxima appear at 4.7 and at  $\sim 6 \text{ \AA}$ , respectively (Figure 15a). In contrast, there is a strong interaction between these species in alcohol-rich environments<sup>66</sup> with a well defined maximum at  $2.5 \text{ \AA}$ . The RDFs for the  $\text{O}_{\text{EtOH}}$ - $\text{O}_{\text{CO}_3}$  (Figure 15b) and  $\text{H}_{\text{EtOH}}$ - $\text{O}_{\text{CO}_3}$  (Figure 15c) atom pairs indicate strong H-bond formation between EtOH and  $\text{CO}_3^{2-}$ . However, during the adsorption of EtOH onto the charge-neutral (104) surface of calcite<sup>65,66</sup>, the ethanol molecules bind strongly with the surface through both electron-donor-acceptor (EDA) interaction between  $\text{O}_{\text{EtOH}}$  and  $\text{Ca}^{2+}$  and H-bond interaction between  $\text{H}_{\text{EtOH}}$  and one of the oxygen atoms of  $\text{CO}_3^{2-}$  forming a layer of ethanol molecules. This EtOH layer transforms the polar calcite surface into a hydrophobic one due to the methyl groups of the ethanol molecules, which then facilitate the removal of water molecules from the surface and formation of second layer of ethanol through hydrophobic interactions. Thus, in a water-rich environment, OH- bearing amino acids are less likely to form  $\text{CaCO}_3$  nucleation sites than during biomineralization where the concentration of  $\text{Ca}^{2+}$ - $\text{CO}_3^{2-}$  ion pairs is generally high.

## 4 Discussion

Insights from our study shed light on the atomistic details of how the  $\text{NH}_2^+$ , protonated and deprotonated  $\text{COO}^-$ , and C-OH functional groups of amino acids or organic molecules interact with  $\text{Ca}^{2+}$ - $\text{CO}_3^{2-}$  ion pairs in water-rich and water-deficient environments relevant to biomineralization of calcium carbonate and natural and anthropogenic environmental situations. We modeled these functional groups as protonated guanidinium ion ( $\text{Gdm}^+$ ), acetate ( $\text{AcO}^-$ ), acetic acid ( $\text{AcOH}$ ), and ethanol ( $\text{EtOH}$ ), respectively, and used multiple computational techniques to study the structure and dynamics of these complexes in both isolated and bulk solvated systems. The gas-phase results indicate that the interactions of charged molecules ( $\text{Gdm}^+$  and  $\text{AcO}^-$ ) with  $\text{Ca}^{2+}$ ,  $\text{CO}_3^{2-}$  ion-pair are significantly stronger than those of neutral molecules and that the presence of the first hydration shell around all these molecular-assemblies is energetically more stable than the dry state due to the formation of favorable H-bonds. Our free energy calculations show that although the free-energy differences between the bound and dissociated ion-assemblies containing  $\text{Gdm}^+$  and  $\text{AcO}^-$  are almost equal at  $\sim 5 \text{ kcal/mol}$ , bound  $\text{AcO}^-$  is more stable with a barrier height of  $\sim 9 \text{ kcal/mol}$ . Thus, the high affinity of arginine and other  $\text{NH}_2^+$  bearing species and glutamate, aspartate, and other  $\text{COO}^-$  bearing species towards the Ca,  $\text{CO}_3$  ion-pair indicates that these functional groups could be the potential locations of

the nucleation sites for the crystallization of calcium carbonate.

The activation barrier energy for the formation of EtOH-CaCO<sub>3</sub> is negligibly small, ~0.5kcal/mol, and thus this molecular assembly is very unstable in a dilute, water-rich environment. However, ethanol or OH- bearing organic molecules may play an important role in controlling the morphology of the crystalline phase by stabilizing the already formed crystalline CaCO<sub>3</sub> surfaces through H-bond interactions with the CO<sub>3</sub><sup>2-</sup> and electron-donor-acceptor interaction with the Ca<sup>2+</sup>. In contrast, AcOH reacts with the neighboring CO<sub>3</sub><sup>2-</sup> and dissociates into AcO<sup>-</sup> and HCO<sup>-</sup>. Experimental studies show that the presence of solvent water expedites this reaction, and thus the formation of a stable molecular assembly with AcOH is not feasible.

## 5 Acknowledgments

This work was supported by the United States Department of Energy, Office of Basic Energy Science through grants DEFG02-10ER16128 and DE-FG02-08ER15929 and also by the Science & Engineering Research Board, Department of Science and Technology, India through grant SERB/LS-2732011. We thank Drs. Geoffrey Bowers and Ozgur O. Yazaydin for helpful discussions.

A computational study of the interaction of  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  with functional groups relevant to  $\text{CaCO}_3$  biomineralization and NOM using DFT, classical molecular dynamics and metadynamics methods to evaluate the structural environments, energetics of these interactions in small molecular clusters, changes in the vibrational frequencies due to ion-association, and the effects of solvation of the clusters in bulk water.
