Accepted Manuscript

This is an *Accepted Manuscript*, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this *Accepted Manuscript* with the edited and formatted *Advance Article* as soon as it is available.

You can find more information about *Accepted Manuscripts* in the [Information for Authors](#).

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard [Terms & Conditions](#) and the [Ethical guidelines](#) still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this *Accepted Manuscript* or any consequences arising from the use of any information it contains.

A Robust Comparison of Dynamical Scenarios in a Glass-forming Liquid

Alessandro Vispa,^a Sebastian Busch,^b Josep Lluís Tamarit,^a Tobias Unruh,^c Felix Fernandez-Alonso,^{d,e} and Luis Carlos Pardo^{*a}

We use Bayesian inference methods to provide fresh insights into the sub-nanosecond dynamics of glycerol, a prototypical glass-forming liquid. To this end, quasielastic neutron scattering data as a function of temperature have been analyzed using a minimal set of underlying physical assumptions. On the basis of this analysis, we establish the unambiguous presence of three distinct dynamical processes in glycerol, namely, translational diffusion of the molecular centre of mass and two additional localized and temperature-independent modes. The neutron data also provide access to the characteristic length scales associated with these motions in a model-independent manner, from which we conclude that the faster (slower) localized motions probe longer (shorter) length scales. Careful Bayesian analysis of the entire scattering law favors a heterogeneous scenario for the microscopic dynamics of glycerol, where molecules undergo either the faster and longer or the slower and shorter localized motions.

1 Introduction

An understanding of the dynamics of glass-forming liquids at temperatures significantly above the glass transition still represents a much-coveted goal so as to establish a sound physical framework to explore the undercooled liquid state. Although we have experimental access to the equilibrium states of the liquid at high temperatures, the very nature of glasses makes it impossible to probe these at temperatures below the glass transition. Therefore, if any theory or explanation is to be extrapolated to understand the undercooled regime from knowledge of high-temperature equilibrium states, a consensus must first exist on the underlying physics of the liquid phase at temperatures above the glass transition. Such a consensus remains a challenge to the field, and often the analysis of experimental data is invariably colored by specific theoretical considerations. The primary aim of this work is to provide a detailed and critical appraisal of QuasiElastic Neutron Scattering (QENS) data by invoking physical models which are as simple and general as possible. In doing so, we address two specific questions about the dynamics of liquid glycerol, a pro-

typical glass-forming liquid: The first one concerns how many distinct dynamical processes are present in glycerol in the sub-nanosecond (ns) regime. The second one concerns whether a HomoGeneus (dynamically driven, hereafter HG)^{1,2} or HeTeroGeneus (structurally driven, HT)³⁻⁵ scenario better describes the QENS data. To avoid the common pitfalls associated with “classical” data-analysis procedures (e. g., use of additional parameters not justified by the information content of the data), we make extensive use of Bayesian inference methods.

Glycerol is one of the most-studied “classical” glass-forming liquids.^{6,7} The dynamics of glycerol have been studied by dielectric spectroscopy (DS),⁸⁻¹² depolarized light scattering,¹³ Nuclear Magnetic Resonance (NMR),^{14,15} and QENS.¹⁶⁻²⁰ Moreover, Molecular Dynamics (MD) simulations have been performed in order to explore the dynamics of this glass-forming liquid.²¹ An early and quite extensive analysis of QENS data on glycerol was performed by Wuttke et al.²²⁻²⁴ in the context of Mode Coupling Theory (MCT). This study made extensive use of phenomenological Kohlrausch-Williams-Watts (KWW) line shapes to describe the slow dynamics. Very recently, Cicerone et al.⁴ have shown that the picosecond (ps) dynamics of glycerol and other glass-forming liquids might be studied by recourse to a two-state scenario where tightly and loosely caged domains coexist. Moreover, the liquid dynamics seem to be driven primarily by structural features. In what follows, we first examine the characteristic time scales of these processes. Since our experiments have been performed as a function of temperature, we will also compare relaxation times with those obtained from DS, in order to gain additional insights into the nature of β_{JG} -relaxation phenomena. Finally, we ask whether our QENS data are better described by the HG or HT via

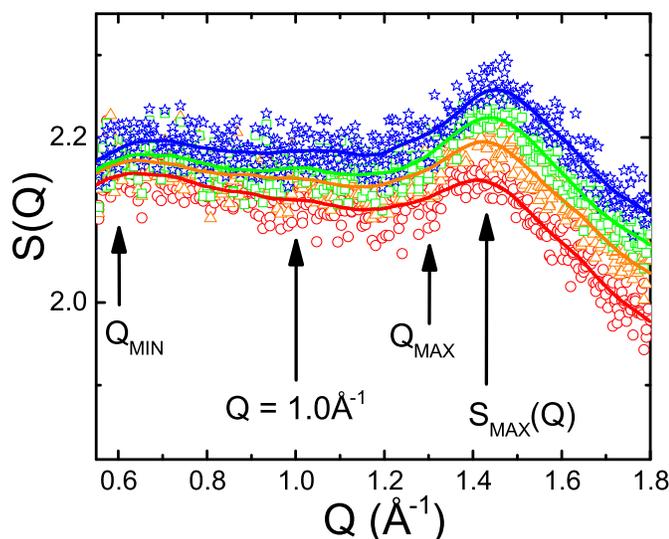

Fig. 1 (color online) Static structure factor $S(Q)$ for glycerol at $T=380$ K (red circles), 345 K (orange triangles), 316 K (green squares) and 292 K (blue stars). The Q -range analyzed is $Q_{\min}=0.6 \text{ \AA}^{-1}$ to $Q_{\max}=1.3 \text{ \AA}^{-1}$. This region is sufficiently far away from the structure factor maximum S_{\max} at around 1.4 \AA^{-1} to avoid strong contributions of coherent scattering. $Q=1.0 \text{ \AA}^{-1}$ is shown because the dynamic range is maximal for this momentum transfer, and so is the amount of information contained in the data. The solid lines are guides to the eye.

recourse to two first-order models built with a minimum number of assumptions.

2 Materials and Methods

2.1 Measurements and data reduction

All experiments were performed using a glycerol sample purchased from Sigma Aldrich with a purity greater than 99%. QENS experiments were performed using the TOFTOF spectrometer at the Heinz Maier-Leibnitz Zentrum (MLZ) in Munich (Germany) using a resolution of $55 \mu\text{eV}$ (full width at half maximum).²⁵ The samples were kept in hollow aluminium cylinders with a sample layer thickness of 0.1 mm. This thin layer ensures a transmission of $\sim 85\%$, thereby rendering multiple scattering effects small. The sample temperature was controlled with a closed-cycle refrigerator, to collect QENS data at $T = 292, 316, 345, 380$ K, corresponding to $T_g/T = 0.65, 0.60, 0.55, 0.50$.

The program FRIDA²⁶ was used for data reduction. From the time-of-flight of the neutrons, the energy transfer between neutron and sample was calculated; the measured double differential neutron scattering cross section was transformed into the scattering function; an angle- and energy-dependent absorption correction was performed on both, the sample measurements and the measurement of a vanadium standard which was used to determine the detector efficiencies and the instrumental resolution; the detector efficiencies were normalized; and finally the momentum transfer Q was calculated from the scattering angle and the energy transfer and slices of constant Q were grouped together in bins of 0.1 \AA^{-1} .

As shown in Fig. 1, the Q -range analyzed is between 0.6 \AA^{-1} and 1.3 \AA^{-1} where the coherent contribution is negligible. In en-

ergy, the spectra were evaluated in the whole accessible region.

2.2 Data evaluation

Following the seminal work of Sivia and Carlile,^{27,28} the analysis of the data has been performed using a Bayesian approach. Instead of simply finding the set of parameters that best fits the data and its related minimum χ^2 , all parameters $\{P_i\}$ and associated χ^2 values compatible with the experimental data and associated uncertainties have been calculated using a Markov-chain Monte Carlo process.^{29,30} Using this method, model selection is then performed by considering the information content of entire χ^2 probability density functions (PDFs), as opposed to relying on a single value of the merit function or its reduced version. All data analysis presented herein have been performed using the FABADA and SIDRA software packages developed in our group. FABADA was used to fit parametric models to the data and has been thoroughly described before.²⁹⁻³¹ SIDRA was used to fit QENS data with a free or parametrized distribution of modes so that the scattering function $S(Q, E)$ can be described as a function of momentum ($\hbar Q$) and energy (E) transfer by:³²

$$S(Q, E) = A(Q)\delta(E) + \sum_{i=1}^n B_i(Q, \Gamma_i) \frac{1}{\pi} \left(\frac{\Gamma_i}{E^2 + \Gamma_i^2} \right) \quad (1)$$

where Γ_i is the energy width of the i -th Lorentzian function and $B_i(Q, \Gamma_i)$ is the weight for each Lorentzian, being thus the collection of $\{B_i(Q, \Gamma_i)\}, i = 1, \dots, N$ the normalized probability distribution function describing the dynamics of the system. $B_i(Q, \Gamma_i)$ can be easily transformed to the time domain so that the intermediate scattering function $I(Q, t)$ can be written down as a distribution of simple exponential functions weighted by $B_i(Q, \tau_i)$.³² There are two main methods to obtain $B_i(Q, \tau_i)$, namely: from a model-free distribution that can be determined, for example, by a maximum entropy method,³² or from a parametrized line shape such as a Gaussian or the Fourier transform of a KWW distribution in the time domain.³³ The maximum-entropy method has the drawback that a KWW distribution is equivalent to the sum of quasi-Gaussian modes,³² i.e., it is not possible to ascertain whether the data are described by one or more dynamical processes. For this reason, we have not adhered to this approach in the present work, restricting ourselves to parametrized Gaussian and KWW distributions.

In order to perform the analysis, the theoretical function $S(Q, E)$ must be convolved with the instrumental resolution $R(Q, E)$ in the energy dimension before comparison to the measured data. When the width of the theoretical function Γ is close to the width of the energy bins of the data ΔE , the convolution process artificially increases the broadening Γ .³⁴ This artifact is especially prominent when fitting a diffusion process, since in this case Γ is proportional to Q^2 . The calculated value of Γ is therefore larger than the true one in the low Q region. In other words, as soon as the line width Γ is similar to the energy bin width ΔE , a deviation from the Q^2 behaviour is observed which is not related to any physical process, but to a numerical problem of the convolution. In order to avoid this effect, the bin width must be chosen smaller than twice the extracted line width, i.e. $\Delta E \leq 2\Gamma$.³⁴

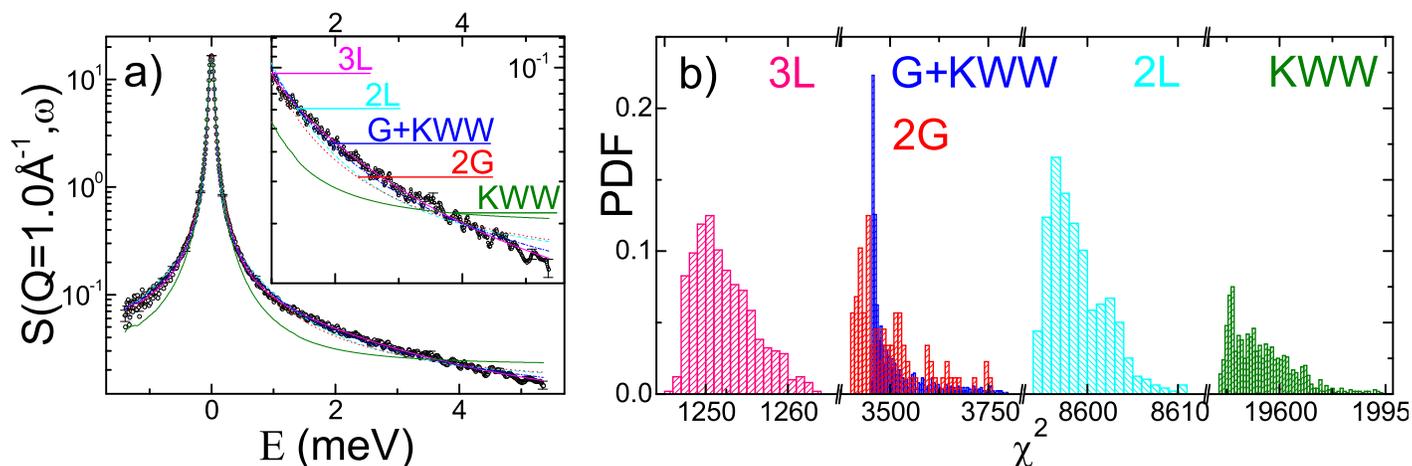

Fig. 2 (color online) (a) Data fits for glycerol at $T = 380$ K and $Q = 1.0 \text{ \AA}^{-1}$ using different models: two lorentzians (2L), three lorentzians (3L), a single KWW relaxation (KWW), KWW plus a Gaussian distribution of relaxation times (KWW+G), and two Gaussian distributions (2G). Using the same colors, panel (b) shows the corresponding χ^2 PDFs.

3 Results and Discussion

3.1 Determination of the number of processes

To answer our first question, i. e., how many dynamical processes are present in the measured dynamics of glycerol, a series of plausible (and widely used) models has been analyzed, namely: a two Lorentzian model (2L), a distribution of modes described by two Gaussian PDFs, and another one described by a KWW plus a Gaussian PDF (G+KWW). We have also compared all of these two-component models with a simple three-Lorentzian model (3L) and, for the sake of consistency, also to a single KWW distribution. In all cases, fits to the data were performed after convolution with the spectral resolution of the instrument. Fig. 2 shows the results of this analysis and the resulting χ^2 PDFs at $T = 380$ K and $Q = 1.0 \text{ \AA}^{-1}$. Model selection has been performed with the program FABADA^{35–37} at $Q = 1.0 \text{ \AA}^{-1}$ because the dynamic range and, therefore, the information content of QENS spectra are maximal at this particular Q . This momentum transfer is dominated by incoherent scattering, as it lies significantly below the first and most pronounced maximum of the measured structure factor located at $Q_{\text{max}} = 1.4 \text{ \AA}^{-1}$ (see also Fig. 1).

Inspection of the resulting χ^2 PDFs evinces that the 3L model provides the best description of the experimental data (cf. Fig. 2). Although one might argue that this conclusion could very well be the result of an increase in the number of fit parameters relative to simpler models, inspection of the underlying and well-separated χ^2 PDFs rules out this possibility in glycerol. In other words, the two-component model fits using any combination of parameters are invariably worse than those corresponding to the 3L model.

Given the popularity of the G+KWW model, we have also performed a series of additional fits to obtain values for the ‘stretching’ parameter β_{KWW} at $Q = 1.0 \text{ \AA}^{-1}$ as a function of temperature. At the lowest(highest) temperature, we find $\beta_{\text{KWW}} \approx 0.5(0.7)$. These values are in closer agreement with dielectric spectroscopy^{8–11} than previous QENS studies²³. Notwithstanding this encouraging result, we stress that our Bayesian analysis does not favour this particular model, as evidenced by the results

shown in Fig. 2.

3.2 Model comparison: homogeneous vs. heterogeneous

In order to gain further insights into the physical basis of the three processes described by the 3L model in glycerol, we have performed further model selection on the *entire scattering function* $S(Q, E)$ accessible in the QENS experiments. The aim of this exercise is to elucidate whether, in addition to the expected translational diffusion of the molecular centre of mass, all molecules are subjected to: either two additional (and distinct) relaxation processes affecting the entire ensemble (HG); or if some molecules are moving faster than others giving rise to so-called islands of mobility (HT).^{38,39} Mathematically the HG can be described by a multiplicative ansatz of dynamical processes in the time domain and, as such, it affects *all* molecules on the time scale of the α -relaxation. The HT, on the other hand, is based on the arithmetic sum of two processes, each one affecting a certain percentage of molecules at α -relaxation time scales. With these considerations in mind, the simplest (two-state) incoherent scattering functions for the HT and HG read, respectively,

$$S(Q, \omega)_{HG} = y_0 + L_D \otimes [a(Q) \cdot \delta(\omega) + (1 - a(Q))L_a] \otimes [b(Q) \cdot \delta(\omega) + (1 - b(Q))L_b] \quad (2)$$

$$S(Q, \omega)_{HT} = y_0 + L_D \otimes \{P[a(Q) \cdot \delta(\omega) + (1 - a(Q))L_a] + (1 - P)[b(Q) \cdot \delta(\omega) + (1 - b(Q))L_b]\}. \quad (3)$$

where L_D is a Lorentzian line describing translational diffusion with a spectral width proportional to the square of the momentum

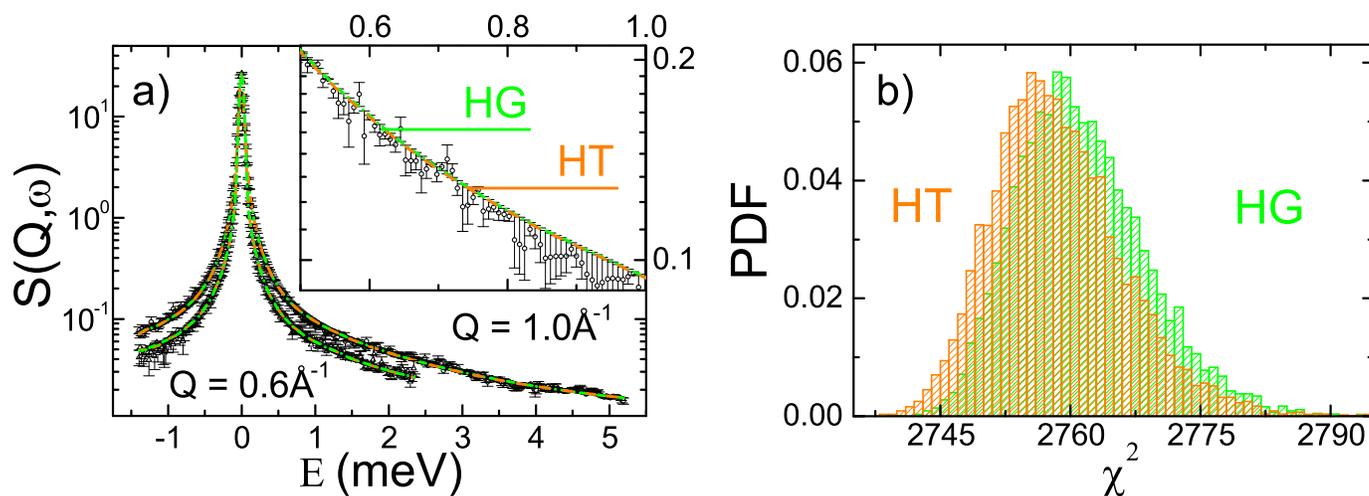

Fig. 3 (color online) (a) Representative QENS spectra for glycerol at $T = 380$ K and associated fits for the HT/HG (solid/dashed lines); (b) χ^2 PDFs obtained from global fits over the *entire scattering function* as discussed in the main text.

transfer, that is, $\Gamma = DQ^2$, where D is the translational diffusion coefficient. We note the intrinsic (linear) dependence of D on Q^2 , a relation that has been used to describe the experimental data as a function of Q using a single fit parameter D . The remaining (localized) motions are described by $[P_i(Q) \cdot \delta(\omega) + (1 - P_i(Q))L_{P_i}]$ with $P_i = a, b$. The dependence of the form factors $a(Q)$ and $b(Q)$ on Q provides a measure of the associated length scales for these motions.

In order to establish whether the spectral widths Γ_i associated with localized motions are Q -independent, we have allowed these to vary across Q at all temperatures. Results for $T = 380$ K are shown in the inset of Fig. 5 and demonstrate that, within experimental uncertainties, they are Q -independent. In view of the above, we have replaced a total of 16 parameters (2 Lorentzian widths across 8 independent Q -values) by 2 Q -independent spectral widths which were then fit simultaneously across all Q slices. This reduction in the number of adjustable parameters results in a drastic decrease in error bars. As explicitly shown by Eqs. 2-3, the use of Q -independent spectral widths to describe the localized modes does not imply that the resulting Lorentzian modes are of constant width, since convolution with the translational component necessarily leads to spectral features of width $\Gamma_i + DQ^2$.

The results of this analysis at two Q s are shown in Fig. 3a (an overview over all fits are shown in Fig. 4), demonstrating that both scenarios can describe the QENS data well. The resulting χ^2 PDFs are shown in Fig. 3b, where χ^2 values correspond to global values across all energy and momentum transfers probed by QENS. Fig. 3b serves to highlight a significant overlap of the χ^2 PDFs for both models, which means that model selection in this particular case is certainly more ambiguous than in the previous case dealing with a determination of the total number of distinct dynamical processes. Although in this case the HT is preferred (both the minimum and maximum of the χ^2 PDF are located at lower values), it is still possible that additional information encoded in an improved prior (or new measurements over a wider range of length and timescales) could change the above conclu-

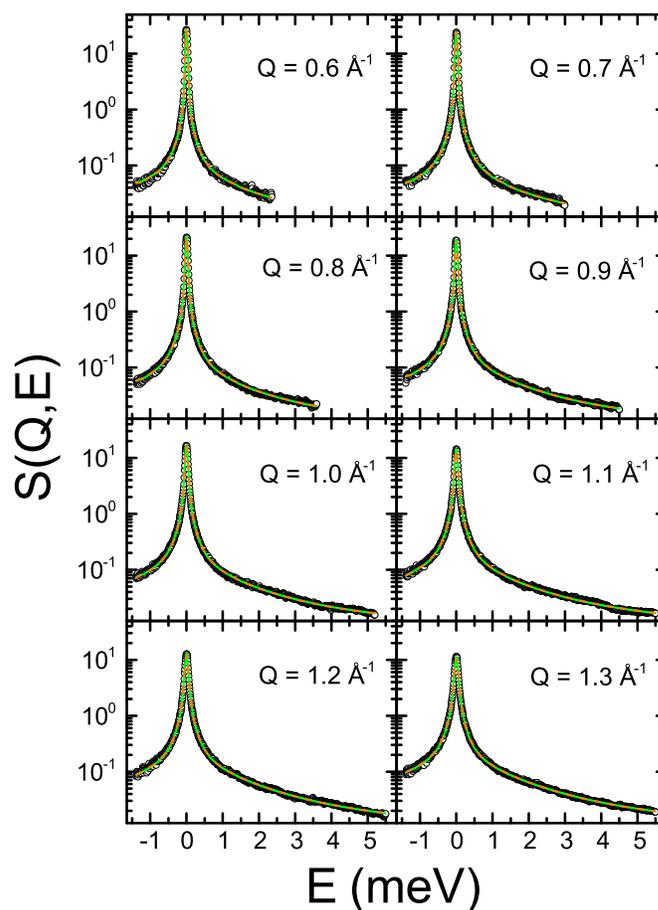

Fig. 4 (color online) The quasielastic scattering function $S(Q, E)$ of glycerol (at 380 K) for all values of Q evaluated in this work. Also shown are the best fits with the two models HG (solid green line) and HT (dashed orange line).

sion. In any case, given the information at hand, *the HT is favored*.

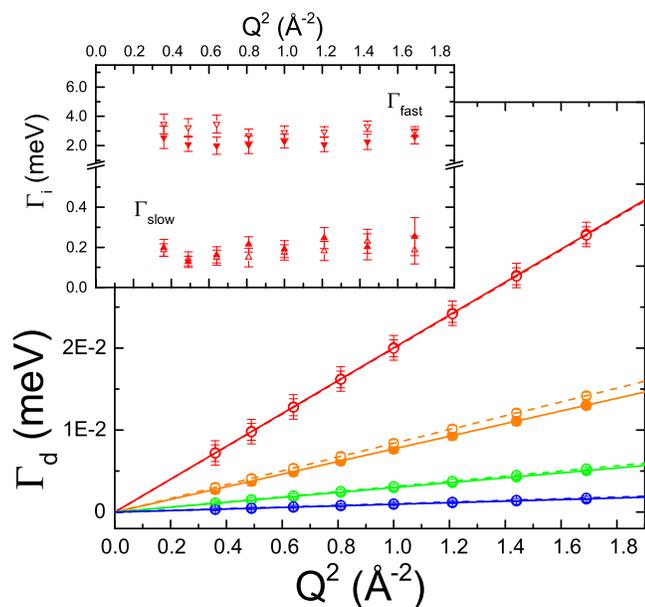

Fig. 5 (color online) Q -dependent linewidth Γ_d (HWHM) of $S(Q, E)$ for different temperatures. At each temperature, a clear Q^2 dependence of Γ_d is observed, compatible with a diffusive motion. The lines show the best fits of the function $\Gamma_d = DQ^2$ to the data. It is evident that diffusion coefficients D obtained for the two models HG (full symbols and solid lines) and HT (open symbols and dashed lines) are very similar.

3.3 Physical parameters extracted from the HG and HT models

In both models, the peak is described by a Lorentzian line shape with a half width at half maximum (HWHM) Γ_d which is related to the diffusion coefficient D by $\Gamma_d = DQ^2$. The diffusion coefficient is obtained for each temperature and for the two tested models (cf. Fig. 5). Across the whole temperature range, the value of the diffusion coefficient is basically independent of the employed model (HG or HT).

Fig. 6 reports the relaxation times $\tau_i = \hbar/\Gamma_i$ obtained for all three processes of the HT and HG model. First of all, we find that the obtained τ_i s are independent of the model chosen and, therefore, their determination is robust. In addition to the relaxation times τ_{slow} and τ_{fast} associated with the two localized processes, we also show the relaxation time τ_{max} at Q_{max} , a dynamical quantity that describes the collective dynamics. As shown in Fig. 6, the temperature dependence of τ_{max} is in good agreement with collective α -relaxation data measured with DS.^{8–11} These two datasets deviate slightly from each other as the temperature is lowered because the timescales associated with translational diffusion increase and, as a result, they approach the intrinsic energy resolution of the QENS experiments.⁴⁰

As discussed previously,⁴¹ the translational diffusion coefficients obtained from the QENS data are in line with literature values. Thus, we may conclude that our quantitative determination of translational diffusion coefficients is robust, further corroborating the physical validity of the priors defined by Eqs. (2)–(3). Concerning the localized modes, we find $\tau_{\text{fast}} = 0.2\text{ps}$ and $\tau_{\text{slow}} = 5.5\text{ps}$, and both are insensitive to temperature. This, perhaps surprising, insensitivity to temperature has been observed in

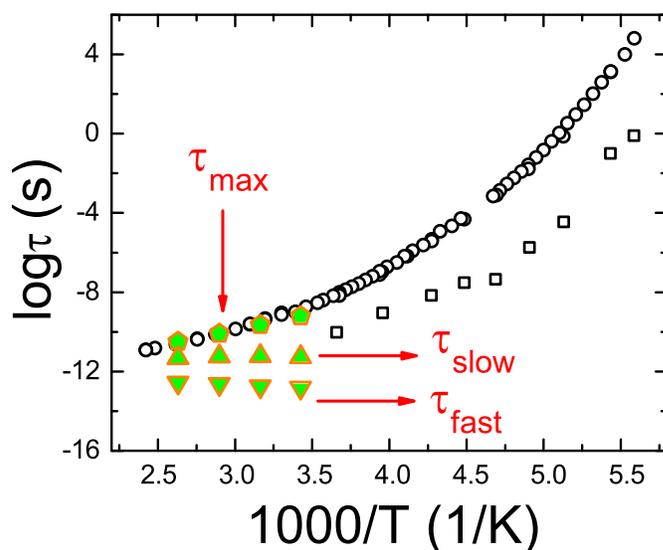

Fig. 6 (color online) Relaxation map of glycerol as a function of reciprocal temperature. Open (filled) symbols represent DS (QENS) data. On the scale of this map, relaxation times for the HT and HG are indistinguishable.

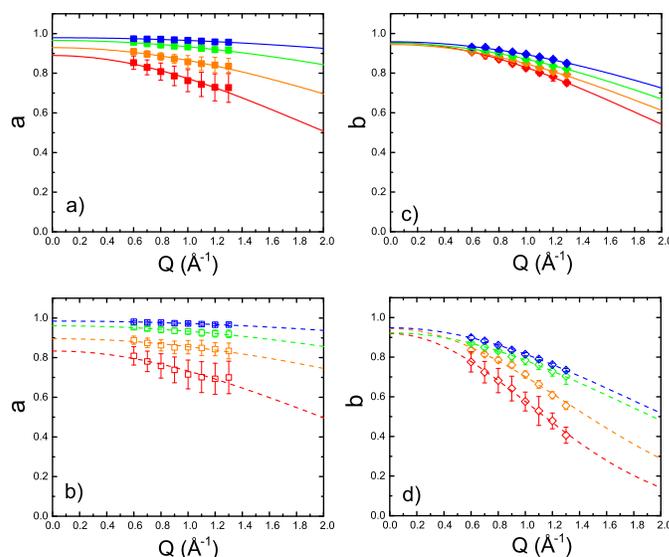

Fig. 7 (color online) Q -dependence of the parameters a (panels a and b) and b (panels c and d) for each temperature extracted from both, the HG model (panels a and c) and HT model (panels b and d). Also shown are fits of $C \exp(-\pi^2 \sigma^2 Q^2)$.

other prototypical strongly associated liquids like hydrogen fluoride.^{42,43} Whether this behaviour is characteristic of this family of complex liquids remains an open question. On the basis of these considerations, it is unlikely that the β_{JG} relaxation measured by DS¹² is related to these dynamical processes probed by QENS (see Fig. 6).

The analysis of the neutron scattering spectra does not only allow to extract the rates or relaxation times of the processes, it is also possible to determine the length scale of the two confined motions. The terms describing these motions of the molecule

and tagged as *slow* and *fast*, respectively, are given in the scattering function by $[P_i(Q) \cdot \delta(\omega) + (1 - P_i(Q))L_{P_i}]$ where $P_i = a, b$. In Fig. 7 we present the Q -dependence of parameters a and b for the two models and at all temperatures. These parameters exhibit the same overall behaviour, namely they decrease with increasing Q or T . Length scales σ associated with slow (τ_{slow}) and fast (τ_{fast}) dynamical processes have been obtained by considering the first term of the cumulant expansion of the structure factor,^{44,45} a Gaussian term in Q that may be written as $C \exp(-\pi^2 \sigma^2 Q^2)$. The prefactor C in this cumulant expansion is used to account for multiple-scattering effects, which translate into an effective reduction of the Elastic Incoherent Structure Factor obtained from the QENS data.³⁴ The fits to the data can be seen in Fig. 7.

For both the HT and HG, we find that the shorter length scales correspond to “slow” movements taking place in the picosecond time range and longer length scales are associated with “fast” movements. This somewhat counter-intuitive result is physically plausible provided that these two motions conform to different microscopic mechanisms. In this context, the microscopic picture recently proposed by Cicerone et al.⁴ offers a natural explanation of our results (see below). The σ values are model dependent both in terms of their magnitude and overall temperature dependence, but in both the HT and HG, they increase with temperature and are invariably larger for faster motions. For the HT, however, both length scales are distinctly different over the entire temperature range investigated in this work, whereas for the HG both length scales converge to the same value at the highest temperature investigated – while the two motions stay well separated with regards to their speed. The HT scenario consists of two populations (slow and fast molecules) the ratio of which shifts with rising temperature in favor of more fast molecules (cf. Fig. 8).

The analysis of the QENS data presented above leads us to the unequivocal conclusion that there are three distinct dynamical processes taking place in liquid glycerol: one associated with the centre-of-mass translational diffusion of the molecule as a whole; and the other two corresponding to localized picosecond (slow) and sub-picosecond (fast) motions, both of which are insensitive to temperature. This result, together with our finding that fast (slow) motions take place over long (short) length scales are *independent of the underlying model chosen to fit the experimental data*.

Concerning the localized motions, it has to be noted that the information provided by the measured scattering function is not sufficient to establish a clear-cut preference for either physical scenario; the HT is favored over the HG but we cannot exclude that additional information might revert this order. For the less likely HG, *all molecules* would be subjected to the same two types of motions, which we call rattling and hopping, at *all times* and also these two mechanisms would need to hold at all temperatures. The (smaller) rattling motion would need to occur on a slower time scale than the (larger) hopping and, at temperatures approaching $T = 380$ K, the two length scales merge (cf. Fig. 8), *although their associated relaxation times are still clearly different* (cf. Fig. 6). Our results for the HG scenario at high temperatures are also compatible with the microscopic mechanism proposed by Mamontov,²⁰ with rattling motions described by confined diffu-

sion on a sphere and fast motions by intramolecular localized motions. Given the information encoded in our QENS data, the HT is the more plausible option, whereby a sizable and temperature-dependent fraction of the molecular ensemble undergoes faster motions over longer length scales. Following the work of Cicerone et al.,⁴ these motions would be associated with molecules belonging to regions in the fluid dominated by collective dynamics. The remainder of the ensemble would then move more slowly over shorter length scales, a contribution that one could tentatively ascribe to “normal-liquid regions”.³ These motions are well separated in relaxation time over the entire temperature range investigated, and show no signs of merging into a single dynamical process.
