Accepted Manuscript

This is an *Accepted Manuscript*, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this *Accepted Manuscript* with the edited and formatted *Advance Article* as soon as it is available.

You can find more information about *Accepted Manuscripts* in the [Information for Authors](#).

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard [Terms & Conditions](#) and the [Ethical guidelines](#) still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this *Accepted Manuscript* or any consequences arising from the use of any information it contains.

Environmental Impact Statement

Relative Contributions of Mercury Bioavailability and Microbial Growth Rate on Net Methylmercury Production by Anaerobic Mixed Cultures

Katarzyna H. Kucharzyk[†], Marc A. Deshusses[†], Kaitlyn A. Porter¹, and Heileen Hsu-Kim^{†*}

The environmental production of the neurotoxin methylmercury occurs through anaerobic microorganisms such as sulfate-reducers. Rates of mercury methylation are known to be influenced by the productivity of these microbes as well as the bioavailability of inorganic Hg for these organisms. However, the conditions that guide the importance of one factor relative to the other are not well defined. This paper describes experiments with mixed cultures of methylating microorganisms that indicate the existence of a threshold in activity of methylating microorganisms (e. g., sulfate reduction rate) where net methylmercury production is sensitive to either microbial growth or to Hg speciation and bioavailability. At environmental sites of interest, knowledge of this threshold in microbial activity could be useful for remediation purposes by allowing a prioritization of actions that can best minimize in-situ production of methylmercury.

1 Abstract

2 Monomethylmercury (MeHg) is produced in many aquatic environments by anaerobic
3 microorganism that take up inorganic forms of Hg(II) and methylate it. Net methylation of
4 Hg(II) appears to be correlated with factors that affect the activity of the anaerobic microbial
5 community and factors that increase the bioavailability of Hg(II) to these organisms. However,
6 the relative importance of one versus the other is difficult to elucidate even though this
7 information can greatly assist remediation efforts and risk assessments. Here, we investigated the
8 effects of Hg speciation (dissolved Hg and nanoparticulate HgS) and microbial activity on the
9 net production of MeHg using two mixed microbial cultures that were enriched from marine
10 sediments under sulfate reducing conditions. The cultures were amended with dissolved Hg
11 (added as a dissolved nitrate salt) and nanoparticulate HgS and grown under multiple carbon
12 substrate concentrations. The results indicated that net mercury methylation was the highest for
13 cultures incubated in the greatest carbon substrate concentration (60 mM) compared to
14 incubations with less carbon (0.6 and 6 mM), regardless of the form of mercury amended. Net
15 MeHg production in cultures exposed to HgS nanoparticles was significantly slower than in
16 cultures exposed to dissolved Hg; however, the difference diminished with slower growing
17 cultures with low carbon addition (0.6 mM). The net Hg methylation rate was found to correlate
18 with sulfate reduction rate in cultures exposed to dissolved Hg, while methylation rate was
19 roughly constant for cultures exposed to nanoparticulate HgS. These results indicated a potential
20 threshold of microbial productivity: below this point net MeHg production was limited by
21 microbial activity, regardless of Hg bioavailability. Above this threshold of productivity, Hg
22 speciation became a contributing factor towards net MeHg production.

23
24 Keywords: mercury methylation potential, bioavailability

26 **Graphical Abstract**

27

28 Introduction

29 Monomethylmercury (MeHg) is a neurotoxic and highly bioaccumulative compound that
30 poses human health risks via dietary fish consumption^{1, 2}. In the aquatic environment, mercury
31 occurs primarily as inorganic species, including many forms of dissolved and particulate
32 inorganic divalent mercury (Hg(II))³. A process essential to the bioaccumulation of mercury is
33 the production of MeHg by anaerobic microorganisms in aquatic ecosystems.

34 Recent research on microbial methylation of mercury has focused on two factors that
35 govern this process: 1) The identification of the methylating microorganisms and the
36 biochemical pathway of methylation; and 2) The chemical speciation of mercury in anaerobic
37 settings and bioavailability of Hg(II) for cellular uptake by methylating microorganisms⁴⁻⁶. In
38 each case, the environmental factors that contribute to MeHg production have been studied in
39 depth. For example, conditions that include anaerobic zones, relatively high amounts of total or
40 dissolved organic carbon, and additions of sulfate to freshwater system are all known to increase
41 the productivity of methylating microorganisms, and subsequently MeHg concentrations⁷⁻¹².
42 Likewise, a fraction of the Hg(II) in anaerobic settings is bioavailable to methylating organisms,
43 and it may include dissolved Hg-ligand species (e.g. dissolved Hg-sulfides) as well as Hg
44 associated with particles³. In anaerobic settings, Hg(II) tends to be primarily associated with
45 particulate phases^{13, 14}, including crystalline HgS mineral phases such as metacinnabar,
46 amorphous or nanostructured HgS, and adsorbed forms of Hg(II) (e.g., to metal sulfide particles
47 and particulate organic matter)³. These various particulate forms of Hg offer a spectrum of
48 reactivity and bioavailability to methylating organisms due to differences in rates of dissolution
49 and desorption, differences in the ability to accumulate at cell interfaces, and for nanoparticles, a
50 potential ability to cross cell membranes¹⁵⁻¹⁸.

51 The relative contribution of microbial productivity and Hg bioavailability for net MeHg
52 production rates is not well established and is the focus of this study. Previous research on this
53 topic focused only on one factor such as sulfate reduction rates or the speciation of inorganic Hg
54 for controlling net MeHg production rates.^{3, 10, 19-22} Research that can control for both factors
55 would provide greater insight to the processes that influence mercury methylation potential in the
56 environment. For example, our previous work with sediment microcosms²³ indicated that in
57 some conditions low nutrient availability can limit the productivity of methylating microbes and
58 subsequently limit MeHg production rates. In other conditions where methylating

1
2
3 59 microorganisms are active, the speciation and bioavailability of Hg may be more important for
4
5 60 controlling MeHg production. The sediment microcosms described in our previous work²³ did
6
7 61 not test many variables in microbial growth rates. Thus, specific conditions in which one factor
8
9 62 dominates over the other needs to be studied in greater depth.

10
11 63 The goal of this study was to compare the relative contributions of microbial productivity
12
13 64 and Hg speciation for net MeHg production in mixed cultures of anaerobic microorganisms.
14
15 65 Anaerobic sulfate-reducing cultures were enriched from two sediment samples obtained from a
16
17 66 marine location. The growth of the organisms was controlled by varying the concentrations of
18
19 67 organic substrates, while the bioavailability of added Hg was controlled by amending the
20
21 68 cultures with either dissolved Hg or nanoparticulate HgS. The rates of net MeHg production
22
23 69 were then compared to growth rates of the organisms, sulfate reduction rates, and gene
24
25 70 abundance for sulfate reducers.

26
27 71
28 72 **Materials and Methods**
29
30 73 **Sediments for microbial enrichments.** Sediment samples were obtained from two locations
31
32 74 (MS-1 and MS-2) of the same marine water body in August 2012. The precise location of the site
33
34 75 cannot be disclosed due to contractual agreements with the site managers. The water depth at the
35
36 76 site was approximately 55 to 75 m, while the surface and bottom temperatures averaged 29.5°C
37
38 77 and 27°C, respectively. At both sampling locations, dissolved oxygen was not detectable
39
40 78 beneath the sediment surface layer, and dissolved sulfide was also not detectable (<1 μM),
41
42 79 indicating anoxic but not extremely reducing conditions (per communication with site
43
44 80 managers). The production of methylmercury in sediments at this site is a concern due to the
45
46 81 presence of Hg-bearing particles in the area. The top layer of the sediment (approximately 5 cm)
47
48 82 was collected in triplicates by Van Veen-type grab samplers, packed into acid-cleaned
49
50 83 polyethylene jars with Teflon-lined caps and immediately frozen at -20°C, and transported to the
51
52 84 lab at Duke University for further analysis.

53
54 85 At the lab a subset of each sample was thawed and characterized for texture (i.e., grain
55
56 86 size), total Hg and MeHg content, and organic carbon content. Sediment moisture content was
57
58 87 determined by drying samples at 110°C for 24 hours; pH was determined in a slurry comprising
59
60 88 of 5 parts distilled water and 1 part sediment. Sediment texture was measured by dispersing the
61
62 89 sediments in an aqueous solution of 2.5 N hexametaphosphate ((NaPO₃)₆) and mixing. The

1
2
3 90 relative size fractions were quantified by the rate of gravitational settling of particles²⁴⁻²⁶. Pore
4
5 91 water was extracted from the sediment by centrifuging the sediments under aerobic conditions at
6
7 92 3000 *g* for 20 min. The supernatant of this centrifuged sample, designated as “pore water” in this
8
9 93 study, was analyzed for sulfate concentration.
10
11 94

12 95 **Preparation of anaerobic mixed cultures for Hg methylation.** The inocula for the mixed
13
14 96 cultures were prepared by enriching sediment slurries for anaerobic microorganisms under
15
16 97 sulfate reducing conditions. These enrichments were prepared by placing 20 g of homogenized
17
18 98 wet sediments from sites MS-1 or MS-2 into serum bottles containing 200 mL of sterile growth
19
20 99 medium developed for sulfate-reducing cultures (see references^{27, 28} and the SI). The serum
21
22 100 bottles were sealed and incubated in the dark at room temperature (20 to 22 °C) for 7 days. After
23
24 101 this time the bottles were mixed end-over-end, large sediment particles were allowed to settle,
25
26 102 and aliquots of the overlying water served as inocula for the Hg methylation experiments.
27
28 103 Enrichments of anaerobic microbial consortia from MS-1 and MS-2 were each performed on two
29
30 104 different occasions. All handling of the sediments, enrichments and the subsequent mixed culture
31
32 105 experiments were conducted in an anaerobic chamber (Coy Labs) with an oxygen-free gas
33
34 106 mixture (90% N₂, 5% CO₂, and 5% H₂).

35 107 The Hg methylation experiments were conducted in 30 mL anaerobic culture tubes
36
37 108 containing sterile sulfate reducing medium and inoculated with the supernatant of the enriched
38
39 109 sediment slurries. In the first round of experiments, the carbon substrate (C-substrate)
40
41 110 concentrations were varied to the following: 0.6 mM, 6 mM, and 60 mM, each comprising a
42
43 111 mixture of 2 parts sodium pyruvate and 1 part lactic acid (mole basis). In the second round of
44
45 112 mixed culture experiments, five different carbon concentrations were tested (0.6 mM, 0.8 mM, 1
46
47 113 mM, 6 mM and 60 mM with the same ratio of pyruvate to lactic acid as in the first experiment).
48
49 114 For each of the carbon concentrations, 20 mL of medium was dispensed into the tubes and 2%
50
51 115 (vol/vol) of the inoculum was transferred.

52 116 Immediately after inoculation of the culture media with variable C-substrate
53
54 117 concentrations, the cultures were amended with either dissolved Hg or nanoparticulate HgS from
55
56 118 their respective stock solutions to a final Hg concentration of 5 nM. The preparation of the
57
58 119 nanoparticulate HgS stock solutions was followed according to previous work²³ and is
59
60 120 summarized in the SI. The nanoparticles comprised of metacinnabar-like structure with primary

1
2
3 121 particle diameter of 3-5 nm²³ and were aggregated to an average hydrodynamic diameter of 25.8
4
5 122 nm ± 2.9 nm (based on light-intensity weighted dynamic light scattering).
6

7 123 Four sets of controls with the culture media containing 60 mM C-substrate were
8
9 124 incubated under the same conditions as the test samples. These included: (1) A blank containing
10 125 the culture medium, microbial inoculum from either MS-1 or MS-2 slurries, and no added
11 126 mercury (i.e., Hg blank); (2) An abiotic control consisting of the same culture medium amended
12 127 with dissolved Hg or nanoparticulate HgS but no microorganisms; (3) A killed control with the
13 128 culture medium inoculated with microorganisms, amended with dissolved Hg or nanoparticulate
14 129 HgS, and spiked with 0.4% (vol/vol) concentrated hydrochloric acid (HCl) (trace metal grade);
15 130 (4) A molybdate control consisting of the inoculated culture medium amended with dissolved Hg
16 131 or HgS nanoparticles, and 20 mM sodium molybdate, a specific inhibitor of sulfate reduction²⁹,
17 132 ³⁰. All culture tubes were capped with gas-tight seals and placed into the anaerobic jar with
18 133 GasPak 150 system (Fisher Scientific) to maintain strict anaerobic conditions. The mixed
19 134 cultures were incubated in the dark on a platform shaker (Eppendorf) at 25 rpm for 64 hours at
20 135 30°C.
21
22
23
24
25
26
27
28
29

30 136 At each time point, replicate culture tubes (n = 2 or 3) were sacrificed and subsampled for
31 137 chemical and biological analyses. Prior to liquid sample collection, the tubes were vortexed, and
32 138 1 mL of gas was collected from the headspace using a gas-tight syringe. The gaseous mercury
33 139 content (e.g., Hg⁰) in the samples was analyzed by injecting the sample into a gas-tight vial filled
34 140 with ultrapure water (Barnstead Nanopure, >18 MΩ-cm) containing 2% (vol/vol) BrCl. These
35 141 samples were then stored for at least 3 days at room temperature prior to total mercury analysis.
36 142 After the collection of the headspace, liquid aliquots were withdrawn for measurements of
37 143 optical density at 660 nm (OD_{660nm}), DNA, total mercury, acid volatile sulfide and sulfate (SO₄²⁻).
38 144 The remainder of the culture was preserved for MeHg analysis by adding 0.4% (vol/vol)
39 145 concentrated hydrochloric acid (HCl) (trace metal grade) and stored at 4°C until analysis.
40
41
42
43
44
45
46
47

48 146 Samples at 10, 48 and 64 hours of incubation were subject to the DNA extraction
49 147 followed by the quantitative PCR analysis with primers targeting sulfate reducing
50 148 microorganisms. The details of this method are described in the SI section. The relative
51 149 abundance of sulfite reductase gene was calculated from the copy numbers of total bacteria in the
52 150 sample and correlated to the net mercury methylation production.
53
54
55
56
57
58
59
60

1
2
3 152 **Chemical analyses.** The concentration of total mercury in liquid samples was quantified by
4
5 153 stannous chloride reduction, gold amalgamation, and cold vapor atomic fluorescence
6
7 154 spectrometry (CVAFS)³¹. For total mercury concentration in sediments, the samples were first
8
9 155 digested in a mixture of 8 mL concentrated HCl and 2 mL concentrated HNO₃ and heated to
10
11 156 90°C for 5 h. After the digestion step, the solution was cooled and diluted for analysis by
12
13 157 CVAFS.

14 158 Methylmercury concentration in liquid samples was quantified by distillation, aqueous
15
16 159 phase ethylation, gas chromatographic separation, pyrolysis and inductively coupled plasma
17
18 160 mass spectrometry³². The efficiency of the distillation step was quantified by spiking each
19
20 161 sample with Me²⁰¹Hg (50 pg mercury) as an internal standard. The recovery of the Me²⁰¹Hg
21
22 162 spike was used to correct for the MeHg concentration in each sample³³.

23 163 Methylmercury in the original MS-1 and MS-2 sediment samples was extracted by acid-
24
25 164 dichloromethane leaching and aqueous back extraction prior to analysis³⁴. Sediment MeHg
26
27 165 concentrations were corrected for extraction efficiency using a MeHg standard (Brooks Rand)
28
29 166 and reported on dry sediment weight basis.

30 167 Total organic carbon (TOC) in sediments was quantified by the difference of total carbon
31
32 168 content and inorganic carbon content of dried sediment samples (i.e. heated to 100°C). Inorganic
33
34 169 carbon content corresponded to the total carbon quantified in dried samples that were further
35
36 170 heated to 400°C for 12 h. All carbon contents were determined using a TOC-V CPH total organic
37
38 171 carbon analyzer (Shimadzu).

39 172 Sulfate concentration was determined by ion chromatography (Dionex ICS-2000,
40
41 173 Sunnyvale, CA) using an AS18 analytical column, ASRS 300 suppressor and KOH eluent
42
43 174 generator. Samples for acid volatile sulfide (AVS) quantification were preserved with ZnSO₄ and
44
45 175 KOH (final concentrations of 20 mM and 4 mM, respectively) and stored at 4° C until analysis.
46
47 176 For analysis, each sample was placed into a closed glass reactor with 1 N HCl, purged with ultra
48
49 177 high purity N₂ for 30 min into a 10% v/v NaOH solution, and analyzed for sulfide concentration
50
51 178 via colorimetry.^{35, 36}

52 179
53 180 **Data Analyses.** Linear-least squares regressions were performed for time-dependent MeHg and
54
55 181 sulfate concentration data from the cultures. The slope values for these regressions were used to
56
57 182 estimate rates of net MeHg production and sulfate reduction. The regression parameters (slope

1
2
3 183 and intercept) were calculated and reported with their respective standard errors. Correlations
4
5 184 were also performed to compare the sulfate-reducing community (expressed as sulfate reduction
6
7 185 rate or gene abundance) with mercury methylation (expressed as net rate of production or % of
8
9 186 total Hg as MeHg). Single-factor analysis of variance (ANOVA) was used to compare rates
10
11 187 between culture treatments (e.g., sulfate reduction rates in dissolved Hg amendments versus nano
12
13 188 HgS amendments). Significant differences between treatment types were designated for
14
15 189 comparisons yielding p-values less than 0.05. All statistical analyses were performed with the
16
17 190 Analysis ToolPak in Microsoft Excel.
18
19 191

192 **Results and Discussion**

193 **Characteristics of sediments for the enrichments.** The analysis of relevant chemical
194
195 194 characteristics of the MS-1 and MS-2 sediments used for the enrichments (Table 1) indicated that
196
197 195 sulfate concentrations in the porewaters were approximately 2700 - 2900 mg L⁻¹. Total Hg
198
199 196 concentrations in MS-1 and MS-2 sediments were 12.2 ± 5.9 mg kg⁻¹ and 16.6 ± 2.8 mg kg⁻¹,
200
201 197 respectively, and reflected elevated mercury concentrations relative to the median crustal earth
202
203 198 concentration (approximately 0.05 mg kg⁻¹ ³⁷). Methylmercury content in sediments was also
204
205 199 high (Table 1). However, the MeHg represented only a small percentage of the total Hg (0.001-
206
207 200 0.002%). Total organic carbon (TOC) content was greater for the MS-1 sediment than for MS-2,
208
209 201 but overall, was relatively low for both sediments (31.8 ± 0.8 mg kg⁻¹ and 4.5 ± 0.6 mg kg⁻¹ for
210
211 202 MS-1 and MS-2, respectively). Thus, the activity of the native microbial community was
212
213 203 expected to be low.
214
215 204

216
217 205 **Growth rates of mixed cultures under variable carbon substrate concentration and type of**
218
219 206 **added Hg.** The growth rates of the mixed cultures depended on the concentration of C-substrate
220
221 207 present in the culture media and was unaffected by the type of mercury added. In all cases,
222
223 208 similar growth patterns were observed, with faster growth kinetics for cultures incubated at the
224
225 209 greatest concentrations of C-substrate (Figure 1). Examination of the growth curves revealed an
226
227 210 initial 2 h to 5 h lag phase followed by a rapid 10-hour increase in cell density, corresponding to
228
229 211 a specific growth rate μ of 0.064 to 0.070 h⁻¹. This fast growth was followed by significantly
230
231 212 slower growth or no additional growth.
232
233 213

1
2
3 214 **Net production of MeHg in mixed cultures.** Net MeHg production depended on the type of
4 215 mercury added (i.e., dissolved Hg and nanoparticulate HgS) and the amount of C-substrate
5 216 present in the growth media (Figure 2). Both mixed cultures exposed to dissolved Hg
6 217 demonstrated net increases of MeHg concentrations during the exponential and stationary phases
7 218 of growth (from approximately 5 h to 64 h incubation time). In the mixed cultures inoculated
8 219 from the MS-1 sediment enrichment (Figure 2A), 10.9%, 22.6%, and 29.8% of the added
9 220 dissolved mercury spike (5 nM total) was converted to MeHg at the end of the experiment for
10 221 mixed cultures incubated in 0.6 mM, 6 mM and 60 mM C-substrate, respectively. For the mixed
11 222 cultures derived from the MS-2 sediment enrichment (Figure 2C), relatively less of the added
12 223 dissolved Hg was converted to MeHg (1.4 to 5.3% as MeHg). This difference between the mixed
13 224 cultures is likely due to differences in composition of microbial populations in the MS-1 and
14 225 MS-2 derived cultures.

15 226 For mixed cultures that received HgS nanoparticles (Figures 2B and 2D), MeHg
16 227 concentrations in most cultures increased during the first 5 h to 24 hours and slowed after this
17 228 point to the end of the experiment. In MS-1 mixed cultures with HgS nanoparticles added, 3.9 to
18 229 12.7% of initial Hg spike was converted to MeHg at the end of the experiment, while in the MS-
19 230 2 mixed cultures, 0.3 to 2.1% of initial Hg was methylated. These percent methylated values
20 231 were 3 to 4 times lower than in respective cultures with dissolved Hg added and the same C-
21 232 substrate concentration. Moreover, these differences between the dissolved Hg and
22 233 nanoparticulate HgS amendments were not caused by variable bacterial growth rates, as cell
23 234 growth was the same regardless of the type of added Hg (Figure 1). Rather, the difference was
24 235 likely due to the limited bioavailability of Hg originating from HgS nanoparticles relative to
25 236 dissolved Hg.

26 237 The mercury added to the culture flasks was, for the most part, fully recovered in the
27 238 culture media during the entire experiment. In both MS-1 and MS-2 mixed cultures amended
28 239 with either dissolved Hg or nanoparticulate HgS, at least 85% of the added Hg was quantified in
29 240 the culture media (Figure S1). Approximately 15 to 25% of the added mercury sorbed to the
30 241 container while less than 1.0% was recovered in the headspace of the culture vials. We also
31 242 hypothesize that the speciation of the Hg changed during the course of the incubation. For
32 243 example, the production of sulfide (Figure S2) from the sulfate reducing community likely
33 244 changed the speciation of Hg in the cultures and the relative partitioning of Hg between

1
2
3 245 dissolved and particulate phases. Nevertheless, the initial form of Hg added to the cultures (i.e.
4
5 246 dissolved Hg or nanoparticulate HgS) played an important role in determining net methylation
6
7 247 rates.

8
9 248 In the Hg blank, killed controls, and abiotic controls, the measured MeHg concentrations
10
11 249 were less than 4.1 pM for all time points (data not shown). These concentrations were much
12
13 250 smaller than the MeHg concentrations observed at the end of the 64-h incubations for all the live
14
15 251 cultures amended with either form of mercury (Figure 2).

16 252
17
18 253 **Consumption of sulfate and abundance of sulfite reductase genes.** The activity of SRB was
19
20 254 evaluated by monitoring sulfate concentrations during the incubation and quantifying the relative
21
22 255 abundance of sulfite reductase genes in the cultures. In all mixed cultures, sulfate concentrations
23
24 256 followed an approximately linear decrease with time (Figure 2). The greatest decrease in sulfate
25
26 257 concentration was observed for cultures incubated with 60 mM C-substrate, an observation
27
28 258 consistent with the expected greater microbial activity at higher substrate concentration.

29
30 259 The addition of sodium molybdate resulted in almost complete inhibition of sulfate
31
32 260 consumption and MeHg production (Figure S3), consistent with previous studies.^{29,30} The
33
34 261 concentrations of MeHg at the end of the incubation in these cultures ranged from 0.06 to 0.16%
35
36 262 of initial mercury spike, thus indicating that the predominant mercury methylators in these mixed
37
38 263 cultures were associated with the sulfate reducing community (to be expected given the
39
40 264 enrichment conditions).

41 265 The abundance of the sulfite reductase *dsrA* gene normalized to the abundance of the 16S
42
43 266 rDNA gene increased with incubation time (Figure S4), as expected for cultures grown under
44
45 267 sulfate reducing conditions. The relative amount of *dsrA* was greatest for mixed cultures
46
47 268 incubated with 60 mM C-substrate (19% for MS-1 and 10% for MS-2 culture). For context, the
48
49 269 abundances of *dsrA* in the surface of marine sediments can vary from 2 to 30%.^{38,39} The
50
51 270 abundance of *dsrA* gene in the MS-1 mixed cultures appeared to increase with each time point
52
53 271 during incubation (Figures S4A and S4B). However, for the MS-2 culture, the abundance of
54
55 272 *dsrA* gene was relatively lower and did not increase appreciably during the first 48 h of the
56
57 273 incubation (Figures S4C and S4D). A slight increase was observed at the 64 h time point, when
58
59 274 the relative *dsrA* gene abundance was 1% to 9%. These values, however, are less than the
60

1
2
3 275 relative *dsrA* gene abundances observed in the MS-1 mixed cultures, consistent with differences
4
5 276 in growth rates and MeHg concentrations between the two mixed cultures.
6
7 277

8
9 278 **Correlations between microbial growth, sulfate reduction, and net MeHg production.** The
10 279 relationships between microbial growth, sulfate reduction, and net MeHg production were
11 280 compared for time points between 10 and 64 hours in the incubation. These time points were
12 281 selected because the largest changes in MeHg concentrations were observed during this time
13 282 frame for the mixed cultures (Figure 2). Cell density of most cultures showed a strong linear
14 283 relation to the MeHg concentrations (Figure 3), similar to other studies^{27, 40}. An exception to this
15 284 trend was observed for the MS-2 mixed culture with dissolved Hg added, where net MeHg
16 285 concentrations increased while cell growth was minimal (Figure 3C).
17
18
19
20
21
22

23 286 Additional comparisons were made between the rates of net MeHg production and sulfate
24 287 consumption for the time periods of most active net Hg methylation (Figure 4). These rates were
25 288 calculated from the slopes of linear regressions for the 10 h to 64 h data points shown on Figure
26 289 2, and also for a second round of enrichment experiments performed with five different C-
27 290 substrate concentrations (time-course data not shown). While we recognize that some of the
28 291 concentrations values were not linear with time, we used this approach to provide an estimate
29 292 that could be used for comparison purposes. The parameters for the regressions are shown in
30 293 Tables S1 and S2.
31
32
33
34
35
36

37 294 When all sulfate reduction rates were compared for the same cultures, the rates did not
38 295 change with the type of Hg added (Figure 4). For example in the MS-1 cultures, sulfate reduction
39 296 rates were 0.25 – 0.5 mM h⁻¹ in the dissolved Hg amendments (Figure 4A) and 0.21 – 0.37 mM
40 297 h⁻¹ in the nanoparticulate HgS amendments (Figure 4B). These rates were not significantly
41 298 different ($p = 0.36$ for single factor ANOVA). Likewise in the MS-2 cultures, the sulfate
42 299 reduction rates were 0.15 – 0.25 mM h⁻¹ in the dissolved Hg amendments and 0.12- 0.34 mM h⁻¹
43 300 in the nanoparticulate HgS amendments ($p = 0.34$) (Figure 4C and 4D). We also note that these
44 301 rates are similar to sulfate reduction rates observed in saline settings that are rich in organic
45 302 matter and highly productive ecosystems (up to 1.5 mM h⁻¹).^{10, 41}
46
47
48
49
50
51
52

53 303 The rates of net methylation were for the most part faster in cultures that received
54 304 dissolved Hg than those that received nanoparticulate HgS. For example in the MS-1 cultures
55 305 that received dissolved Hg, net MeHg production rates were 8.7 – 18.1 pM h⁻¹ (Figure 4A), while
56
57
58
59
60

1
2
3 306 the cultures receiving nanoparticulate HgS had rates of 1.4 – 5.4 pM MeHg h⁻¹ (Figure 4B).
4
5 307 Similar trends were observed for the MS-2 cultures, although the difference was smaller (1.1 –
6
7 308 4.4 pM h⁻¹ in dissolved Hg amendments; 0.17 – 1.7 pM h⁻¹ in the nanoparticle HgS amendments,
8
9 309 Figure 4C and 4D). For context, the rates of net MeHg production shown in Figure 4 were
10
11 310 similar to or greater than rates observed previously in sediment slurries amended with the same
12
13 311 amount of mercury (0.5 – 3 pM h⁻¹).²³

14 312 The difference in methylation rates between dissolved Hg and nanoparticulate HgS
15
16 313 amendments is consistent with expectations that dissolved Hg is more bioavailable to the
17
18 314 microorganisms than nanoparticulate HgS. However, the difference diminished at low sulfate
19
20 315 reduction rates. In other words, the slope of the regression line in Figure 4A is greater than the
21
22 316 slope of the regression for Figure 4B . A comparison of slope values for Figures 4C and 4D was
23
24 317 not warranted, as both values were not significantly different from zero ($p > 0.05$).

25 318 The contribution of the sulfate reducers in the mixed cultures is further highlighted in
26
27 319 Figure 5, where the percentage of methylated mercury is plotted as a function of the relative
28
29 320 abundance of *dsrA* genes. Regression analysis indicated significant correlations ($p < 0.05$, $n=9$)
30
31 321 between these two parameters for the mixed culture from MS-1 (Figures 5A and 5B). The
32
33 322 correlations indicated that cultures spiked with dissolved Hg showed a steeper positive trend
34
35 323 (slope = 1.4 (% as MeHg)×(% *dsrA* abundance)⁻¹, Figure 5A) than the nanoparticulate HgS
36
37 324 amended ones (slope = 0.65 (% as MeHg)×(% *dsrA* abundance)⁻¹, Figure 5B). Similarly, for MS-
38
39 325 2 cultures, there was a steeper positive trend in amendments with dissolved Hg (slope = 0.67,
40
41 326 Figure 5C) relative to the culture amended with nanoparticulate HgS (slope = 0.13, Figure 5D).
42
43 327 The slope values for the MS-2 culture were smaller than the MS-1 culture due to the smaller
44
45 328 abundance of *dsrA* genes in MS-2 (<6%) relative to the MS-1 (5-20%).

46 329 The trends shown in Figures 4 and 5 suggest that if the experiments were performed at
47
48 330 low microbial growth rates (i.e., sulfate reduction rates much less than 0.1 mM h⁻¹), net MeHg
49
50 331 production would likely be similar regardless of the type of Hg added. The results of this study
51
52 332 did not have sufficiently low sulfate reduction rates to fully demonstrate this phenomenon.
53
54 333 However in our previous experiments with sediment slurry microcosms²³, cultures with low
55
56 334 sulfate reduction rates (ca. 5 × 10⁻³ mM h⁻¹) had produced MeHg at the same net rate even though
57
58 335 they received forms of Hg with different bioavailability (i.e., dissolved Hg and nanoparticulate
59
60 336 HgS). In this case the low productivity of the microbial community, as indicated by low sulfate

1
2
3 337 reduction rates, was the limiting factor for controlling net MeHg production. In contrast, at high
4
5 338 sulfate reduction rates (such as those shown in Figure 4) the bioavailability of Hg was important
6
7 339 for controlling net MeHg production. The notion of growth-limited versus bioavailability-limited
8
9 340 mercury methylation would imply the existence of a threshold sulfate reduction rate. However,
10
11 341 the quantification of this threshold cannot be firmly established with this data set due to
12
13 342 relatively large uncertainties of the regression parameters (i.e. slope and intercept) for the data in
14
15 343 Figure 4. Further work should include a broader range of microbial growth rates, particularly at
16
17 344 low growth conditions.
18
19 345
20 346

21 347 **Net methylation potential was greater in MS-1 cultures than in MS-2 cultures.** The mixed
22
23 348 cultures derived from MS-1 had a net production rates of MeHg (Figure 4A and 4B) that were 2
24
25 349 to 10 times faster than the culture enriched from MS-2 (Figure 4C and 4D), regardless of the
26
27 350 form of mercury supplied. Likewise, sulfate reduction rates for the MS-1 cultures were generally
28
29 351 faster than rates for the MS-2 cultures.

30 352 The differences between these two mixed cultures are not known, but could be explained
31
32 353 by a number of factors. For example, the MS-1 and MS-2 cultures originated from two different
33
34 354 original sediment samples. Thus, the enrichments produced two distinct microbial communities
35
36 355 that likely differed in abundance of methylating and demethylating microorganisms. While the
37
38 356 data indicated that sulfate reducing microorganisms were the major organisms in both cultures
39
40 357 and the principal methylators of Hg (as indicated by the molybdate controls and the positive
41
42 358 relationships between sulfate reduction, C-substrate concentration, and MeHg concentrations),
43
44 359 not all sulfate reducers are capable of MeHg production²⁸. Thus, the relative abundance of
45
46 360 methylators was likely greater for MS-1 cultures than for MS-2 cultures. As there are many
47
48 361 possible explanations for such functional differences between the mixed cultures, further analysis
49
50 362 is needed for the overall microbial community composition and biomolecular signatures specific
51
52 363 to the Hg methylation phenotype.
53 364

53 365 **Environmental implications.** Our results show that net mercury methylation is related to the
54
55 366 bioavailability of mercury and microbial growth, as demonstrated in a previous study³. The new
56
57 367 finding here is the possible existence of a threshold in activity of methylating microorganisms
58
59
60

1
2
3 368 (i.e., sulfate reduction rate in our experiments) where net MeHg production is sensitive to either
4
5 369 microbial growth or to Hg speciation and bioavailability. At environmental sites of interest,
6
7 370 knowledge of this threshold in microbial activity could be useful for remediation purposes by
8
9 371 allowing a prioritization of factors that influence net MeHg production. For example, at field
10
11 372 sites of relatively low activity for methylating microorganisms, remedial actions that attempt to
12
13 373 reduce Hg bioavailability may not be effective. Rather, the remediation strategy should focus on
14
15 374 those measures that suppress the activity of the methylators (e.g., aeration, preventive measures
16
17 375 for eutrophication). In contrast, for sites above the threshold of microbial activity, actions could
18
19 376 aim to reduce both microbial activity of methylators and the bioavailability of Hg.

20 377 The results of this research also demonstrated that microbial growth and carbon substrate
21
22 378 concentration played an important role in net MeHg production. Despite the similar growth
23
24 379 yields over the 64 h incubation time, MS-1 and MS-2 mixed bacterial cultures methylated
25
26 380 mercury at different rates and yields. Given the higher percentage of SRB found in MS-1 culture
27
28 381 and a rapid steady increase in *dsrA* gene copy numbers parallel to the increase in net MeHg
29
30 382 production, we may assume that this culture consisted of either a greater abundance of Hg
31
32 383 methylators or microorganisms with higher rates of methylation. Likewise, the MS-2 culture
33
34 384 could have comprised of more MeHg degrading microbes. Phylogenetic analysis of both cultures
35
36 385 could assist in the understanding of this phenomenon.

37 386 In the mixed culture experiments for this study, sulfate reduction rates were used as a
38
39 387 proxy for the activity of methylators since the experiment was designed to enrich for sulfate
40
41 388 reducing microorganisms. This research also showed that relative gene abundance for the sulfate
42
43 389 reducers could be an indicator of activity of the methylating community. However, in the natural
44
45 390 environment, other anaerobic microorganisms including iron reducers and methanogens are
46
47 391 known to methylate Hg⁴²⁻⁴⁴. Future work is needed to include a broader diversity of methylating
48
49 392 microorganisms. This work would require a more appropriate parameter to signify the
50
51 393 productivity of all methylating microorganisms and perhaps should quantify gene expression in
52
53 394 addition to gene abundance. The recent discovery of a gene cluster directly linked to Hg
54
55 395 methylation^{42, 45} provides a promising path forward in this respect.

56 396 Overall this study demonstrated that differentiation of key factors affecting mercury
57
58 397 methylation can be achieved by designing experiments that simultaneously control for the initial
59
60 398 mercury speciation and microbial activity. Such an approach may provide a basis for the

1
2
3 399 development of methods to quantify mercury methylation potential and conceptual models that
4
5 400 quantitatively link mercury methylation potential to specific changes in geochemical and
6
7 401 biological conditions in the field.

Figure 1. Growth of microorganism, as shown by optical density (OD) at 660 nm in mixed anaerobic cultures extracted from MS-1 (A,B) and MS-2 (C,D) sediments, grown under different C-substrate concentrations (0.6 mM, 6 mM and 60 mM), and amended with either dissolved Hg (A,C) or nanoparticulate HgS (B,D). The error bars represent 1 s.d. for triplicate biological samples.

Figure 2. Net production of methylmercury (filled symbols) and reduction of sulfate (open symbols) in mixed anaerobic cultures from MS-1 (A,B) and MS-2 (C,D) sediments, grown under different C-substrate concentrations, and amended with either 5 nM dissolved Hg (A,C) or 5 nM nanoparticulate HgS (B,D). The error bars represent 1 s.d. for triplicate biological samples. Linear regressions were performed for the 10 - 64 h data points; the regression parameters are listed in Table S2.

Figure 3. Relationship between methylmercury concentration and cell density of mixed microbial cultures enriched from MS-1 (A, B) and MS-2 (C, D) sediments grown under different C-substrate concentrations, and amended with either dissolved Hg (A, C) or nanoparticulate HgS (B, D). The error bars represent 1 s.d. for triplicate biological samples. Linear regression parameters are listed in Table S3.

Figure 4. Net MeHg production rate as a function of sulfate reduction rate calculated between 10 and 64 hours for mixed microbial cultures grown at different C-substrate concentrations. Mixed cultures were enriched from MS-1 (A, B) and MS-2 (C, D) sediments and were amended with either dissolved Hg (A, C) or nanoparticulate HgS (B, D). The error bars represent 1 s.d. for triplicate samples in the test groups. Some errors bars are smaller than the data points. Solid black lines correspond to linear least squares regression of the data.

Figure 5. Net methylation of mercury (as % of total Hg) as a function of *dsrA* gene relative abundance for the 10 to 64 h incubation time points for mixed microbial cultures grown at different C-substrate concentrations. Mixed cultures were inoculated from enrichments of MS-1 (A, B) and MS-2 (C, D) sediments and were amended with either dissolved Hg (A, C) or nanoparticulate HgS (B, D). Solid black lines correspond to linear least squares regression of the data.

Table 1. Characteristics of original sediments used in enrichment experiments. Concentrations represent the mean \pm standard deviation of triplicate samples. Sediment concentrations are reported on a dry weight basis.

Parameters	Sediment sample ID	
	MS-1	MS-2
Sediment texture	Clay loam	Sandy loam
Clay (%) (< 2 μm)	63	9
Silt (%) (2-50 μm)	28	10
Sand (%) (> 50 μm)	9	81
pH (pore water)	7.6	8.0
Total mercury in sediment (mg kg^{-1})	12.2 \pm 5.9	16.6 \pm 2.8
Methyl mercury in sediment (ng kg^{-1})	145 \pm 25.6	381 \pm 40.8
TOC in sediment (mg kg^{-1})	31.8 \pm 0.8	4.5 \pm 0.6
Sulfate (pore water, mg L^{-1})	2934 \pm 273	2749 \pm 418
Wet-to-dry mass ratio	1.34	1.28

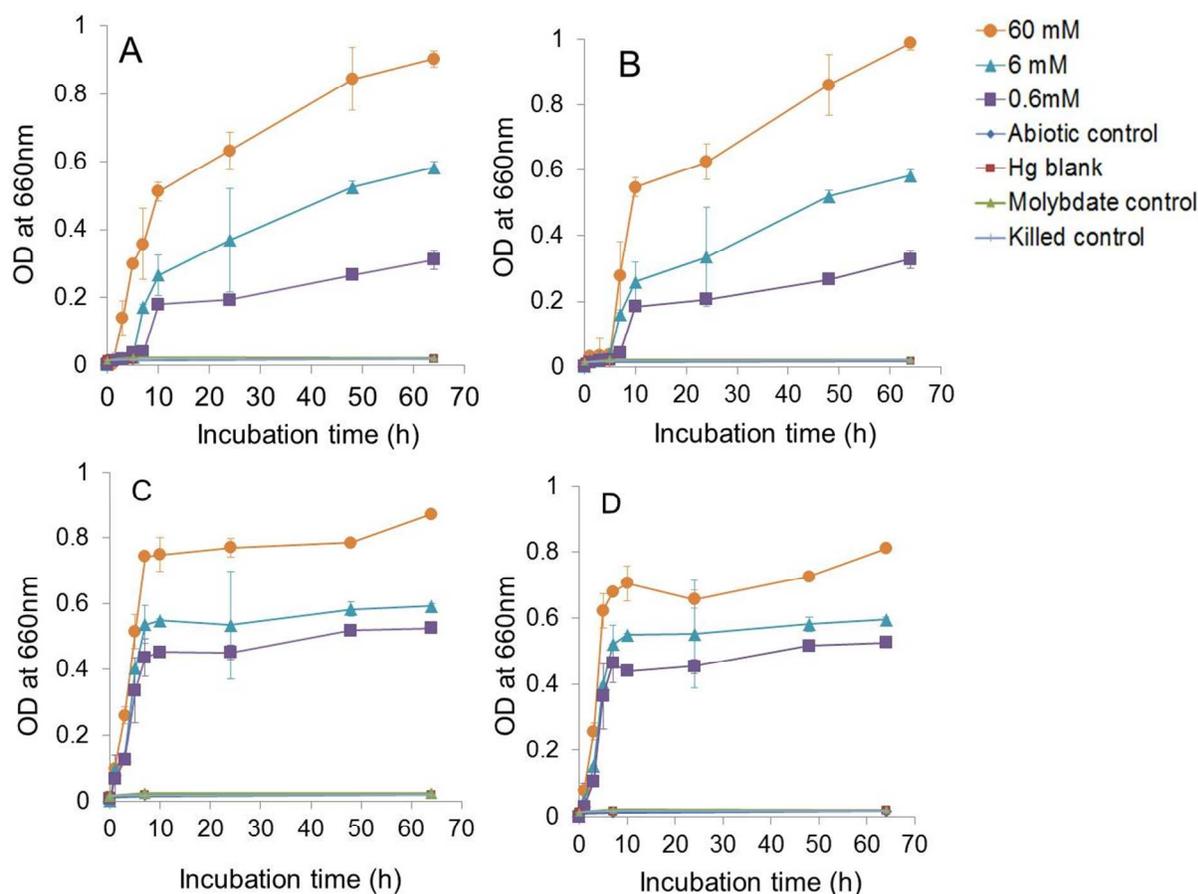

Figure 1. Growth of microorganism, as shown by optical density (OD) at 660 nm in mixed anaerobic cultures extracted from MS-1 (A,B) and MS-2 (C,D) sediments, grown under different C-substrate concentrations (0.6 mM, 6 mM and 60 mM), and amended with either dissolved Hg (A,C) or nanoparticulate HgS (B,D). The error bars represent 1 s.d. for triplicate biological samples.

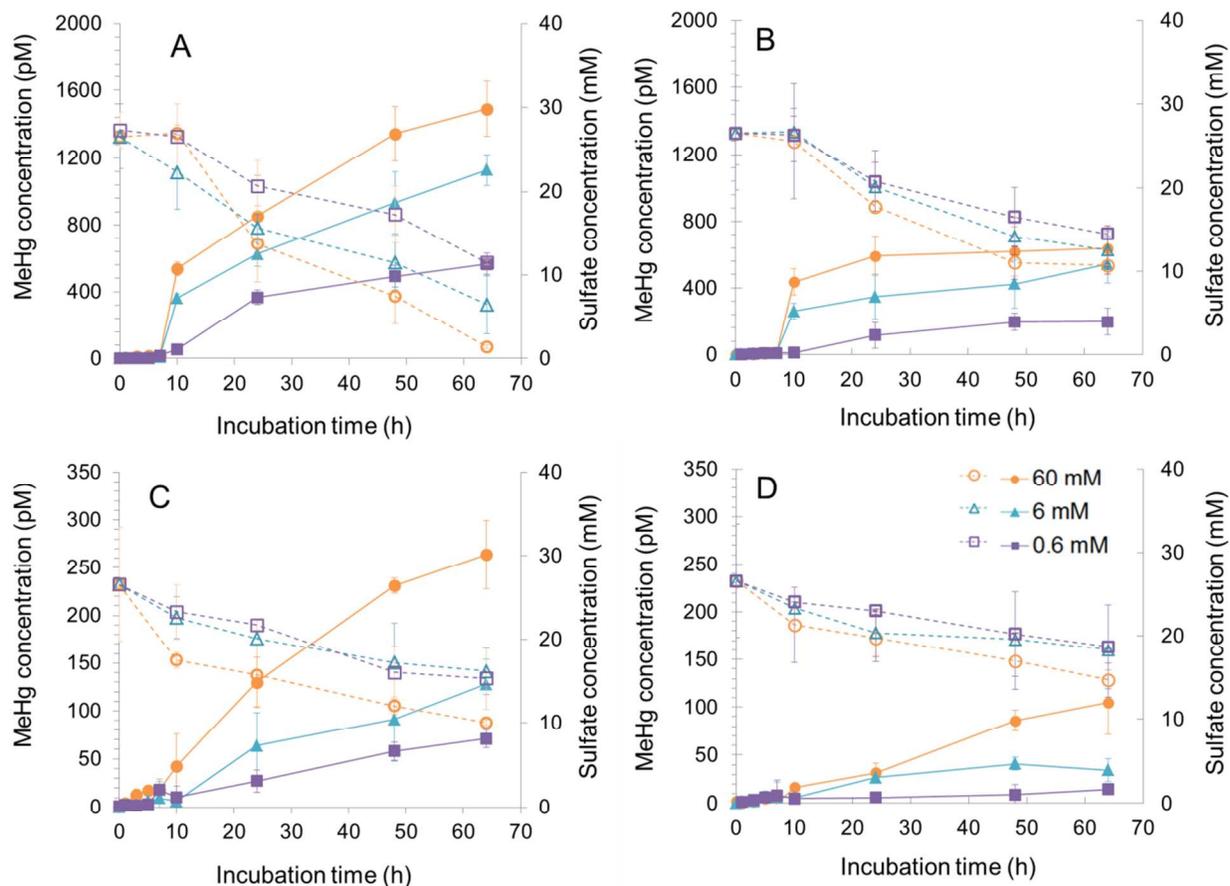

Figure 2. Net production of methylmercury (filled symbols) and reduction of sulfate (open symbols) in mixed anaerobic cultures from MS-1 (A,B) and MS-2 (C,D) sediments, grown under different C-substrate concentrations, and amended with either 5 nM dissolved Hg (A,C) or 5 nM nanoparticulate HgS (B,D). The error bars represent 1 s.d. for triplicate biological samples. Linear regressions were performed for the 10 - 64 h data points; the regression parameters are listed in Tables S1 and S2.

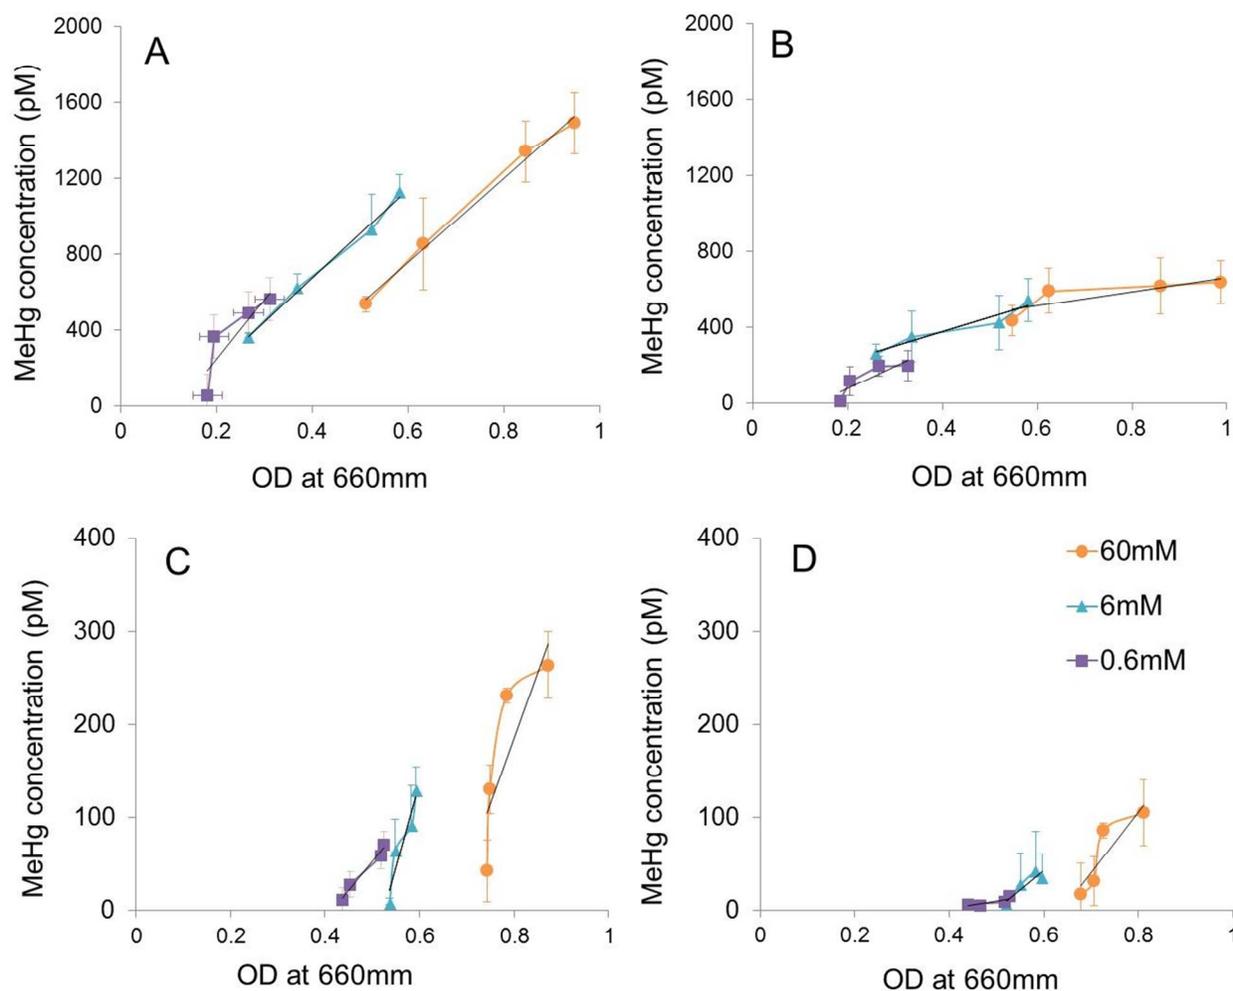

Figure 3. Relationship between methylmercury concentration and cell density of mixed microbial cultures enriched from MS-1 (A, B) and MS-2 (C, D) sediments grown under different C-substrate concentrations, and amended with either dissolved Hg (A, C) or nanoparticulate HgS (B, D). The error bars represent 1 s.d. for triplicate biological samples. Linear regression parameters are listed in Table S3.

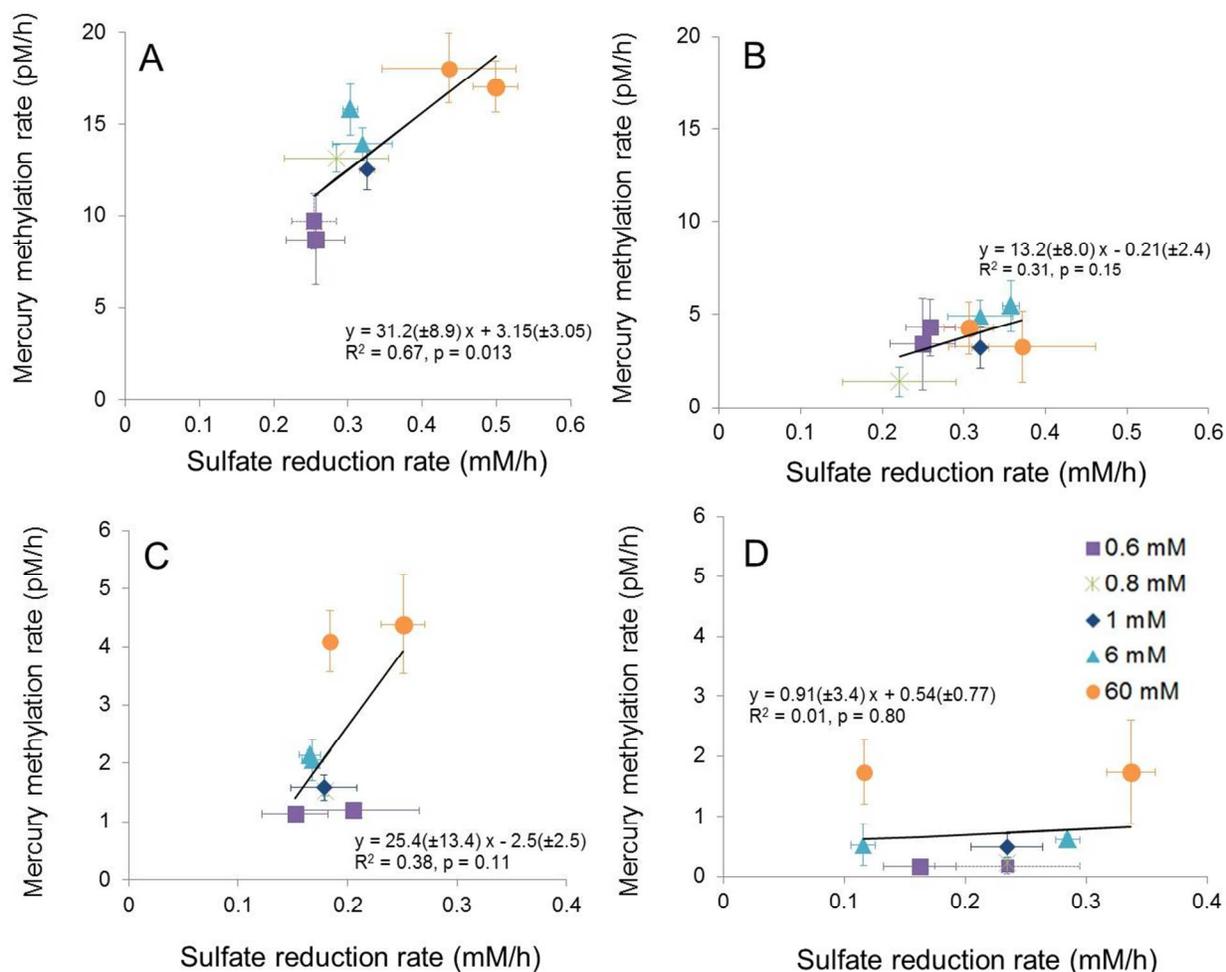

Figure 4. Net MeHg production rate as a function of sulfate reduction rate calculated between 10 and 64 hours for mixed microbial cultures grown at different C-substrate concentrations. Mixed cultures were enriched from MS-1 (A, B) and MS-2 (C, D) sediments and were amended with either dissolved Hg (A, C) or nanoparticulate HgS (B, D). The error bars represent 1 s.d. for triplicate samples in the test groups. Some errors bars are smaller than the data points. Solid black lines correspond to linear least squares regression of the data.

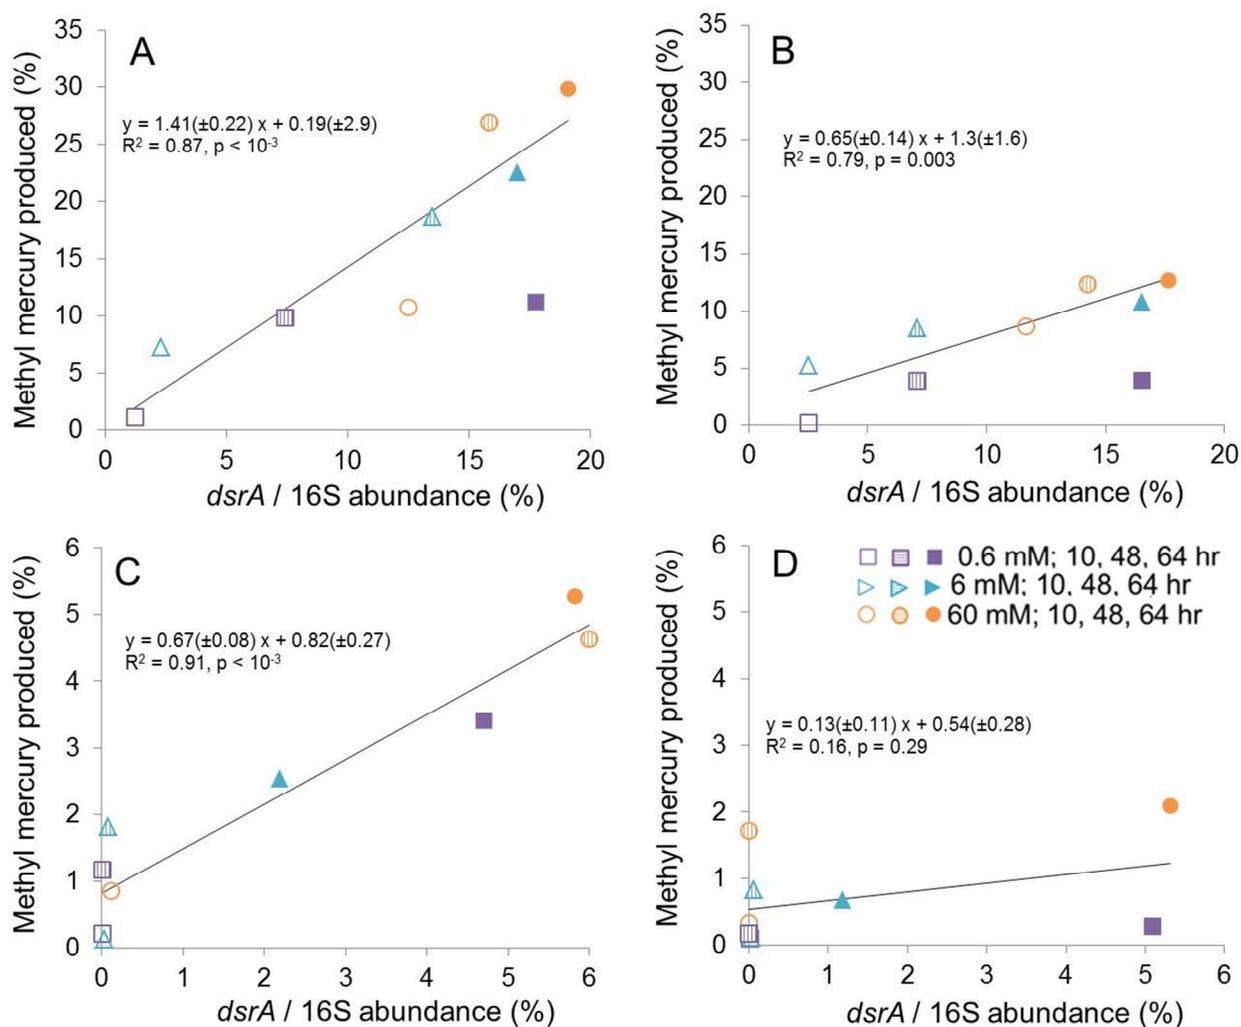

Figure 5. Net methylation of mercury (as % of total Hg) as a function of *dsrA* gene relative abundance for the 10 to 64 h incubation time points for mixed microbial cultures grown at different C-substrate concentrations. Mixed cultures were inoculated from enrichments of MS-1 (A, B) and MS-2 (C, D) sediments and were amended with either dissolved Hg (A, C) or nanoparticulate HgS (B, D). Solid black lines correspond to linear least squares regression of the data.
