Pressure Effects on Sulfide Electrolytes for All Solid-State Batteries

Jean-Marie Doux, Yangyuchen Yang, Darren H.S. Tan, Han Nguyen, Erik A. Wu, Xuefeng Wang, Abhik Banerjee, Ying Shirley Meng.

Abstract

All solid-state batteries are believed to be safer than their liquid counterparts owing to their use of nonflammable solid electrolytes. Nevertheless, unlike liquid electrolyte batteries, stack pressure is required during cycling to avoid contact losses between the electrodes and the solid electrolyte. Although recent studies have shown stack pressures to affect the capacity utilization of alloying anodes, investigation of stack pressures on solid-state battery cyclability has not been done so far. In this work, both the effects of initial fabrication pressure, and the operating stack pressure on the electrolyte’s ionic conductivity and battery performance have been analyzed; the results show that initial fabrication pressure directly affects the porosity of the electrolyte and therefore overall performance of the cell. Low operating stack pressure reduces the apparent ionic conductivity due to poor contact between the electrolyte and current collectors, but does not detrimentally affect the cyclability of solid-state batteries. These results can explain inconsistencies in the literature and provide a guideline toward standardized solid-state battery testing conditions and proper reporting benchmarks of performances in solid-state batteries.

Introduction

All solid-state batteries (ASSBs) are expected to revolutionize the Li-ion battery landscape thanks to several advantages: the use of non-flammable electrolytes that improves its intrinsic safety and its potential to enable metallic Li anodes, allowing for substantial increase in energy density. Whereas stack pressure is deemed required to ensure proper contact of electrodes with the solid-electrolyte and also inhibit delamination during cycling due to electrode expansion and contraction, there are no reports thus far of how stack pressure affects the performance of all solid-state batteries. Most literature reports today use solid-state cells designed to apply uniaxial stack pressure, the value of which is often not mentioned or approximative. Nevertheless, the stack pressure has been shown to strongly influence the capacity of alloying anodes, the electrochemical stability window of solid electrolytes, and even the cyclability of lithium metal in ASSBs. It is necessary to understand the effect of the stack pressure on solid-state batteries to allow for proper experimental design and optimization of performance parameters.

In contrast, the pressure used to fabricate the sulfide solid-state electrolyte pellet (by cold-pressing) has been widely reported by the community, as it directly affects the porosity of the electrolyte. Studies have already shown
that a lower fabrication pressure (which results in higher porosity) reduces the apparent ionic conductivity of the electrolyte.\textsuperscript{12,13} However, the effect of operating stack pressure on this ionic conductivity also needs to be characterized.\textsuperscript{14,15} This may explain the large differences in electrochemical measurements in the literature for the same solid electrolyte material.

In this work, we designed a solid-state battery holder with a load cell that allows accurate control of the stack pressure. From this, the effect of both the fabrication and the stack pressure has been studied at the electrolyte and at the half cell level, using a LiNbO\textsubscript{3}-coated LiNi\textsubscript{0.80}Co\textsubscript{0.15}Al\textsubscript{0.05}O\textsubscript{2} (LNO-NCA) | Li\textsubscript{6}PS\textsubscript{5}Cl (LPSCl) | Li-In alloy solid-state battery. First, we show that fabrication pressure has a direct impact on the solid electrolyte pellet porosity, as confirmed by the focused ion beam (FIB) 3D reconstruction. Once sufficiently high fabrication pressure is achieved, the relative density of the pellet no longer increases, and the ionic conductivity attains its maximal value. At lower fabrication pressures, lower electrolyte density reduces the measured ionic conductivity of the electrolyte. This lower conductivity has a negative impact on the cyclability and rate capability of the all solid-state battery. Secondly, we found that operating stack pressure has a negligible impact on the electrolyte conductivity as long as good contact between the electrolyte and the current collector is established, which can be achieved by using a soft material such as carbon powder. Similarly, the all solid-state battery performances are not affected by the operating stack pressure as the electrodes already have good electronic contact with the current collector.

Discussion

Table 1: Conductivity of the argyrodite Li\textsubscript{6}PS\textsubscript{5}Cl solid-state electrolyte as reported in the literature. Fabrication pressure, stack pressure and electrode material are detailed when reported.

</table>
With reference to Table 1 summarizing literature reports on ionic conductivity of argyrodite Li$_6$PS$_5$Cl, large discrepancies can be noticed. Whereas some of these variations could easily be explained by slight differences in room temperature conditions during the conductivity measurement, some values differ as large as two orders of magnitude. Upon closer examination, it appears that the solid-state sulfide electrolyte is densified by cold pressing at widely different fabrication pressures in each report. As fabrication pressure has a direct effect on the electrolyte’s porosity; larger contributions from the grain boundaries are expected at lower fabrication pressure, and therefore, a lower ionic conductivity.\textsuperscript{28,29} This large variation in fabrication pressure can likely explain part of the discrepancies between these reported conductivity values, as can the presence of impurities, degree of crystallinity/amorphization of the material, particle size (influencing the densification process), and so on.\textsuperscript{28} Nevertheless, while typical parameters such as fabrication pressure and current collector material are often reported (from stainless steel to carbon powder to silver paste), there are no mentions of the operating stack pressure used during the conductivity measurement so far. In order to determine the most suitable protocol to measure and report the conductivity of sulfide solid-state electrolytes, the influence of these parameters must be studied.

![Figure 1](image)

**Figure 1**: a) Design of the solid-state battery holder with a load cell to monitor the stack pressure applied to the battery during cycling and conductivity measurement. b) For conductivity measurement and battery cycling, pellets are first made by uniaxial pressure at the fabrication pressure using a hydraulic press and are then cycled in the battery holder at the predetermined stack pressure.

**Figure 1a** describes the experimental setup used to measure the applied stack pressure during the electrochemistry measurements. The solid-state battery is built inside a polyether ether ketone (PEEK) pellet mold using titanium plungers that double as current collectors. The assembly is then placed in a cell holder on which a controlled stack pressure is applied by tightening the nuts on the three bolts. PEEK insulating discs prevent an external short circuit of the cell through the metallic holder. A load cell connected to a calibrated digital meter (in MPa using a materials test frame) provides accurate reading of the stack pressure during cycling. Two different
pressures were investigated on the conductivity of the solid-state sulfide electrolyte and on the cycling performances of an all-solid-state battery: the fabrication pressure and the operating stack pressure.

Figure 2: a) Conductivity of Li$_6$PS$_5$Cl as a function of the stack pressure using titanium plungers or pressed carbon powder as electrodes. The stack pressure was increased to 70 MPa and subsequently decreased to 5 MPa (as indicated by the arrows). Error bars represent the standard deviation on 4 samples. b) Effect of stack pressure on the cycling stability (at room temperature) of LiIn | LPSCI | NCA solid-state batteries. Each pellet of the electrolyte and batteries were made using a fabrication pressure of 370 MPa.

Figure 2a shows the conductivity of Li$_6$PS$_5$Cl electrolyte as a function of the operating stack pressure, using titanium plungers or carbon powder as current collector. When using titanium current collector, it appears that a low stack pressure induces a large contact impedance which is reflected on the low ionic conductivity value: at 2 MPa, the conductivity is only 0.2 mS.cm$^{-1}$ whereas it exceeds 2.0 mS.cm$^{-1}$ at 70 MPa. A hysteresis can also be observed: after releasing the stack pressure from 70 MPa, the conductivity at lower pressures is significantly higher than before. These observations show that the contact interface between the soft sulfide electrolyte and the hard titanium plunger depends strongly on the stack pressure. To avoid this, it is possible to use carbon powder as the current collector as it will conform to the surface and provide an electronically-conductive interface. When using carbon, the ionic conductivity becomes almost independent of the applied stack pressure, ensuring a reliable measurement of the electrolyte’s performance. These results suggest that most discrepancies in the literature on the conductivity of argyrodite LPSCI electrolyte can be explained by the differences in current collector and stack pressure used. Similar results have also been obtained on the Li$_7$P$_3$S$_{11}$ solid-state electrolyte; the ionic conductivity varies between $10^{-4}$ and $10^{-3}$ S.cm$^{-1}$ as shown in Figure S1 of the Supplementary Information. It is expected that this contact impedance can be seen on most Li and Na sulfide solid-state electrolytes and therefore it is recommended to use carbon powder as electrodes when measuring the electrolyte ionic conductivity.

When cycling solid-state batteries, the electrodes are usually relatively soft; Li metal or Li-In alloy anodes are ductile materials, and anode/cathode composites are made in part with sulfide solid-state electrolyte and carbon
powder, also soft materials. Therefore, based on these results on the electrolyte conductivity, we can expect the influence of operating stack pressure on the cycling performances in solid-state batteries to be negligible. **Figure 2b** shows the room-temperature cycling stability of two similar Li-In | LPSCl | LNO-coated NCA all-solid-state batteries. LNO coating was used on the NCA cathode as it has been shown to prevent it from reacting with the electrolyte during cycling.\(^{30}\) The first one has been cycled under a constant stack pressure of 25 MPa whereas for the second one, the stack pressure was increased every 5 cycles between 5 and 125 MPa and then released to 5 MPa. As expected, due to the softer electrode materials, the stack pressure does not have a distinguishable effect on the cycling stability of the cell. These experiments also allowed us to determine that further investigation of the fabrication pressure effect can be done using a generic constant stack pressure of 25 MPa.

*Figure 3: a) Conductivity and relative density of Li\(_6\)PS\(_5\)Cl electrolyte as a function of the fabrication pressure, and b) Nyquist diagrams of the electrochemical impedance spectra at the same fabrication pressures. All measurements were performed with a stack pressure of 25 MPa. Error bars represent the standard deviation on 4 samples.*

*Figure 3a* presents the evolution of the relative density of Li\(_6\)PS\(_5\)Cl pellets and their ionic conductivity (as determined by electrochemical impedance spectroscopy shown in **Figure 3b**) as a function of the fabrication pressure used to densify the electrolyte material. When increasing the fabrication pressure from 50 to 250 MPa, the relative density increases from 68.3 to 75.4 % and the ionic conductivity shows a similar trend, increasing from 0.99 mS.cm\(^{-1}\) to 2.06 mS.cm\(^{-1}\). Further increasing the fabrication pressure has a progressively smaller impact on the relative density of the pellet and therefore a limited effect on the ionic conductivity; 2.28 mS.cm\(^{-1}\) is obtained at 370 MPa. These results confirm that the relative density – and therefore the porosity – of the solid-state electrolyte also influences the measured ionic conductivity. The Nyquist diagrams (**Figure 3b**) show that at lower fabrication pressure, the appearance of a semicircle at the high-frequency region can be attributed to the contribution of grain boundaries to impedance of the system. As fabrication pressure increases, this contribution is reduced and cannot be identified anymore when the fabrication pressure exceeds 250 MPa. On oxide solid-state electrolytes, similar behavior is usually seen; increasing the relative density of the pellet by sintering reduces
the grain boundary contribution and therefore increases the ionic conductivity.\textsuperscript{26,29} In the case of sulfide electrolytes, the grain boundaries have nevertheless a high ionic conductivity compared to oxides,\textsuperscript{31} as even with a porosity of more than 30\%, LPSCI still exhibits an ionic conductivity higher than 1 mS.cm\textsuperscript{-1}. For oxide electrolyte materials on the other hand, a relative density higher than 90\% is usually sought for, as the grain boundary impedance is much higher; even an increase of 10\% of porosity can lower ionic conductivities by an order of magnitude.\textsuperscript{32}

![SEM images of FIB cross-sections of Li\textsubscript{6}PS\textsubscript{5}Cl electrolyte pellets made with a fabrication pressure of 50 MPa (a) and 370 MPa (b), with their corresponding relative density estimated by physical measurements. The resulting FIB reconstructions show the porosity in blue for the c) 50 MPa pellet and d) 370 MPa pellet.](image)

Figure 4: SEM images of FIB cross-sections of Li\textsubscript{6}PS\textsubscript{5}Cl electrolyte pellets made with a fabrication pressure of a) 50 MPa and b) 370 MPa, with their corresponding relative density estimated by physical measurements. The resulting FIB reconstructions show the porosity in blue for the c) 50 MPa pellet and d) 370 MPa pellet.

Figure 4 shows room-temperature cross-section SEM images and FIB 3D reconstructions of the voids distribution of LPSCI pellets densified at fabrication pressure of 50 MPa (Figure 4a, c) and 370 MPa (Figure 4b, d) respectively. The cross-sectional images clearly show a higher quantity of small grains at 50 MPa, indicating that the densification is not complete; in addition, some large pores can also be seen. On the other hand, the pellet densified at 370 MPa appears denser and made of larger grains. As a cross-section view is not representative of the volume distribution of the porosity, FIB 3D reconstruction was performed. While a large number of interconnected voids can be seen for the 50 MPa pellet, the porosity of the 370 MPa pellet is lower as the grains are bigger. This physical observation of the porosity confirms the resistive contribution of the grain boundaries seen by EIS. For a comparison, FIB cross-section SEM was also performed at cryogenic temperatures for the pellet.
pressed at 370MPa and the image is shown in Figure S3. The image confirms that no beam damage or degradation occurs during ion milling and imaging at room temperature.

Figure 5: a) Cycling stability at C/10 and b) rate performance as a function of the fabrication pressure of LiIn | LPSCl | NCA solid-state batteries. All of these cells were cycled at room temperature at a stack pressure of 25 MPa.

The cycling stability at C/10 at room temperature of four similar solid-state batteries, built using a fabrication pressure of 50, 150, 250 and 370 MPa, is shown on Figure 5a. The cycling performances of the three cells made at 150, 250 and 370 MPa are similar, with no distinguishable differences in Coulombic efficiency or discharge capacity over 40 cycles. The cell made with a fabrication pressure of 50 MPa on the other hand shows a significantly lower specific capacity after 40 cycles: only 103 mAh.g\(^{-1}\) compared to around 115 mAh.g\(^{-1}\) for the three other batteries. This indicates that the higher electrolyte impedance due to the low fabrication pressure has a direct impact on the cycling stability of the cell. This higher impedance also has a negative effect on the rate performances of the solid-state battery: as shown on Figure 5b, the cell made with the fabrication pressure of 50 MPa shows much lower specific capacities at high rates. At a rate of 2C, this cell shows almost no capacity whereas the three other cells (150, 250 and 370 MPa) still exhibit capacities around 10 and 15 mAh.g\(^{-1}\). These experiments show that the fabrication pressure – and hence the densification of the electrolyte – is critical for the cell performances. It is therefore necessary to focus on reducing the porosity of the electrolyte layer, which can be done by improving the particle size distribution, by using hot pressing or spark plasma sintering.\(^{33,34}\)

The approach of high initial fabrication pressure followed by low operating stack pressure can be further extended to ASSBs in larger formats. As manufacturing ASSBs in pouch formats can potentially reach areal sizes between 30 – 300 cm\(^2\) or more,\(^{35,36}\) the large uniaxial forces needed to maintain constant high stack pressures during operation make it mechanically impractical. From our earlier discussions, it can be concluded that high pressures are only necessary during cell fabrication, which can be achieved in large formats using hot roll-to-roll processing instead of the areal pressure applied in laboratory scale cells. Once the ideal relative densities are achieved in each
electrode / electrolyte layer, the large format type cells can then be operated under relatively low stack pressures without compromising cell performance.\textsuperscript{35,37}

**Conclusion**

In this work, the effect of fabrication pressure and operating stack pressure on the performances of solid-state electrolyte and batteries was investigated. The inconsistencies seen in the literature on the ionic conductivity of Li\textsubscript{6}PS\textsubscript{5}Cl can be explained by the differences in operating stack pressure and the material used as electrodes for the EIS measurements: using carbon powder shows an increase of the ionic conductivity of approximately one order of magnitude compared to solely using titanium plungers at the same stack pressure. A similar behavior is expected in most sulfide electrolytes and it is recommended to use carbon electrodes when evaluating the electrolyte conductivity to minimize the contact impedance. For solid-state batteries, since the fabrication pressure was shown to influence the electrolyte porosity, the fabrication pressure thus also has a large impact on cycling stability and rate performances of the cell. At a lower fabrication pressure (50 MPa), significantly higher porosity generates more grain boundary impedance which is detrimental to the cell performance; the capacity retention and rate capability is significantly improved in ASSBs prepared at high fabrication pressure (370 MPa).

On the other hand, the operating stack pressure does not have a major influence on cycling stability, showing that it is possible to cycle sulfides based ASSBs at a reasonably low stack pressure without the need for complex or bulky housing materials. We believe these results allow for a better understanding of pressure effects on cell performances and emphasizes the importance of reporting operating stack pressure used, in order for the community to standardize testing protocols in sulfide-based all-solid-state batteries.
