The optical properties of nanoparticle assemblies can be tailored *via* hybridization of plasmon modes. Isotropic core/satellite superstructures made of spherical nanoparticles are known to exhibit coupled modes with a strongly scattering (radiative) character, and provide hot spots yielding high activity in surface-enhanced Raman scattering (SERS). However, to complement this functionality with plasmonic heating, additional absorbing (non-radiative) modes are required. We introduce herein anisotropic superstructures formed by decorating a central nanorod with spherical satellite nanoparticles, which feature two coupled modes that allow application for both SERS and heating. On the basis of diffuse reflectance spectroscopy, small-angle X-ray scattering (SAXS), and electromagnetic simulations, the origin of the coupled modes is disclosed and thus serves as a basis toward alternative designs of functional superstructures. This work represents a proof-of-principle for the combination of high SERS efficiency with efficient plasmonic heating by near-infrared irradiation.

## Introduction

Noble metal nanoparticles (NPs) are versatile building blocks for self-assembled colloidal superstructures with tailored optical functionality.<sup>1,2</sup> Hierarchical multi-particle architectures in particular are recognized as “colloidal plasmonic molecules” because their ensemble properties largely differ from those of the individual components.<sup>3,4</sup> Their self-assembly can be guided, both in 2D and 3D, by bio-recognition<sup>5,6</sup> and other attractive forces.<sup>7</sup> Colloidal plasmonic molecules can localize light at the nanoscale, yielding highly confined electric fields which are often exploited for surface-enhanced Raman spectroscopy, *e.g.* as SERS-encoded tags,<sup>8,9</sup> cellular imaging,<sup>10</sup> or biomarker detection.<sup>11</sup> Strategies for high SERS brightness include spiky<sup>12</sup> and undulated particle surfaces,<sup>13,14</sup> as well as cluster-encasing<sup>15</sup> and multilayer

adsorption<sup>16</sup> of smaller particles on a central core NP. Assemblies consisting of a larger core NP surrounded by a monolayer of smaller NPs are commonly referred to as core/satellite superstructures.<sup>17,18</sup> Such superstructures have been reported as nanosensors for various sensing modalities<sup>19</sup> including sensitivity toward enzymatic activity,<sup>20</sup> induced disassembly,<sup>21</sup> or changes in chiroptical activity.<sup>22</sup>

Today's applications, however, require multifunctional nanosensors that not only detect analytes, but can also exert a chemical and/or physical stimulus. Controlled nano-heating in particular has become a research focus for applications such as targeted drug delivery,<sup>23</sup> photo-thermal therapy,<sup>24</sup> and photo-chemotherapy.<sup>15</sup> Therefore, efficient nano-heaters are required, which should be designed to absorb and convert incident light into heat.<sup>25</sup> Efficient heat transfer can already be observed for small gold nanospheres<sup>26</sup> and their aggregates.<sup>27</sup> Notwithstanding, the field of thermo-plasmonics and optical heating is currently extending toward more complex plasmonic nanostructures.<sup>28–30</sup> A particularly interesting challenge is designing superstructures that allow for both analyte detection at high sensitivity and efficient nano-heating upon excitation at the biologically relevant near-infrared (NIR) regime.<sup>31</sup> For this purpose, control over the radiative (scattering) and non-radiative (absorbing) contributions of superstructures plays a key role.<sup>32</sup> However, the coupled modes of isotropic core/satellite structures, composed of spherical NPs, are limited to the visible range and become increasingly more radiative with increasing size.<sup>18,33</sup> This issue could be circumvented by breaking the symmetry. An anisotropic particle, like a gold

nanorod, should allow red-shifting the coupling mode into the NIR range. However, the plasmonic interactions<sup>3,34</sup> become more complex in anisotropic structures, as has been shown for single-satellite nanorod pairs<sup>35</sup> and substrate-supported clusters.<sup>36,37</sup> In addition, we hypothesize that the choice of a suitable anisotropic core can achieve control over the balance between absorbing and scattering contributions. It should be noted that quantification of these contributions is not straightforward because standard UV/vis/NIR transmission spectroscopy only provides information on the total extinction (the sum of both radiative and non-radiative losses). For substrate-supported nanostructures, Link *et al.* reported the demanding combination of dark-field and photo-thermal imaging to differentiate spectral losses.<sup>32</sup> For nanostructures dispersed in liquid, the ensemble-average spectral losses can be measured by diffuse reflectance spectroscopy using an integrating sphere, as recently reported.<sup>18</sup>

Here we present anisotropic supra-colloidal structures consisting of a nanorod core decorated with spherical satellite NPs. These superstructures exhibit dominantly absorbing coupled modes, which were quantified by diffuse reflectance spectroscopy. Small-angle X-ray scattering was employed to analyse the superstructures' structural properties. We discuss the origin of the coupled modes to provide insight into the plasmonic coupling phenomena. Finally, we show as a proof-of-principle that high SERS brightness can be combined with efficient plasmonic heating by near-infrared illumination.

## Results and discussion

### Synthesis of anisotropic assemblies

The assembly of anisotropic core/satellite superstructures was directed by electrostatic interactions between oppositely charged building blocks (Fig. 1a). For this purpose,  $16 \pm 2$  nm sized nanospheres (AuNSs) were synthesized following Turkevich *et al.*<sup>38</sup> and subsequently coated by a negatively charged polyelectrolyte P(SS-co-MA), which is a copolymer of 4-styrenesulfonate (SS) and maleic acid (MA). The carboxyl groups of the MA units could enable post-functionalisation by esterification/amidation<sup>39</sup> or covalent cross-linking in order to increase the long-term stability of the coating, as well as the core/satellite structure after assembly and thus extend their applicability in biological media.<sup>40</sup> Gold nanorods (AuNRs) were prepared by the seeded growth method,<sup>41</sup> yielding average length of  $74 \pm 7$  nm and width of  $33 \pm 2$  nm ( $AR = 2.2 \pm 0.3$ ), as determined by TEM image analysis (Fig. S1†). Subsequently, the NRs were functionalized by a two-step ligand exchange of cetyltrimethylammonium bromide (CTAB) against first cetyltrimethylammonium chloride (CTAC) and second 11-mercaptoundecyl trimethylammonium bromide (MUTAB). The transition from a mobile CTA<sup>+</sup> bilayer to a more robustly attached monolayer of MUTA<sup>+</sup> molecules is driven by the high binding affinity of thiols to gold. After coating, both building blocks were washed multiple times with pure water to remove excess unbound ligands because those might interfere

**Fig. 1** Anisotropic core/satellite assemblies: (a) Schematic illustration: controlled adsorption of small P(SS-co-MA)-coated NSs (satellites) onto MUTAB-functionalized NRs (cores) yielding colloidal superstructures; representative TEM and SEM images. (b) Photographs and (c) normalized UV/vis/NIR extinction spectra of the assemblies AuNR@AuNS (blue) compared to the building blocks (green: AuNRs; red: AuNSs). (d) Spectral losses measured by diffuse reflectance spectroscopy of the assembly, showing contributions from absorption (blue) and scattering (red) to the total extinction (dashed black line). Both coupled modes are predominantly non-radiative.

during the assembly step. The UV/vis/NIR extinction spectra of the satellite and core NPs before and after coating/functionalization remained essentially unchanged, indicating colloidal stability and absence of aggregation (Fig. S2, Table S1†). The negatively charged AuNSs (satellites) were found to adsorb onto the positively charged AuNRs (cores) upon mixing, forming core/satellite superstructures (Fig. 1a). An excess of satellites minimizes bridging between non-saturated cores. The electrostatic assembly resulted in AuNR@AuNS superstructures with a high satellite coverage (Fig. S3 and S4†), close to the jamming limit, which will be discussed below.<sup>18</sup> After the assembly step, the superstructures were added to a dilute P(SS-co-MA) solution to saturate the free core surface between adsorbed satellites with the copolymer. An excellent long-term stability was evidenced by their unaltered plasmonic signature, which remained almost unchanged, even 6 months after the synthesis (Fig. S5†). The dispersions of the satellites, the cores, and their superstructures display wine-red, greenish, and blueish colours, respectively (Fig. 1b). The spectral features are significantly altered upon assembly (Fig. 1c). The localized surface plasmon resonance of AuNS@P(SS-co-MA) is centred at 521 nm (red line in Fig. 1c); AuNR@MUTAB cores show transversal and longitudinal plasmon modes at 516 nm and 656 nm (green line), respectively. Interestingly, the final purified AuNR@AuNS superstructures show three plasmon bands at 510–545 nm, 598 nm, and 795 nm (blue line). Because the individual spectral losses cannot be discriminated by conventional UV/vis/NIR spectroscopy, we performed diffuse reflectance spectroscopy using an integrating sphere (see ESI.2†). Fig. 1d presents the contributions of absorption (blue line) and scattering (red line) to the total extinction (dashed black line). All coupled modes are found to be dominated by absorption and thus, predominantly non-radiative. Quantification of radia-

tive and non-radiative losses by non-assembled building blocks is shown in Fig. S6.† In the following, we provide detailed characterization of the structural features of the assemblies, to allow a reliable correlation between their optical and structural properties.

### Structural characterization

Due to the complex three-dimensional structure, scanning (SEM) and transmission (TEM) electron microscopy techniques can only give a first impression of the structure from a small number of self-assembled nanostructures. The parameters that are particularly critical for plasmonics, such as interparticle distances and average surface coverage, are hardly accessible by EM imaging. Also, the size polydispersity of the NP building blocks (the cores particularly) and the resulting polydispersity in surface coverage should be taken into account in a complete analysis. For these reasons, we decided to use SAXS, which grants access to ensemble-averaged structural information at the nanoscale. The scattering spectra reflect the distribution of sizes and distances for each sample with sub-nanometre resolution. Because repeated distances and sizes appear more prominently, SAXS is the method of choice to evaluate the structural properties of supra-colloidal assemblies.

Fig. 2a shows the scattering curves of the NP building blocks (red, green) and their assemblies (blue). The individual NPs display the expected repeating fringes, which can be

described analytically considering satellites as spheres and rods as cylinders with hemi-spherical end-caps (see ESI.3†). Polydispersity in size and shape was accounted for in the fits by averaging over a Gaussian distribution of core sizes (length and width, Table S2†). The assemblies show additional scattering contributions, specifically in the range from 0.1 to 0.5 nm<sup>-1</sup>, which can be attributed to the presence of the satellites. To quantify the ensemble-averaged number of satellites and their distance to the core, numerical modelling is necessary. Although analytical models for similar structures (*e.g.* raspberry) exist,<sup>42,43</sup> they have been shown not to correctly reproduce the high correlation of satellite NPs.<sup>18</sup> Therefore, we applied 3D atomistic modelling (ESI.3†),<sup>18,41,44</sup> which involves calculating the scattering curves of 3D structures comprising randomly distributed scattering centres using Debye's scattering equation (eqn (1)).<sup>45</sup>

$$I(q) = \sum_i \sum_j f_i f_j \frac{\sin(qr_{ij})}{qr_{ij}} \quad (1)$$

Here,  $I(q)$  is the intensity of the scattered wave,  $q = 4\pi \sin(\theta)/\lambda$  is the scattering vector,  $r_{ij} = |r_i - r_j|$  is the distance between atoms  $i$  and  $j$ , and  $f_i$  is the atomic scattering factor of the  $i$ -th atom. To validate our numerical approach, the data for nanorods were also evaluated by 3D atomistic modelling (Fig. S7†). Since the resulting parameters (length:  $74 \pm 8$  nm; width:  $34 \pm 7$  nm; see Table S2†) were fully consistent with the analytical SAXS fitting and TEM results (Fig. S1†), we could confidently move on toward modelling of the anisotropic superstructures.

Shown in Fig. 2b is a 2D map for the two main parameters averaged over the whole ensemble: core-to-satellite distance and satellite coverage, *i.e.* the ratio between the area occupied by all satellites (excluding the NP coating) and the surface area of the core NR (eqn (S1)†). Each point gives the mean square error (MSE) as a measure of the quality of the fit to the experimental data. The uncertainty of these ensemble parameters can be estimated from cross-sections through the global minimum (domain of lowest MSEs) within the parameter space (Fig. 2c and d). It can be assumed with high confidence that the average core-to-satellite distance ranges between 1 and 2 nm (Fig. 2d), whereas the overall surface coverage is 36–45% (in agreement with 39%, as estimated by TEM image analysis; Fig. S4†), which corresponds to  $18 \pm 2$  satellite particles per nanorod (Table S2†). This value is very close to the jamming limit of *ca.* 50%, *i.e.* the maximum saturation for randomly sequentially adsorbed (RSA) particles on curved surfaces. We conclude herefrom that the satellites are not closely packed, as could be guessed from TEM images (Fig. S3†). Because of their negative surface charge, the satellites can be considered repulsive with a larger “soft” diameter. Considering the excluded space by electrostatic repulsion, it can be assumed that the core particles are almost completely saturated with randomly distributed satellites. With this configuration, one might initially expect additional plasmonic contributions due to inter-satellite coupling of closely arranged particles, but this is

**Fig. 2** Structural characterization: (a) SAXS scattering curves (grey) and modelled data for assemblies (blue) and separate building blocks (red: spheres, green: rods). (b) Analysis of the assemblies: MSE mapping of the free-parameter space by atomistic 3D modelling. For assemblies formed by random sequential adsorption, the maximum surface coverage is limited because of jamming (dashed line). Cross-sections for variations in surface coverage (c) and core-to-satellite distance (d) at the global minimum (domain of lowest MSE). Gaussian fits (grey) serve as guides-to-the-eye.

not the case. The nearest-neighbour spacing of satellites is determined by the steric hindrance of their swollen polyelectrolyte coating and repulsive (negative) surface charges. As a consequence, the spacing between two satellites would be at least twice as large as the core-to-satellite spacing (Fig. S8†). Therefore, the satellites' short-range coupling to the comparatively larger core can be expected to out-range the inter-satellite coupling. To test this assumption, we have taken a closer look into the plasmonic interactions and near-field coupling for such anisotropic superstructures. A detailed description of the coupled modes will also provide information on their optical properties, and thus on the possibilities for multifunctionality.

### Correlation of structural and optical properties

Plasmonic hybridization is an electromagnetic analogue to molecular orbital (MO) theory, which allows to intuitively analyse coupling scenarios.<sup>3</sup> With the aim of describing the plasmonic response (shifting and splitting of modes), a complex nanostructure is first conceptually broken down into its elementary building blocks. Then, based on the energetic levels of the elemental plasmons, interactions between the constituents can be predicted or reconstructed. The resulting

hybrid modes differentiate between bonding and antibonding modes, in resemblance with MO theory. Hybridization theory has already been applied to dimers of nanospheres<sup>3,34,46–48</sup> as well as rod–sphere heterodimers,<sup>35</sup> which basically represent single-satellite superstructures (Fig. S12†). The main question here is whether the concept of hybridization can be applied to multi-satellite superstructures. To answer this question, both mode splitting and collective dipole–dipole interactions must be analysed. First, we consider a simplified 2D system that contains only particles in the excitation plane (Fig. S10†), to facilitate the differentiation of the various contributions before proceeding to 3D assemblies.

For anisotropic superstructures, plasmonic coupling can take place in all three principal axes (Fig. 3a–c), one representing a longitudinal excitation and two associated with transversal excitations. Either case, on the left of the diagram the mode of the core rod is shown, with a different energy depending on its orientation ( $R_L$  for the longitudinal one at 690 nm and  $R_T$  for the transversal one at 520 nm). The orbit of satellites is shown on the right, modelled as a degenerate ensemble of individual dipoles (S, 525 nm). The polarization in each of the components can be deduced from their corresponding surface charge density distributions (the gradient of the local

**Fig. 3** Plasmonic coupling in anisotropic core/satellite superstructures: Simplified hybridization diagrams of 2D assemblies in the principal planes of excitation: (a) longitudinal, (b) transversal along the long axis and (c) transversal along the short axis. Surface charge density distributions with the orientations of induced dipoles are indicated by arrows. (d–f) Calculated extinction cross-sections of the fundamental plasmonic modes: spheres S, rod  $R_L$  and  $R_T$ , and bonding coupled modes  $C_L$  and  $C_T$ . Electric-field enhancements of the excited bonding modes are included for each orientation. (g–i) Ensemble-averaged balance between radiative ( $C_{Abs}$ , light red) and non-radiative contributions ( $C_{Sca}$ , light blue) in 3D assemblies and exemplary surface charge distributions for the bonding modes.

electric field). Hybridization theory predicts that, by combination, mode splitting takes place.

Probably the most intuitive situation is an external field aligned along the longitudinal axis of the nanorod. The 2D superstructure shows a pronounced red-shifted mode ( $C_L$ , 780–800 nm), representing the energetically favourable state, in which the dominant core charges lead to reorientation of the satellites. Meanwhile, the locations of high surface charge density also correspond to strong confinements of the electric field  $E/E_0$ . These hot spots are particularly pronounced in the satellite-core gaps near the tips (Fig. 3d). The present dipole-dipole interactions (Fig. S3a†) agree well with the expectations derived from hybridization models of rod-sphere heterodimers as single-satellite assemblies (Fig. S12a†). The second coupled mode is much weaker and located close to the primitive mode of the satellites (S). Initially, one might expect this to indicate the presence of unbound satellites in the solution. However, EM studies have shown that this is not the case. The question arises whether this mode could be assigned to be of antibonding type. Hybridization theory postulates the bonding mode to be redshifted (with respect to the primitive plasmon of the rod core) and the antibonding mode to be blue shifted with respect to the primitive plasmon of the spheres. In practice however, both experimental and theoretical findings have been reported showing slightly red-shifted antibonding modes, at first glance, in disagreement with hybridization theory.<sup>3,46,47</sup> This abnormality was attributed to either additional interactions with interband electrons (in the case of heterometallic Au/Ag assemblies<sup>46</sup>) or to screening/quenching of repulsive interactions (for homometallic Au assemblies<sup>47</sup>). For the multi-satellite structures, the obtained surface charges reveal dipole-dipole interactions, in line with expectations, but the overall charge pattern is weak (Fig. S13a†). This might be indicative for destructive interactions with other longitudinal modes (possibly of higher-order).

The mode splitting of the transversal rod mode ( $R_T$ , 520 nm) proceeds analogously, so it can be viewed from two different perspectives (Fig. 3b and c). Although the resulting modes are basically the same, it makes sense to consider both perspectives, as the seamless transition from an anisotropic to an isotropic-core superstructure can be shown very nicely. We first take the perspective in which both the wave vector  $k$  and the polarization of the electric field  $E$  are perpendicular to the long axis of the nanorod (Fig. 3b). Because the energetic mismatch between core and satellites is low, all components can be excited simultaneously by the external field. The dominant mode at 600 nm shows a uniform charge distribution on the core and a consequent reorientation of the dipolar charges of the satellite particles (close to the tips). The dipole-dipole interactions correspond to a bonding-type mode (Fig. S13b†). Contrary to  $C_L$  (Fig. 3d), the strongest hot spots of  $C_T$  are not located near the rod ends but at its sides (Fig. 3e). The weaker second mode at 520–540 nm corresponds to energetically unfavourable dipolar interactions (Fig. S13b†). Second, from the perspective along the nanorod (parallel to  $k$ , Fig. 3c), the assembly looks like a superstructure with an isotropic

core.<sup>18</sup> Comparing the mode splitting in Fig. 3e and f, it appears that the intensity and redshift magnitude of the low-energy mode depend on the number of satellites involved. The corresponding surface charges reveal favourable interactions at lower energy and unfavourable interactions at higher energies (Fig. S13c†). For details, see ESI.5.† In summary, the plasmonic interactions present in 2D multi-satellite rod@sphere assemblies follow the principles of hybridization theory.

So far, we have only considered 2D assemblies (Fig. 3a–f), whereas 3D assemblies are much more affected by satellite disorder and structural diversity, with a multitude of possible configurations. To assess the influence of disorder, 40 randomly generated 3D configurations (based on the best-match parameters of structural analysis, Table S2, Fig. S10†) were averaged. Fig. 3g–i presents the non-radiative ( $C_{Abs}$ ) and radiative ( $C_{Sca}$ ) contributions of NP building blocks and assemblies. Although the coupled modes ( $C_L$ ,  $C_T$ ) are broadened by ensemble-averaging and inter-satellite coupling (Fig. S11†), they remain dominantly absorbing. The distinct scattering contribution in  $C_L$  originates from the longitudinal rod mode  $R_L$ . Still, in all cases, the absorption cross-section is further increased upon assembly. The exemplary surface charge distributions of 3D assemblies in Fig. 3g–i agree well with the coupling behaviour described above (for 2D assemblies).

From this analysis, clear rules for the design of superstructures can be derived: (1) If the elementary modes are mainly absorbing, the coupled modes will also be strongly absorbing. (2) If one of the elementary modes has a significant scattering contribution, this radiative component will be transferred to the coupled mode.

### SERS efficiency

Based on the above theoretical discussion, the suitability of these superstructures as colloidal SERS nanosensors were investigated. Within superstructures with a broken symmetry, the different hot-spot positions (gaps near rod tips *versus* sides) can be selectively excited by the choice of the respective laser wavelength (Fig. 4a). Here, the question arises which of the coupled plasmon modes displays a higher SERS performance. We first measured the Raman scattering from dispersions of the superstructures without additional analytes (Fig. 4b). A gold concentration of 0.25 mM Au<sup>0</sup> (determined spectroscopically by the extinction at 400 nm) was found to be sufficient to detect the local surface chemistry within the hot spots. Although the SERS intensity of 10–40 counts per mW is relatively weak, the SERS signature can be assigned to the characteristic signals of the coating on the nanorod cores, MUTA<sup>+</sup>, and on the spherical satellites P(SS-co-MA). Guided by reference measurements (Fig. S14, Table S5†), some signals could be assigned to the trimethylammonium head group ( $\nu\text{CN}^+$  760 cm<sup>-1</sup>,  $\nu\text{CH}_3$  1295–1457 cm<sup>-1</sup>) and the skeletal vibrations of the C<sub>11</sub>H<sub>22</sub> alkyl chain ( $\nu\text{CC,ali}$ . 1029–1191 cm<sup>-1</sup>,  $\nu\text{CH}_2$  1215–1461 cm<sup>-1</sup>) of MUTA<sup>+</sup>. Likewise, other signals indicate spectral contributions from styrenesulfonate (SS:  $\nu\text{CS}$  793 cm<sup>-1</sup>,  $\nu\text{CC,ar}$ . 995 cm<sup>-1</sup>) and maleic acid (MA:  $\nu\text{CH}_2$  1449 cm<sup>-1</sup>,  $\nu\text{COO}$  1578 cm<sup>-1</sup>) in the P(SS-co-MA) coating.

**Fig. 4** SERS brightness of coupled modes: (a) Selected wavelengths for the excitation of the bonding coupled modes at 633 nm ( $C_T$ ) and 785 nm ( $C_L$ ). (b) SERS signature of the unlabelled assemblies in water (top), with indicated contributions from  $MUTA^+$  (green) and  $P(SS-co-MA)$  coating (red), by spectral deconvolution (bottom). (c) SERS spectra of assemblies before (grey) and 1 h after labelling (black) with 1  $\mu M$  NTP, upon excitation at 633 nm ( $C_T$ , top) and 785 nm ( $C_L$ , bottom). (d) Corresponding analytical enhancement factors (AEFs) determined 1 h after labelling. (e) Time-dependence of the AEFs indicating complete adsorption of NTP after 1 day. All samples contained 0.25 mM  $Au^0$ .

The true quality of SERS amplification is demonstrated by the addition of 4-nitrothiophenol (NTP, Fig. S14<sup>†</sup>) as an aromatic model analyte. Fig. 4c compares the SERS gains at two different excitation lines, 633 nm and 785 nm, for samples with 0.25 mM  $Au^0$  without NTP (grey lines) and at 1 h after addition of NTP (1  $\mu M$ , black lines). The characteristic signals of NTP occur with significantly higher intensities of up to 1500–1800 counts per mW (Table S3<sup>†</sup>), keeping all experimental conditions the same. For the quantification of the analytical enhancement factors (AEFs),<sup>49</sup> we used the prominent signals of the symmetrical stretching vibration of the nitro group  $\nu NO_2$  at 1330  $cm^{-1}$  and the stretching of the aromatic phenyl ring  $\nu CC,ar$  at 1570  $cm^{-1}$ . For this purpose, we first determined experimentally the non-enhanced molar Raman cross-sections ( $I_{RS}/c_{RS}$ ) of NTP for 633 nm and 785 nm excitation, using a series of reference concentrations below the solubility limit (Fig. S15<sup>†</sup>). Then, the AEF values were calculated by means of eqn (2), based on the intensity  $I_{SERS}$  and NTP concentration ( $c_{SERS} = 1 \mu M$ ) in the SERS experiments (Fig. 4d).

$$AEF = \frac{I_{SERS}}{I_{RS}} \frac{c_{RS}}{c_{SERS}} \quad (2)$$

The AEF values quantify the performance of SERS-active liquids (colloidal dispersions) for analytical chemistry applications, provided that all experimental procedures are clearly

stated and a sub-monolayer coverage of the analyte is ensured (Table S4<sup>†</sup>).<sup>49</sup> The obtained AEFs (after 1 h) range between  $(2.3 - 2.6) \times 10^4$  at 633 nm excitation and  $(0.73 - 1.0) \times 10^5$  at 785 nm excitation (Fig. 4d, Table S3<sup>†</sup>). While at 633 nm, the enhancement ratio of the investigated Raman modes is balanced, the signal yield of  $\nu NO_2$  predominates at 785 nm. In a direct comparison, the signal yield at 785 nm is about 3–4 times higher than at 633 nm. This implies that the longitudinal coupled mode  $C_L$  (in the NIR range) is better suited for SERS than the transverse coupled mode  $C_T$ . These results suggest that the analyte finds its way into the hot spots, *i.e.* the gaps between the core and the satellites. It is however unclear whether the analyte adsorbs uniformly throughout the superstructure or at preferred sites. The preferential adsorption of NTP onto the  $MUTA^+$ -functionalized core could be expected because of coulombic attraction to the  $NO_2^-$  group. However, the positive charge of the NR core should be reversed by the adsorption of  $P(SS-co-MA)$ -encapsulated satellite NPs and free  $P(SS-co-MA)$  from solution, which was added to saturate the unoccupied sites of the core surface. The thiol group of NTP might in principle bind to all accessible areas of the gold surface. At the same time, part of the core surface might be inaccessible because of  $MUTA^+$  ligands. In any case, it is ensured that even for an exclusive adsorption on cores or satellites, the basic precondition of a sub-monolayer of NTP would be met (Table S4<sup>†</sup>). In addition, incomplete analyte adsorption is a source of error that can affect the significance of SERS results. To evaluate whether all NTP molecules have been removed from the solution after incubation for 1 h, further measurements were carried out after 1 day and after 4 days (Fig. 4e, Table S3<sup>†</sup>). It turned out that, after 1 day the AEF values increased by about 18–21%, to  $(0.9 - 1.2) \times 10^5$ . After 4 days, no further increase could be recorded and the values remained constant, indicating complete adsorption of analyte.

For a Raman marker at non-resonant conditions, the SERS results show a remarkably high signal yield per mole Au (AEF/ $c_{Au}$  of  $4.88 \times 10^5 \text{ mM}^{-1}$ ). To the best of our knowledge, this is one of the highest AEF/ $c_{Au}$  efficiency values presented in the literature for SERS-active colloidal dispersions.<sup>44,50</sup> The normalization of AEF values by  $c_{Au}$  is recommended because AEF values by themselves suffer from poor comparability. Especially for colloidal (average) SERS experiments, the analyte to nanostructure surface ratio is a critical parameter. Since the effective surface area and the number of adsorbed analyte molecules are hard to evaluate precisely, we utilize the volume content of NPs by  $c_{Au}$ <sup>51</sup> to relate signal output to material input.

### Plasmonic heating efficiency

After SERS activity has been demonstrated, we present the suitability of our superstructures for plasmonic heating. The conversion of absorbed light into heat is based on photo-thermal relaxation processes during the plasmonic excitation.<sup>27</sup> Accordingly, non-radiative contributions (absorption cross-section) and matching of the excitation wavelength are crucial factors toward effective heat generation.<sup>52</sup> We therefore performed heating experiments to compare the superstructures to

**Fig. 5** Plasmonic heating efficiency: (a) Exemplary heating/cooling cycles of assemblies (blue) and building blocks (green: rods; red: spheres). Heating efficiency (b) and molar rate of heat transfer (c) for excitation at 808 nm. (d) Spectral losses measured by diffuse reflectance spectroscopy of the spherical satellites (top), the rod-shaped cores (middle), and the assemblies (bottom) showing non-radiative (blue) and radiative contributions (red) to the total extinction (black, dashed).

the separate building blocks. For this purpose, 1 mL aliquots for each morphology were illuminated with a laser at 808 nm (710 mW), and the temperature reached at the surface was monitored with a thermal camera. In this way, heating and cooling curves (Fig. 5a) were recorded. Once thermal equilibrium with the environment was reached, the spherical NPs used as satellites were found to cause only a slight temperature increase of 2–3 °C, even at a high Au<sup>0</sup> concentration of 0.55 mM. The nanorod core NPs yield a temperature increase of about 12 °C, at a lower concentration of 0.36 mM Au<sup>0</sup>. Finally, the superstructures result in the highest temperature gain (15 °C), with even lower material requirements (0.13 mM Au<sup>0</sup>).

The heating efficiency  $\eta$  is a measure for the quality of the light-to-heat conversion (Fig. 5b). Following the method described by Roper *et al.*,<sup>26</sup> this corresponds to the quotient of the delivered thermal energy  $\Delta Q(Q_{\text{sample}} - Q_{\text{medium}})$  and the energy provided by the incident laser power  $P$ , considering the optical density (extinction, Ext<sub>808</sub>) of the sample (see ESL.8†).

$$\eta = \frac{Q_{\text{sample}} - Q_{\text{medium}}}{P(1 - 10^{-\text{Ext}_{808}})} \quad (3)$$

The transient temperatures shown in Fig. 5a display an exponential behaviour.  $Q_{\text{sample}}$  and  $Q_{\text{medium}}$  are obtained by fitting the characteristic decay times of the experimental data (Fig. S16†). The heating efficiency is a property defined for a single particle, and it is independent of concentration. Besides, it does not consider how many photons a particle is interacting with; only how many of such photons are trans-

formed into heat. However, for the comparison that we are doing here, it may be more purposeful to directly compare the generated heat output ( $\Delta Q$ ) to the required material input, in terms of sample concentration ( $c_{\text{Au}}$ ). In this way, we avoid misinterpretations given by very different extinction cross-sections of each particle type. Accordingly, we define the molar rate of heat transfer (Fig. 5c) as

$$\frac{\Delta Q}{c_{\text{Au}}} = \frac{Q_{\text{sample}} - Q_{\text{medium}}}{\text{Ext}_{400}/2.4 \text{ mM}^{-1}} \quad (4)$$

in which we use the extinction at 400 nm as a close estimation of the Au<sup>0</sup> content in the sample medium.<sup>51</sup> The small spherical NPs (red) show the highest heating efficiency (Fig. 5b), above 90%. However, the delivered amount of heat per mole is below 0.1 W mM<sup>-1</sup> (Fig. 5c) because their extinction cross-section at the laser wavelength is very low (Fig. 5d, top). In this case, a mismatch of the excitation wavelength with the plasmon resonance is the cause of a reduced heat generation. The same argument applies to the core nanorods (Fig. 5d, middle), which exhibit a conversion efficiency of 43% but a limited molar heat transfer rate of  $0.53 \pm 0.05 \text{ W mM}^{-1}$ . The excitation wavelength matches well with the C<sub>L</sub> mode of the superstructures (Fig. 5d). The assembly of spheres and rods displays an increased heating efficiency, as compared to bare rods, which reaches 53% (Fig. 5b). This behaviour is due to more pronounced non-radiative properties, as can be observed by comparing Fig. 3g–i. The result is a high molar heat transfer rate of  $1.7 \pm 0.26 \text{ W mM}^{-1}$  (Fig. 5c). At first glance, this suggests that a concentration of 0.42 mM Au<sup>0</sup> would in principle suffice to completely convert irradiated light into heat. However, a quantitative conversion cannot be obtained for the given experimental conditions because of the finite interaction volume and limited light path of the laser beam.<sup>25</sup> Recently, heating experiments showing laser-induced aggregation of nanorods have been reported.<sup>53</sup> In our experiments, however, no aggregation or reduced colloidal stability could be observed even after repeated heating/cooling cycles, as verified by UV/vis/NIR spectroscopy. This further confirms the high colloidal stability of the P(SS-co-MA) coating (in the absence of stabilizing ligands) and the possibility of exploiting the superstructures as stable heaters.

Still, it is not fully understood how nanoscale control over optical heating in complex plasmonic systems can be achieved.<sup>54</sup> The superstructures presented herein exemplify an increase of heating efficiency by hierarchical structuring. The interparticle thermalization in this case, appears to be aided by plasmon coupling.<sup>28</sup> Because the nanospheres are very strongly absorbing but cannot be excited directly (by the external field of the laser), the core particle is essential for heat generation.<sup>55</sup> The nanorod core acts as an optical nanoantenna and is the key element in the conversion of light to heat. As the primary excitable component, it excites the surrounding spherical satellites by its own induced electric field. As a result, the generated heat combines contributions from both the core and coupled satellites. Optically, this can be witnessed

by the increased absorption power of the assembly (Fig. 3g and 5d), thereby increasing the efficiency of optical heating.

## Conclusions

The decoration of gold nanorods with spherical NPs results in anisotropic superstructures with satellite coverages (36–45%) close to saturation, limited by surface jamming (*ca.* 50%). The short core-to-satellite gaps of  $1.5 \pm 0.5$  nm, as determined by SAXS analysis, result in strongly coupled building blocks. The characteristic spectral losses of anisotropic colloidal assemblies were investigated, both theoretically and experimentally. Our findings demonstrate that symmetry breaking in the superstructures grants control over the balance between absorption and scattering properties. This was exemplified for nanorod cores which gave access to intense coupling modes with a dominating non-radiative character in the NIR.

These superstructures may serve as colloidal SERS nanosensors in dispersed state with enhancements on the order of  $10^4$  (transversal) and  $10^5$  (longitudinal), by selective excitation at 633 nm or 785 nm, respectively. Their high SERS brightness even allowed to detect the low-intensity spectral background of the coating layers on the building block NPs. The longitudinally coupled mode in the NIR range is particularly well-suited for SERS detection with a remarkably high signal yield per mol Au ( $AEF/c_{Au}$  of  $4.9 \times 10^5$   $\text{mM}^{-1}$ ) for a Raman marker (NTP) at non-resonant conditions.

The superstructures' suitability for plasmonic heating was evaluated by laser irradiation at 808 nm, which falls in a region of low attenuation in biological tissues. We demonstrated that the effectiveness of heat generation relies on both the non-radiative character of the specific plasmon mode and matching to the excitation wavelength. The superstructures showed increased heating efficiency (53%) and molar rates of heat transfer ( $1.7 \pm 0.3$   $\text{W mM}^{-1}$ ) compared to their building blocks. Our results evidence that the heating efficiency can be increased by hierarchical structuring. Because the small non-aggregated nanospheres cannot be excited in the NIR, the nanorod core is required as an optical nanoantenna. Aided by the strong plasmon coupling, the excitation is conveyed to the surrounding nanospheres. Consequently, both the core and the coupled satellites may contribute to heating and the light-to-heat conversion efficiency is augmented.

Thus, balancing of non-radiative and radiative contributions is a key step toward the design of multifunctional nanosensors that combine high SERS and heating efficiencies. In the context of increased structural control, guided assembly<sup>56</sup> at the core surface might even grant access to chiroptical anisotropic superstructures.<sup>57</sup>
