Received 22nd October 2020, Accepted 28th October 2020

DOI: 10.1039/d0fd00123f

Urbanization is an ongoing global phenomenon as more and more people are moving from rural to urban areas for better employment opportunities and a higher standard of living, leading to the growth of megacities, broadly defined as urban agglomeration with more than 10 million inhabitants. Intense activities in megacities induce high levels of air pollutants in the atmosphere that harm human health, cause regional haze and acid deposition, damage crops, influence air quality in regions far from the megacity sources, and contribute to climate change. Since the Great London Smog and the first recognized episode of Los Angeles photochemical smog seventy years ago, substantial progress has been made in improving the scientific understanding of air pollution and in developing emissions reduction technologies. However, much remains to be understood about the complex processes of atmospheric oxidation mechanisms; the formation and evolution of secondary particles, especially those containing organic species; and the influence of emerging emissions sources and changing climate on air quality and health. While air quality has substantially improved in megacities in developed regions and some in the developing regions, many still suffer from severe air pollution. Strong regional and international collaboration in data collection and assessment will be beneficial in strengthening the capacity. This article provides an overview of the sources of emissions in megacities, atmospheric physicochemical processes, air quality trends and management in a few megacities, and the impacts on health and climate. The challenges and opportunities facing megacities due to lockdown during the COVID-19 pandemic is also discussed.

Introduction

Megacities (metropolitan areas with populations over 10 million) present a major global environmental challenge. Rapid population growth, unsustainable urban development, and increased energy demand by transportation, industrial, commercial, and residential activities, have led to large amounts of emissions to the atmosphere that subject the residents to the health risks associated with

^aMolina Center for Energy and the Environment, La Jolla, California 92037, USA. E-mail: ltmolina@mce2.org^bDepartment of Earth, Atmospheric and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, Massachusetts, 02139, USA. E-mail: ltmolina@mit.edu

harmful pollutants, and impose heavy economic and social costs. The dispersion of pollutants generated locally causes regional haze and acid deposition, damages crops and changes in the Earth's radiative balance. Long-range transport of pollutants influences air quality in regions far from the megacity sources. However, as centers of economic growth, scientific advancement, technology innovation, and social and cultural activities, well-planned and densely populated urban centers can take advantage of the benefits of agglomeration by providing proximity to urban infrastructure and services and optimizing energy consumption, thus reducing atmospheric pollution and creating sustainable livable cities for the residents.^{1,2} This is especially critical as the phenomenon of urbanization continues in almost all countries across the world.

In 1970, only 37% of the world's population lived in urban areas; this increased to 55% by 2018 and is projected to increase to 68% by 2030, with almost 90% of the growth happening in Asia and Africa,^{3,4} as shown in Fig. 1. In 2018, about 23% of the world's population lived in 550 cities with at least 1 million inhabitants, of which 50 cities had populations between 5 million and 10 million, and 33 cities had more than 10 million inhabitants (loosely defined as megacities). The world is projected to have 43 megacities (representing 8.8% of the global population of 8.5 billion) by 2030, with most of them located in developing countries,³ many are facing the challenge of growing their economies and managing the environment to provide better quality of life and cleaner and breathable air for the population.

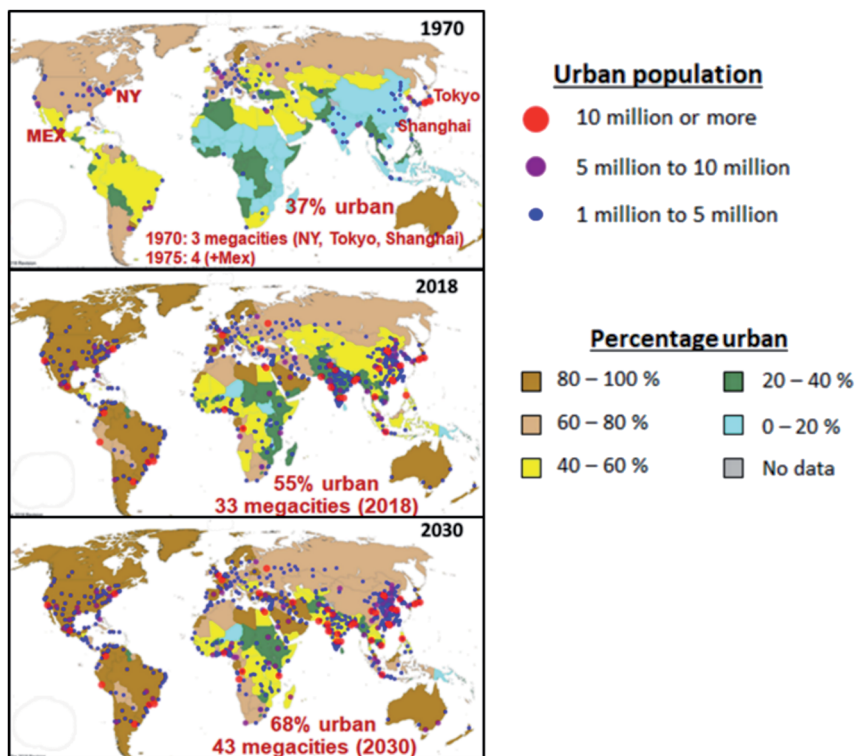

Fig. 1 Evolution of megacities, showing percentage urban and urban agglomeration by size (adapted from the UN World Urbanization Prospect, 2018 revision).⁴

Activities from megacities are responsible for the emissions of primary pollutants, including gaseous species such as volatile organic compounds (VOCs), nitrogen oxides (NO_x), carbon monoxide (CO), sulfur dioxide (SO₂), ammonia (NH₃) and air toxins (*e.g.*, benzene, 1,3-butadiene), some of which contribute to the formation of secondary pollutants such as ozone (O₃) and secondary aerosols; semi-volatile species (*e.g.*, polycyclic aromatics, dioxins, furans); particulate matter (*e.g.*, combustion soot, dust); and metals (*e.g.*, lead, mercury). Despite the large amount of research that has been conducted, including air quality monitoring, field measurements and modeling studies, the sources and processes of emissions generated in megacities that lead to high concentrations of major pollutants such as ozone and secondary particulate matter, are still not well understood, thus limiting our ability to mitigate air pollution and make air quality forecasts to alert the residents of potentially unhealthy air pollution episodes.

This article will provide an overview on the sources of emissions in megacities, atmospheric physicochemical processes, air quality trends and management programs in a few megacities, and the impacts on health and climate change. The final section describes the challenges and opportunities facing the megacities due to lockdown during the COVID-19 pandemic. There is a very large volume of literature articles and topics related to megacities, this article will not be able to cover all of them, but will present the main ideas and include references where more information is available.

Sources of emissions in megacities

Emissions from megacities are caused by a wide variety of anthropogenic and natural sources. The major anthropogenic sources include: (i) mobile sources: on-road vehicles such as passenger cars, commercial buses and trucks, motorcycles and three-wheelers; non-road vehicles such as aircraft, marine vessels, construction and agricultural equipment; (ii) stationary sources such as factories, refineries, boilers and power plants; and (iii) area sources: small-scale industrial, commercial and service operations; municipal solid waste facilities/landfills and wastewater treatment plants; consumer products; residential heating/cooling and fuel use; construction activities; mining operations; agricultural activities and confined animal feeding operations. Natural (biogenic) sources include vegetation, wind-blown soils, volcanoes, lightning, forest and grassland fires, and sea salt spray.

The following sections provide an overview of some of the major sources and control strategies.

Transportation

In many megacities and large urban centers around the world, emissions from the transportation sector are a major source of air pollution.^{1,2,5} The combustion of fossil fuels from mobile sources are responsible for large emissions of particulate matter composed of black carbon, organic carbon and other inorganic components, CO₂, CO, NO_x, VOCs and air toxics. The emissions contributions from mobile sources may vary widely among the megacities, depending on the technical characteristics of the vehicle fleet, the quality of the fuels consumed, the level of local development and intensity of economic activities, and the volume of vehicular travel.

Several megacities have implemented measures to reduce emissions from on-road vehicles, including improvement of vehicle technology and fuel quality, implementation of strict international vehicle emission standards, replacement of diesel with natural gas, and introduction of hybrid and electric vehicles. Some megacities have introduced more efficient mobility through a number of strategies, such as improving the efficiency and security of the public transportation network to encourage use of public transit, expanding infrastructure for non-motorized transportation (walking and cycling); reducing traffic congestion by limiting the circulation of vehicles (*e.g.*, “No drive day” in Mexico and many megacities) (SEDEMA, <http://www.aire.cdmx.gob.mx>) and road pricing (*e.g.*, London) (<https://tfl.gov.uk/modes/driving/congestion-charge>).

In the last decades, technological advances have been responsible for significant changes observed in the energy performance, fuel efficiency, and emissions reductions of vehicle fleets (<https://www2.arb.ca.gov/>). Few other polluting sources have been so dramatically affected by improvements in emission control technology as motor vehicles. As a result of the technological and regulatory measures implemented, many megacities with high vehicle turnover or retrofit rates have experienced overall vehicle emission reductions despite large increases in fleet size, particularly for gasoline-powered vehicles. However, reductions of emissions from some megacities in developing countries have been more difficult to achieve, partly due to limited access to economic instruments that promote the acquisition of emission control technologies and fleet turnover programs. Reducing transport-related emissions will continue to present a challenge with growing urban population and transportation demand for both people and freight. It is important to integrate land-use planning, infrastructure development and transportation management in the design of policy options.

In addition to on-road vehicles, non-road vehicles such as agricultural and construction equipment can substantially contribute to emissions of particulate matter, CO₂, CO, NO_x and VOCs. In contrast to on-road vehicles, there is no regulation on the emissions levels for in-use non-road vehicles and they are often kept in service for several decades. Their relative emissions contributions increase over time as emissions from on-road vehicles continue to be reduced by advanced technologies.^{6–8}

Industry

Stationary sources such as factories, refineries, and power plants, are large emitters of SO₂, PM, CO₂, and NO_x. Some cities have enacted measures to regulate emissions from industrial facilities, such as reducing coal consumption and emissions in Chinese megacities by implementing a “coal to gas” strategy and end of pipe programs (dedusting, desulfurization and denitrification) for industries; restricting use of cleaner coal in coal-fired power plants in Indian megacities; substitution of fuel oil for natural gas in Mexico City. Some cities, such as Los Angeles and Mexico City, have relocated large stationary emission sources, including refinery and power plants, out of the city.^{6,9}

Area sources

Area sources, although they may not emit very much individually due to their small size, when added together, they account for significant contributions of PM,

CO₂, VOCs, NH₃, SO₂ and hazardous air pollutants (air toxics) (<https://www.epa.gov/urban-air-toxics/area-sources-urban-air-toxics>). In contrast to large stationary sources, area sources are in general, required to meet less stringent emissions limits. Many micro industries are in the informal industry sector, which are not effectively regulated; they are too small and there are too many to be inventoried, contributing to one of the largest uncertainties in emission estimates.

Municipal solid waste (MSW) is the third largest source of global anthropogenic methane emissions, generating about 800 million tons of CO_{2eq} annually;¹⁰ it is also a significant source of black carbon and CO₂. Many cities have recycling and waste separation programmes – some are converting organic waste into compost. Landfill is the most widespread method for final waste disposal, followed by capturing of the landfill gas for power generation as part of the integrated waste management program. Many megacities, with large urban populations, are host to some of the world's largest landfills. Along with urban population growth, the amount of solid waste generated in megacities is expected to continue to increase, which will pose a major challenge for MSW management.

The use of solid fuels for cooking and heating continues to be a major source of emissions with adverse health effects. Some cities are promoting the use of cleaner fuel, such as liquefied petroleum gas (LPG). However, emissions from LPG leakage in homes, businesses and during distribution can contribute to substantial emissions of VOCs (mainly propane and butane), as shown in Mexico City.^{11,12} Many cities are promoting energy efficiency programs for public and private buildings, including incentives for using renewable-energy technologies, such as solar heating systems and solar water heaters.

As the emissions of urban VOCs from transport-related sources have decreased due to technological advances and regulatory measures, volatile chemical products (VCPs) from sources such as consumer products (personal care and household products), aerosol coating, painting, solvent use and pesticides have gained in importance. A study by McDonald *et al.*¹³ found that VCPs have emerged as the largest photochemical source of urban organic emissions, highlighting the need for regulatory actions to control the sources.

In some megacities, especially in developing regions, the agricultural sector is a large source of emissions, generated from raising domestic animals, operation of heavy-duty farming machinery, application of nitrogen based fertilizers and chemical pesticides, and burning of crop residues. Agriculture has evolved as a major source of global ammonia emissions. Enteric fermentation from ruminant livestock is one of the largest sources of methane; numerous studies are underway to mitigate the enteric methane production as well as livestock manure management.¹⁰

Biomass burning

Biomass burning is one of the largest sources of trace gases and aerosols emitted to the global atmosphere and is the dominant source for black carbon and primary organic aerosols.¹⁴ Aerosols emitted by biomass burning significantly alter regional and global radiation balance and affect cloud properties and precipitation.^{15–17} Fire smoke is also a major source of greenhouse gases, including CO₂, CH₄, and nitrous oxide (N₂O). Other emitted pollutants include

CO, volatile, semi-volatile, and nonvolatile organic compounds, NO_x, NH₃, HCN and HONO.

There are many sources and fire types related to biomass burning emissions; some are natural sources such as forest fires, while others, such as emissions from burning of crop residue, municipal solid waste, residential wood burning for cooking and heating, and biofuel for brick production, are the result of human activities. Different approaches have been used to estimate emission factors for biomass burning, including direct measurements over fires in field experiments,¹⁸ aircraft measurements,^{19–22} and laboratory measurements.²³ Andreae and Merlet²⁴ compiled emission factors for about 100 trace-gases and aerosols emitted from burning of savannas and grasslands, tropical forest, extratropical forest, domestic biofuel, and agricultural waste burning. The compilation was updated by Andreae¹⁴ to include the number of species and the burning types. Akagi *et al.*²⁵ have also compiled emission factors for open and domestic biomass burning for use in atmospheric models.

In spite of the significant progress in emission factor measurements, detection and quantification of fires, there is still a need to improve the accuracy in the activity estimates, both for open burning and biofuel use. Once released, the gas and particle emissions undergo substantial chemical processing in the atmosphere. In some cases, this processing may lead to compounds that are more detrimental to human health. In the case of wildfires, some of the large number of compounds from fire smoke are not found in a typical urban atmosphere; more research is needed to better understand the chemical processes forming secondary pollutants,²⁶ especially as smoke plumes are transported into urban population centers.²⁷

Agricultural residue burning has been a common practice in many regions around the world to control pests and weeds and to prepare the land for the next crop, which releases a large amount of aerosols and trace gases to the atmosphere.^{14,24,25} In some countries in South America, *e.g.*, Argentina and Brazil, the burning of stubble has decreased substantially due to investment in direct drilling, known as no-till, which seeds into untilled soil without removing stubble; restrictions on burning; and the use of machinery for harvesting.¹⁰ Prescribed burning is an important forest management tool to reduce fuel loading and improve ecosystem health. Most of the burning tends to occur in the non-summer months and is a major source of combustion products to the atmosphere. Wildland fires are a natural occurrence (but often caused by arson and deliberate clearing of rain forest); they are a critical part of ecosystems. However, the area burned in recent years has markedly increased, as demonstrated by the fires in the Amazon, Indonesia, and the western USA. Several studies have documented the importance of climate change on the increasing frequency and size of fires in the western USA, especially in California. A warmer and drier climate is expected to lead to more frequent and more intense fires near or within populated areas.^{27–29}

Many megacities in developing countries still use biomass and fossil fuels (wood, agricultural wastes, charcoal, coal and dung) for residential and industrial cooking and heating; these are a major source of several gases and fine particles in developing countries, and in the wintertime in developed regions.^{18,25,30} Another important source is open garbage burning, which occurs not only in rural, but also in urban areas, especially in cities that do not have adequate solid

waste disposal facilities such as landfills.¹⁰ In some cities, small scale brick production is an important source of urban pollution because of the burning of high polluting fuels such as wood, coal and dung, emitting significant levels of black carbon, organic carbon and other pollutants.^{31–33}

The chemical composition of biomass burning particles shows a wide variety of organic compounds, fragments, and functional groups,^{26,34,35} in addition to the classic tracer levoglucosan.³⁶ Recent work shows the important contribution of secondary organic aerosol to biomass emissions.³⁷ Health effects of biomass burning, similar to hydrocarbon burning, has been shown to include carcinogenic compounds in varying amounts depending on fuel, burning conditions, and secondary contributions.

Fireworks

Other sources that are important contributors to seasonal emissions in some megacities include fireworks, which are traditionally displayed to celebrate New Year's Day around the world, Diwali in India and Spring Festival (Lunar New Year) in China, as well as national holidays such as Bastille day in France, Independence Day in the USA. Li *et al.*³⁸ identified five different types of particles (fireworks' metal, ash, dust, organic carbon–sulfate, and biomass burning) as primary emissions from firework displays in Nanning, China during Chinese New Year. Retama *et al.*³⁹ detected large amounts of K^+ , Cl^- , SO_4^{2-} , biomass burning and semi-volatile oxygenated organic aerosol, as well as trace gases such as SO_2 , NO_2 , CO and HONO during a Christmas Eve and New Year's Eve fireworks display in Mexico City. Chen *et al.*³⁵ also investigated a July 4th fireworks display in the South Coast Air Basin and found unusual trace organic fragments, nitrate, ammonium, sulfate, and alcohol groups, at submicron mass persisted for five days after emission. The bursting of firecrackers and fireworks displays substantially increase the particle pollution leading to some countries (*e.g.*, India) restricting their sales and use. Yao *et al.*⁴⁰ reported significant air quality and public health improvement in Shanghai during the Spring Festival from 2013 to 2017 after the government imposed restrictions on the use of fireworks.

Atmospheric physicochemical processes in megacities

Air quality in megacities is strongly influenced by several factors, including geographical location, demography, meteorology, atmospheric processes and the level of industrialization and socioeconomic development. Since the 1952 London killer fog episode and the discovery of Los Angeles smog in the late 1940s, important progress has been made in the last few decades in understanding the sources of emissions and the atmospheric processes contributing to pollution episodes and how best to control them. Exposure to smoke from burning sulfur-rich coal was correlated with sickness and death during weather-induced pollution episodes in London. The UK Parliament responded by passing a Clean Air Act in 1956,⁴¹ which restricted the burning of coal and provided incentives for fuel switching. While coal-related air pollution has improved in some cities, using cleaner coal with low-sulfur content and emission control technologies (*e.g.*, baghouses), coal-burning power plants remain one of the largest contributors of

SO₂ and co-emitted pollutants, including NO_x, PM and CO₂ in some regions of the world, especially in emerging economies in Asia.⁴²

In the early 1950s, Arie Haagen-Smit and his coworkers discovered the nature and causes of Los Angeles smog: principally that a major component of smog is O₃ formed by NO_x (produced by combustion sources, cars, heaters, *etc.*) and VOCs (from evaporation of gasoline and solvents, *etc.*) in a complex series of chemical reactions that also produce other oxidants and secondary aerosols.⁴³ They also reported that synthetic polluted air exposed to sunlight could cause plant damage observed by Middleton *et al.*⁴⁴ Since then, high O₃ levels have been observed in many urban areas throughout the world, and photochemical smog – induced primarily from transport and industrial activities – is now recognized as a major persistent environmental problem and a priority research area for atmospheric scientists.

Fig. 2 shows an overview of our current understanding of the complex physicochemical processes taking place in the atmosphere.

Gas phase chemistry

Gaseous pollutants (*e.g.*, SO₂, NO_x, CO, CH₄, CO₂, VOCs, *etc.*) are emitted from both anthropogenic and natural sources. Anthropogenic sources are associated with human activities such as transportation, solvent consumption, and industrial emissions. Natural processes occurring in vegetation, soils, marine ecosystems, volcanos, biomass burning, animals, lightning, *etc.*, also result in emissions of these pollutants. Biological sources are a subset of natural sources and include predominantly those of microbial activities in soils and vegetation. Emitted gaseous pollutants are subsequently oxidized by ambient free radicals including

Fig. 2 Overview of atmospheric physicochemical processes. The red boxes highlight the complexities, nonlinearities and uncertainties. Primary emissions are denoted by red arrows and secondary reactions are denoted by black arrows (adapted from Kroll *et al.*⁴⁵).

OH, O₃, peroxy radicals (RO₂), and NO₃. OH is mainly produced by the UV-photolysis of O₃ and is the most important radical because it reacts with most atmospheric species leading to oxidation reactions that produce O₃ and secondary aerosols (SOA, sulfates, and nitrates) in the troposphere. The products and by-products of these oxidation reactions depend not only on the compound being oxidized, but also on the concentrations of other species that may affect this oxidation chemistry.^{46–50}

In urban environments, there are many VOC sources of anthropogenic and biogenic origin. VOC oxidation initiated by OH during the daytime produces a number of organic products of oxygenated functional groups, such as aldehyde, ketone, alcohol, carboxylic acid, hydroperoxide, percarboxylic acid, and peroxyacyl nitrate groups.^{51,52} The relative abundance of these products depends on the VOC structure, the NO_x level, temperature, relative humidity (RH), and the solar intensity. Some compounds formed in the first oxidation step undergo additional oxidation reactions to yield multi-functional groups, and the resulting multi-generations of products are of lower volatility and higher solubility in comparison with their parent compounds.

NO_x plays an important role in determining the fate of peroxy radical intermediates (HO₂ and RO₂). Under relatively clean (low-NO) conditions, peroxy radicals will react with other peroxy radicals or (in the case of RO₂) will isomerize; under polluted urban conditions, peroxy radicals will react with NO, forming NO₂, which rapidly photolyzes in the daytime, producing O₃.⁵³ However, the ambient levels of OH, HO₂, and RO₂ radicals not only depend on NO_x but also simultaneously on the VOC abundance and VOC reactivity. This dual NO_x and VOC-reactivity dependency ultimately controls the chemical regimes of O₃ production. Therefore, successful emission control policies strongly depend on determining the chemical regimes of O₃ production.

The sensitivity of O₃ production to changes in concentrations of precursor VOCs and NO_x is complex and nonlinear.^{53–55} Under high VOC concentrations and low NO_x concentrations, O₃ production rates increase with increasing NO concentrations (NO_x limited) due to increases of NO₂ through reactions of NO and peroxy radicals. But at higher NO_x, O₃ production rates decrease with increasing NO_x (NO_x saturated) due to OH and NO_x termination reactions that form HNO₃ and alkyl nitrates. The additional NO_x also serves as a sink for OH radicals, slowing down the oxidation of VOCs and suppressing O₃ production. NO_x can also sequester O₃ in temporary reservoirs such as NO₂ and N₂O₅; in these conditions, lower NO_x emissions can lead to higher O₃ concentrations. This result could suggest that O₃ production in polluted urban areas, as is the case in many megacities, may be in the NO_x saturated regime.^{56–59} However, recent studies indicate that O₃ production can have marked spatially different chemical regimes within megacities due to the heterogeneous distribution of VOC and NO_x sources, VOC reactivity, and meteorological conditions.^{60,61}

During the night-time, the oxidation of NO *via* O₃ and organic radicals has two main effects: it depletes night-time O₃ levels and accumulates NO₂ and NO₃ radicals that subsequently form N₂O₅ and HNO₃ through heterogeneous reactions.⁶² This condition increases the early morning NO₂/NO ratios and affects O₃ production during the next day by increasing the contribution of excited oxygen atoms *via* NO₂ photolysis. The accumulated NO₂ and nitrate can also form HONO through surface-catalyzed reactions,⁶³ further impacting the accumulation of free radicals.

Particulate matter

Particulate matter (PM) can be emitted directly from anthropogenic sources such as factories, power plants, automobiles, diesel engines, construction sites, unpaved roads, fires, *etc.* Natural sources of PM include sea salt, dust, pollen, volcanic eruptions, *etc.* Others form in complex reactions in the atmosphere of gaseous chemicals, such as VOCs, SO₂ and NO_x that are emitted from power plants, industries and automobiles, as described above. The most important PM is the “inhalable coarse particles” with diameters 10 μm and smaller (PM₁₀), and “fine particles” with diameters 2.5 μm and smaller (PM_{2.5}). PM₁₀ are generated mainly by road traffic, agriculture, and mining, while PM_{2.5} are primary combustion particles or are formed as secondary pollutants. PM_{2.5} are more harmful to health because they can get deep into the lung. PM_{2.5} are also responsible for visibility impairment. PM_{2.5} and PM₁₀ are regulated by USA clean air standards because of their known association with degraded visibility and detrimental health effects (US Clean Air Act, <https://www.epa.gov/laws-regulations/summary-clean-air-act>).^{64–66} While the widespread availability of PM_{2.5} measurements often make it the best proxy for epidemiological studies of populations, physiological studies of health effects have shown that the causes of cell degradation are most likely from specific toxic compounds, which are also regulated and include such compounds as polycyclic aromatic hydrocarbons (PAHs) that are associated with fossil fuel combustion and black carbon.

The abundance and chemical constituents of PM_{2.5} vary considerably in urban cities, depending on the complex interplay between meteorology, emissions, and

Fig. 3 Non-refractory submicron composition measured in urban and urban outflow regions from field measurements, all in units of μg m⁻³ at standard temperature (273 K) and pressure (1013 hPa) (adapted from Nault *et al.*⁶⁹).

chemical processes.^{67,68} Fig. 3 shows the average measured chemical composition of submicron PM (PM_{1}), which typically comprises most of the $PM_{2.5}$ for various megacities, urban areas, and outflow regions around the world.⁶⁹ A substantial fraction of urban PM_{1} is organic aerosol (OA), which is composed of primary OA (POA, organic compounds emitted directly in the particle phase) and secondary OA (SOA, formed from chemical reactions of precursor organic gases). SOA is typically a factor of 2 to 3 higher than POA for these locations.

More recently, ultrafine particles (UFP, particles with diameter 0.1 μm or less) have become increasingly important in urban air because they are produced predominantly from local combustion processes with major contributions from vehicular exhaust and new particle formation (NPF) in cities.^{70–73} Particles that are smaller than 1 μm have both longer lifetimes and higher probability of penetration into alveolar sacs in the lungs, and even smaller “nanoparticles” (<100 nm in diameter) have been shown to have some of the most toxic exposures. Recent evidence suggests that nanoparticles and transition metals, which are also associated with fossil fuel combustion, may play an important role.^{74–79}

Currently, particle mass concentration has been used for regulatory air quality standards. However, this metric accounts mainly for larger particles with larger mass, while particle number concentration (PNC) has been used as a metric for UFP, which are smaller with little mass. de Jesus *et al.*⁸⁰ evaluated the hourly average PNC and $PM_{2.5}$ from 10 cities over a 12 month period and observed a relatively weak relationship between the two metrics, suggesting that control measures aiming to reduce $PM_{2.5}$ do not necessarily reduce PNC. It is important to monitor both $PM_{2.5}$ and UFP for health impact assessment.

For developing effective pollution control strategies and exposure risk assessment, it is necessary to know the contribution of the various sources of pollutants. Several techniques have been used in source apportionment studies of PM, including chemical mass balance (CMB) and positive matrix factorization (PMF) analysis on filter-based chemical speciation data, carbon mass balance modeling of filter-based radiocarbon (¹⁴C) data, aerosol mass spectrometry or aerosol chemical speciation monitoring coupled with PMF. While significant progress has been made in evaluating the sources of pollutants, some sources remain poorly characterized, such as food cooking and open trash burning (see *e.g.*, Molina *et al.*⁸¹ for Mexico City).

Pandis *et al.*⁸² investigated the PM pollution in five cities (Athens, Paris, Pittsburg, Los Angeles and Mexico City) and found that reductions of emissions from industrial and transportation related sources have led to significant improvements in air quality in all five cities; however, other sources such as cooking, residential and agricultural biomass burning contribute an increasing share of the PM concentrations. These changes highlight the importance of secondary PM and the role of atmospheric chemical processes, which complicate the source apportionment analysis. Xu *et al.* (DOI: 10.1039/D0FD00095G) evaluated the fine OC and $PM_{2.5}$ in Beijing using different methods (CMB, PMF and AMS/ACSM-PMF) and found that the fine particles were mainly secondary inorganic aerosols, primary coal combustion and biomass burning emissions. Although there are some consistencies, modeled contributions for several sources differed significantly between the different methods, particularly for cooking aerosols.

New particle formation

New particle formation (NPF) has been observed under diverse environmental conditions and accounts globally for about 50% of the aerosol population in the troposphere.⁸³ NPF occurs in two distinct stages.⁸⁴ The first step involves the formation of a critical nucleus during the transformation from vapor to liquid or solid. The second step is the growth of the critical nucleus to a larger size (>1–3 nm) that competes with the removal of newly nucleated nanoparticles by pre-existing aerosols. Various species have been suggested to account for aerosol nucleation and growth, including sulfuric acid, organic acids from oxidation of VOCs, ammonia/amines, and ions.^{85–91} However, there is a lack of consistent mechanisms to explain NPF under diverse atmospheric conditions, especially in heavily polluted atmosphere of megacities.^{92–94}

Extensive efforts have been made to elucidate the fundamental mechanism relevant to atmospheric NPF from field measurements, laboratory experiments, and theoretical calculations. Previous field studies include measurements of ultrafine particles down to approximately 1 nm in size, gaseous concentrations of nucleating precursors (such as H₂SO₄, NH₃, and amines), and pre-nucleation clusters.^{95,96} Numerous laboratory experiments have been conducted to understand aerosol nucleation.^{92,97–99} In addition, theoretical investigations of aerosol nucleation have been carried out to determine the stability and dynamics of pre-nucleation clusters using thermodynamic data from quantum chemical calculations.^{100–102}

NPF events occur with a frequency of 50, 20, 35, and 45% in spring, summer, fall, and winter, respectively, in Beijing.^{102–104} NPF events have been occasionally measured in Houston during several campaigns.^{105,106} In addition to the correlation with elevated SO₂,¹⁰⁷ the contribution of secondary condensable organics to NPF is implicated in Houston.¹⁰⁸ On the other hand, NPF events are rarely measured in Los Angeles.¹⁰⁹ One plausible explanation is that the heavy accumulation of pre-existing particles and low levels of SO₂ lead to unfavorable conditions for aerosol nucleation in the Los Angeles basin.¹¹⁰ NPF events are frequently observed during field campaigns in Mexico City^{81,111,112} and are usually accompanied with a high level of SO₂,¹¹³ indicating that the oxidation of SO₂ contributes to the formation and growth of freshly nucleated particles. The polluted layer substantially ventilated from the Mexico City basin represents another potential factor in driving NPF in the afternoon, which is characterized by a decrease in pre-existing particle concentrations preceding the NPF events.¹¹⁴

A recent study shows the striking formation of NPF in urban air by combining ambient and chamber measurements.⁹¹ By replicating the ambient conditions (*i.e.*, temperature, relative humidity, sunlight, and the types and abundance of chemical species), the existing particles, photochemistry, and synergy of multipollutants play a key role in NPF. In particular, NPF is dependent on pre-existing particles and photochemistry, both of which impact the formation and growth rates of freshly nucleated nanoparticles. Synergetic photooxidation of vehicular exhaust provides abundant precursors, and organics, rather than sulfuric acid or base species, dominating NPF in the urban environment.

Another laboratory chamber study by Wang *et al.*¹¹⁵ reported that airborne particles can grow rapidly through the condensation of ammonium nitrate (NH₄NO₃) under conditions typical of many urban environments in wintertime,

such as Beijing and Delhi. NH_4NO_3 exists in a temperature-dependent equilibrium with gaseous NH_3 and HNO_3 , but NH_4NO_3 can quickly condense onto newly formed clusters at temperatures below $5\text{ }^\circ\text{C}$, allowing the clusters to reach stable particle sizes before they are scavenged by other existing particles in the atmosphere. Moreover, at temperatures below $-15\text{ }^\circ\text{C}$, NH_3 and HNO_3 can nucleate directly to form NH_4NO_3 particles. The formation of new particles through NH_4NO_3 condensation could become increasingly important as the SO_2 emissions continue to reduce due to pollution controls implemented in many cities. This may in turn imply the importance of controlling NO_x and NH_3 emissions.

Based on the observations in Beijing over a period 14 months, Kulmala *et al.* (DOI: 10.1039/D0FD00078G) found that almost all present-day haze episodes in Beijing originate from NPF, suggesting that air quality can be improved by reducing the gas phase precursors for NPF, such as dimethyl amine, NH_3 and further reductions of SO_2 emissions, as well as anthropogenic organic and inorganic gas-phase precursor emissions.

Secondary organic aerosol

Formation of secondary organic aerosol (SOA) involves a complex multiphase process and represents one of the most poorly understood topics and a frontier research area in atmospheric chemistry.^{67,116–118} This complex process consists of photochemical oxidation, nocturnal reactions, heterogeneous reactions, nucleation and condensation/partitioning.^{68,119} A conventional view is that SOA formation is dominated by absorptive partitioning of low- and semi-volatile oxidation products associated with VOCs oxidation by OH , NO_3 and O_3 . VOCs species are characterized by functionality, reactivity and aerosol formation potential, which are different from single precursors of secondary inorganic aerosols. SOA can be formed by some primary organic aerosol (POA) species, which evaporate and are oxidized, further repartition into aerosols.^{120,121} Evidence from laboratory, field, and theoretical calculations have also suggested that aqueous phase chemistry represents a significant pathway for SOA production.^{35,122–128}

Atmospheric models typically underestimate the SOA mass measured in field studies if only traditional SOA precursors are considered.^{122,129–131} Inclusion of non-traditional SOA precursors, such as organic gases from POA evaporation and di-carbonyls, has helped to bring better closure between models and observations.^{132–136} However, there are still inconsistencies between modeled and measured SOA yields, which can be explained by several factors, including incorrect emission inventories, missing precursors, and unaccounted processes of gas-to-particle conversion.^{13,68}

Nault *et al.*⁶⁹ investigated the production of anthropogenic SOA (ASOA) in urban areas across three continents (see Fig. 3) and observed that it is strongly correlated with the reactivity of specific VOCs; the differences in the emissions of aromatics and intermediate- and semi-volatile organic compounds (IVOC and SVOC) influence the ASOA production across different cities. Emissions from fossil fuel sources (*e.g.*, gasoline, diesel, kerosene, *etc.*) and volatile chemical products (VCPs, such as personal care products, cleaning agents, coatings, *etc.*) contribute nearly similar amounts to estimated ASOA, further supporting the important role of VCPs in urban air quality.¹³

Sulfate formation

The main source of the sulfate in the atmosphere is the multiphase oxidation of SO_2 , including gas-phase oxidations by OH and stabilized Criegee Intermediates (sCI), aqueous reactions in cloud or fog droplets, and heterogeneous reactions associated with aerosol water.¹³⁷ The gas-phase oxidation of SO_2 is dominated by the reaction with OH radicals. At the typical atmospheric level of OH radical, the lifetime of SO_2 from the reaction with OH is about one week.⁶⁷ Additionally, the sCI chemistry has been proposed to potentially contribute substantially to the SO_2 oxidation, and exert profound effects on sulfate formation.¹³⁸

The aqueous-phase conversion of dissolved SO_2 to sulfate driven by O_3 and hydrogen peroxide (H_2O_2) is an important chemical formation pathway in cloud/fog water, but the two SO_2 oxidation pathways still cannot close the gap between field observations and modeling studies.¹³⁹ Aqueous SO_2 oxidation by O_2 catalyzed by transition metal ions (TMI) in models has improved sulfate simulations,¹⁴⁰ and recent studies have further revealed the enhanced effect of TMI during in-cloud oxidation of SO_2 (ref. 141). However, during wintertime haze days free of cloud or fog in North China, rapid sulfate production has been observed^{142,143} showing that the sulfate formation mechanism is still not well understood.

A laboratory/field study of wintertime haze events in Beijing and Xi'an has indicated that the aqueous oxidation of SO_2 by NO_2 is key to efficient sulfate formation under the conditions of high RH and NH_3 neutralization,^{143,144} Li *et al.*¹⁴⁵ proposed a SO_2 heterogeneous formation pathway, in which the SO_2 oxidation in aerosol water by O_2 catalyzed by Fe^{3+} , is limited by mass resistance in the gas-phase and gas-particle interface, and closes the gap between model and observation. A recent experimental study has highlighted that the oxidation of SO_2 by H_2O_2 in hygroscopic, pH-buffered aerosol particles occurs more efficiently than under cloud water conditions, because of high solute strength.¹⁴⁶ Furthermore, another recent study¹⁴⁷ has unraveled a novel sulfate formation mechanism, showing that SO_2 oxidation is efficiently catalyzed by black carbon (BC) in the presence of NO_2 and NH_3 , even at low SO_2 levels (down to a few ppb) and an intermediate RH range (30–70%). The sulfate formation mechanism during wintertime haze days in China is still controversial considering the uncertainties of the aerosol pH value, rather low oxidants level, and possible loss of active sites in BC.

Nitrate formation

The gas-phase reaction between NO_2 and OH to form nitric acid is the dominant formation pathway for nitric acid during the daytime,¹⁴⁸ corresponding to a lifetime of about a day for NO_2 . The heterogeneous reaction between HNO_3 and NH_3 in the particle-phase to form ammonium nitrate also regulates the gaseous HNO_3 concentration. Depending on the RH, the ammonium nitrate formed exists in a solid or an aqueous form consisting of NH_4^+ and NO_3^- , and the correlation between gaseous HNO_3 and particle-phase nitrate is dependent on equilibrium partitioning.¹⁴⁹ Also, amines react with nitric acid and ammonium nitrate to form aminium nitrates by acid-base and replacement reactions, respectively.⁹⁰ The heterogeneous hydrolysis reaction of dinitrogen pentoxide (N_2O_5) on surfaces of deliquescence aerosols dominates the nocturnal nitrate formation in the urban atmosphere.^{150,151} There is also substantial evidence of nitrate enhancement in fog

conditions.³⁵ In addition, although N_2O_5 is photolytically liable during daytime, the heterogeneous N_2O_5 hydrolysis still contributed 10% of HNO_3 during heavy haze days in winter, which is caused by substantial attenuation of incident solar radiation by clouds and high $\text{PM}_{2.5}$ mass loading.¹⁵² In addition to inorganic nitrate, the oxidation reactions of VOCs in the presence of NO_2 produce peroxy nitrates (RO_2NO_2) and strongly-bounded mono and multifunctional alkyl nitrates (RONO_2). There are two main pathways for RONO_2 production: OH-initiated oxidation of hydrocarbons in the presence of NO_x during the daytime, and nitrate radical (NO_3)-initiated oxidation of alkenes during the nighttime.¹⁵³

Aerosol radiative effect

Aerosol radiative forcing has been identified as one of the largest uncertainties in climate change research.¹⁵⁴ Aerosols influence Earth's radiative balance directly by scattering or absorbing solar radiation to cool or warm the atmosphere and dim the surface (direct effects); further induce adjustments of the surface energy budget, thermodynamic profile and cloudiness (semi-direct effects); and indirectly by serving as cloud condensation nuclei (CCN) and ice nuclei (IN) to change cloud properties such as cloud lifetime, reflectivity and composition (indirect effects). IPCC (2013) has used the new terminology of aerosol–radiation interaction (ARI) to refer to the combination of aerosol direct and semi-direct effects, and aerosol–cloud interaction (ACI) to refer to the aerosol indirect effects. The amount of forcing depends on their physical (size and shape) and chemical (surface chemistry, hygroscopicity, *etc.*) properties and on their residence times in the troposphere.

Aerosol radiation interaction has also significantly contributed to the PM pollution during haze days.⁶⁸ It is well established that ARI cools the surface but heats the air aloft, increases the atmospheric stability, enhances accumulation and formation of $\text{PM}_{2.5}$ in the planetary boundary layer (PBL), and eventually deteriorates the air quality during haze days.^{155–157} Wu *et al.*¹⁵⁷ have revealed that the ARI contribution to near-surface $\text{PM}_{2.5}$ concentrations increased from 12% to 20% when $\text{PM}_{2.5}$ concentrations increased from 250 to 500 $\mu\text{g m}^{-3}$ during a persistent and severe PM pollution episode in the North China Plain. However, modification of photolysis caused by aerosol absorbing and/or scattering solar radiation (referred to as aerosol–photolysis interaction or API) changes the atmospheric oxidizing capability and influences secondary aerosol formation. Coatings also affect the ratio of absorption to scattering, and these control changes in radiative forcing.¹⁵⁸ Simulations have revealed that API hinders secondary aerosol formation and substantially mitigates the PM pollution caused by ARI.¹⁵⁹

It is worth noting that ARI or API is highly sensitive to the single scattering albedo (SSA) that is dependent on aerosol composition, particularly regarding absorbing aerosols including BC and brown carbon (BrC).¹⁵⁹ Primary BC and BrC aerosols undergo chemical transformation in the atmosphere, by coating with organic and inorganic constituents, commonly referred to as the aging process.¹⁵⁸ Aging of primary aerosols not only changes the particle mixing state (*i.e.*, from externally to internally), but also alters the particle properties, including the morphology, hygroscopicity, and optical properties, further enhancing aerosol absorption capability.^{117,160–162}

Air quality management in megacities

Air quality management in megacities is a dynamic process. The design of effective emission control strategies in megacities requires detailed information on the pollutant concentrations and meteorological parameters provided by air quality monitoring networks and the key sources of pollution and their spatial distribution, characterized by emission inventory. In addition, scientific research is needed to provide information on the transport and transformation of

^a Air quality standards for O₃, SO₂, NO₂, and CO in Mexico and the USA are reported in parts per million (ppm); they are converted to $\mu\text{g m}^{-3}$ for comparison at a reference temperature of 298 K and barometric pressure of 1 atm. ^b The annual fourth-highest daily maximum 8 hour concentration, averaged over 3 years. ^c Lead: in areas designated nonattainment for the Pb standards prior to the promulgation of the current (2008) standards, and for which implementation plans to attain or maintain the current (2008) standards have not been submitted and approved, the previous standards (1.5 $\mu\text{g m}^{-3}$ as a calendar quarter average) also remain in effect.

pollutants in the atmosphere. Combining air quality observations, emission inventory, meteorology, and atmospheric chemistry enables air quality models to be developed which can be used to evaluate past episodes, assess different emission reduction strategies, and make air quality forecasts. Changes in emissions and other circumstances may identify new air quality problems and require updating and enforcing policy measures.

Since 1987, the WHO has produced air quality guidelines designed to inform policy makers and to provide appropriate targets in reducing the impacts of air pollution on public health. Currently, many countries have established ambient air quality standards to protect the public from exposure to harmful level of air pollutants and are an important component of national risk management and environmental policies. National standards vary according to the approach adopted for balancing health risks, technological feasibility, economic, political and social considerations, as well as national capability in air quality management. Some countries set additional standards for lead and CO. Table 1 presents the current air quality standards for O₃, PM₁₀, PM_{2.5}, SO₂, CO, Pb and NO₂ for China, India, Mexico and the USA, together with the WHO guidelines.¹⁶³

The WHO estimated that about 90% of the world's population breathe polluted air, many of the world's megacities exceed WHO's guideline levels for air quality by more than 5 times.¹⁶⁴ Fig. 4 shows the annual average of PM_{2.5} for a three-year period (2017, 2018, and 2019) for the megacities where data is available; this includes London, Seoul and Chengdu.

The data were compiled by IQAir¹⁶⁵ from real-time, hourly data from government monitoring stations, validated PM_{2.5} monitors operated by private

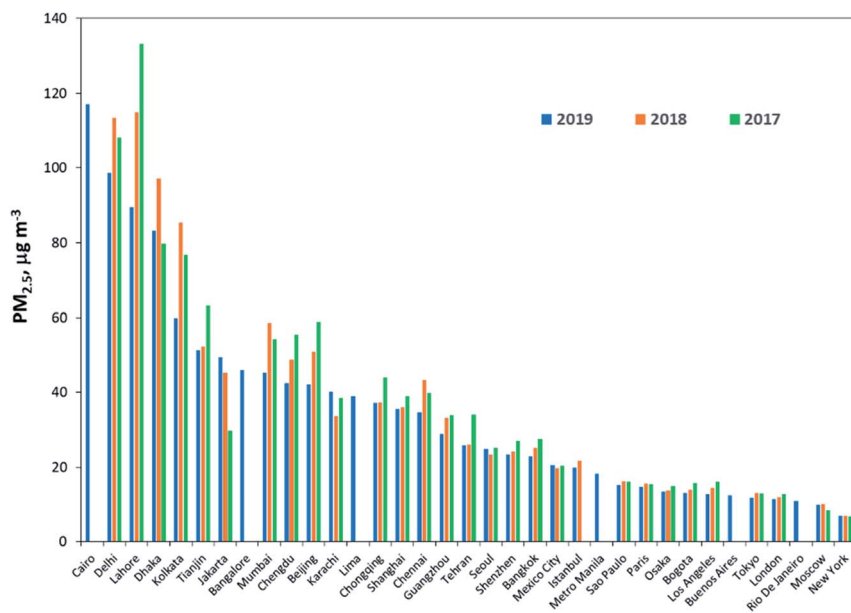

Fig. 4 Annual average of PM_{2.5} for the three-year period 2017–2019. Source: IQAir.¹⁶⁵ Data sources include real-time, hourly data from government monitoring stations, validated PM_{2.5} monitors operated by private individuals and organizations. Cairo, Rio de Janeiro, Bangalore, and Lima are from WHO¹⁶⁶ data (for the year 2015 or 2016).

individuals and organizations. Ideally, the monitoring data used to calculate the average annual PM concentrations should be collected throughout the year, for several years, to reduce bias owing to seasonal fluctuations or to a non-representative year. However, data for most cities are not available for trend analysis. Some of the megacities were not included in the report; the data were taken from WHO¹⁶⁶ for a single year reported in 2015 or 2016.

The PM_{2.5} levels for all the megacities shown in Fig. 4, with the exception of New York, are above the WHO guideline value of 10 $\mu\text{g m}^{-3}$. The megacities with the highest PM_{2.5} concentrations are located in South Asia; however, comparison of the three-year data show reduction in the PM_{2.5} levels in the cities from 2018 to 2019. Much of this can be attributed to increased monitoring data, economic slowdown, favorable meteorological conditions and government actions. For example, 2019 marked the launch of India's first National Clean Air Program, which set PM_{2.5} and PM₁₀ targets and outlined new strategies for tackling air pollution. However, India still has a relatively limited air quality monitoring network, with many communities lacking access to real-time information.¹⁶⁷

The data shown in Fig. 4 are the annual average; however, there is a large seasonal variation for some cities (Delhi, Lahore, Dhaka, Kolkata), as shown in Fig. 5, due to geographical location and prevailing meteorology. The PM_{2.5} concentrations are the highest in November to January, and the lowest from July to September, as monsoon rains wash out airborne particulates, leading to cleaner air. During the winter, emissions from residential heating, burning of crop residues, and intensive brick production lead to higher PM_{2.5} concentrations in these cities. The landlocked geography of Delhi and the coastal location of Mumbai influence the distribution of air pollutants in the two cities.¹⁶⁸

Lahore ranks as one of the megacities with the highest annual PM_{2.5} concentrations, weighted by city population. Until recently, there was no government monitoring in Pakistan. The data provided in the IQAir¹⁶⁵ report (2019) comes from low-cost sensors operated by individuals and non-governmental organizations. Recently the Pakistan government cited air

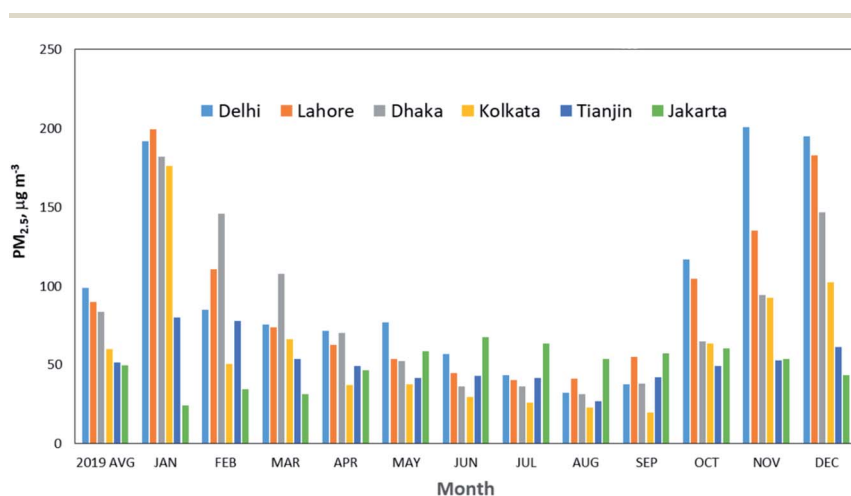

Fig. 5 Monthly average of PM_{2.5} concentrations for the six megacities with the highest PM_{2.5} concentrations in 2019. Source: IQAir.¹⁶⁵

pollution as a key priority and has reinstated the monitoring infrastructure in Lahore. Current anti-smog measures include stricter emission standards on factories and penalties for high-polluting vehicles and farmers burning crop stubble.

Although more countries are taking action and more cities are now included in the air quality database, there are still many cities that do not have ambient monitoring and their residents do not have access to air quality information where pollution levels may be high. For example, South America is the most urbanized region of the world; five of the megacities are located in this continent: Bogotá (Colombia), Buenos Aires (Argentina), Rio de Janeiro (Brazil), São Paulo (Brazil) and the metropolitan area of Lima-Callao (Peru). Recently, Gómez Peláez *et al.*¹⁶⁹ reviewed the air quality trends of the criteria pollutants collected by the automatic monitoring networks of 11 metropolitan areas in South America, including four megacities (Rio de Janeiro, São Paulo, Buenos Aires, and Lima). Despite concerted efforts to monitor air quality, the data provided by environmental authorities in some cities are of poor quality, making it difficult to assess the air quality trends and take action for critical air pollution episodes. Integration of the emission from the whole continent and their application in an air quality model are essential to investigate the effect of long-range transport and to construct air quality and emission control strategies for the entire region. Integrated coordination due to transboundary pollution transport, mainly from the biomass burning in the Amazon basin, is essential, especially considering the record-breaking number of Amazon fires in 2019 and again in 2020. Analysis of an aerosol particles' chemical composition and optical properties during the biomass burning season in 2014 showed that, depending on the wind direction, smoke plumes from central Brazil and southern regions of the Amazon basin can be transported over São Paulo.¹⁷⁰

In February 2020, the United Nations Environment Programme (UNEP), together with the UN-Habitat and IQAir, launched the world's largest air quality platform, bringing together real-time air pollution data from over 4000 contributors, including governments, citizens, communities, and private sectors.¹⁷¹ This partnership covers more than 7000 cities worldwide and aims to empower governments to take action to improve air quality, allowing citizens to make informed health choices, and businesses to make investment decisions promoting a cleaner and greener environment.

The following describe the air quality trends and air quality management programs for Los Angeles, the Mexico City metropolitan area and four Chinese megacities. While the differences in the governance, economics, and culture of the megacities greatly influence the decision-making process, all have overcome severe air pollution and have made significant progress in reducing concentrations of harmful pollutants by implementing comprehensive integrated air quality management programs. The experience can be valuable for other megacities.

Air quality in the Los Angeles basin

The Los Angeles metropolitan area had 12.5 million inhabitants in 2018 (UN, 2018a) and is the second-most populated urban area in the United States, after the New York–Newark metropolitan area. The multi-county South Coast Air Basin

(SoCAB), which consists of Orange County and the urban portion of Los Angeles, Riverside, and San Bernardino Counties with a population of 18 million, is one of the air basins in California designated for air quality management (<http://www.aqmd.gov>). The basin is bordered by the Pacific Ocean on the west and mountains on the other three sides, which limit horizontal ventilation. During the summer, the coastal air basin is often under the influence of a large-scale subsidence inversion that traps a layer of cool marine air. Pollutants emitted from various sources during the day are pushed by onshore sea breeze to the inland valleys, undergoing photochemical reactions and producing O₃ and other oxidants. Stagnant high pressure systems with subsidence aloft allow pollutants to accumulate near the ground, causing high smog episodes.

Following the recognition of Los Angeles photochemical smog as a severe environmental problem in the 1940s, comprehensive emissions control efforts have been implemented by the air quality management authorities, the California Air Resources Board (CARB) and the South Coast Air Quality Management District (SCAQMD) principally, particularly in the transportation sector, which plays a major role in the air pollution problem. The urban center is decentralized; major commercial, financial and cultural institutions are geographically dispersed, relying on a vast network of interconnected freeways. The emissions control measures included the introduction of unleaded gasoline and an eventual complete ban of lead in gasoline, three-way catalytic converters, stringent NO_x control for ozone and PM_{2.5}, low-sulfur fuels, and diesel particle filters. Other regulations such as controls on power plants and boilers have reduced smog-forming oxides of nitrogen emissions, rules on consumer products such as

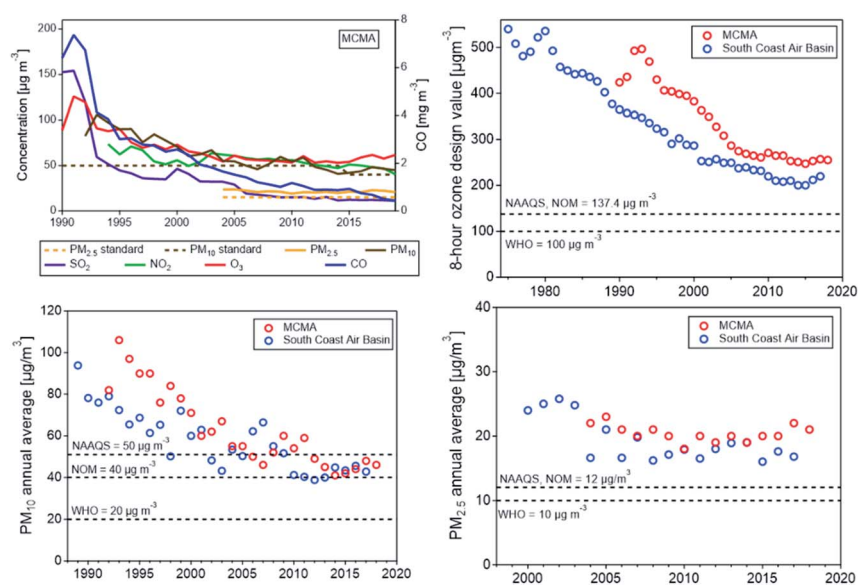

Fig. 6 Comparison of air quality trends (for O₃ and PM) in the Mexico City metropolitan area (MCMA) and South Coast Air Basin (SoCAB) using the same metrics. Graphs plotted with data from SIMAT (<http://www.aire.cdmx.gob.mx/>) and SoCAB (<http://www.aqmd.gov>).

paints and solvents have limited volatile organic compounds, and other controls on gasoline components, chrome platers, dry cleaners, and other sources have reduced levels of airborne toxics.^{6,172}

Other emission sources include goods movement sources, such as railroads, ocean-going vessels, commercial harbor craft, cargo handling equipment, drayage trucks, and transport refrigeration units. California adopted the first-in-the-nation regulation requiring ocean-going vessels to use cleaner fuel when near the California coast in 2008, which has been effective in reducing SO₂ emission from ships.¹⁷³ Emissions from ports have also been reduced by making shore power available to docked ships that previously idled their engines, while the more polluting drayage trucks are either removed from service or retrofitted.⁶ The Advanced Clean Car Regulation (<https://ww2.arb.ca.gov/our-work/programs/advanced-clean-cars-program>) is the latest of a series of technology-forcing standards aimed at limiting passenger vehicle emissions and reducing smog as well as mitigating climate change.¹⁷⁴ As a result of the stringent emissions reduction measures, peak ozone levels and PM_{2.5} concentrations in Los Angeles today are about one third of their level in 1970. Nevertheless, the ozone concentration is frequently still above the current USA ambient 8 h ozone standard of 70 ppb (see Fig. 6).

One of the main challenges is that a substantial fraction of the ozone in Southern California is transported into the region from outside its border, which is not subject to local control. This includes the baseline ozone concentrations, which are not affected by continental influences, such as ozone transported from the Pacific¹⁷⁵ and the background ozone (the ozone concentration that would be present if anthropogenic precursor emissions were reduced to zero), which are affected by continental influences such as deposition to continental surfaces, vegetation, production from natural ozone precursors (*e.g.* from trees, soils and lightning).¹⁷⁶ This could be as high as 89% of the USA NAAQS (62.0 ± 1.9 ppb) and that about 35 years of additional emission control efforts will be needed to meet the NAAQS.

Altuwayjiri *et al.* (DOI: 10.1039/D0FD00074D) investigated the long-term variations in the contribution of emission sources to ambient PM_{2.5} organic carbon (OC) in the Los Angeles basin and the effect of the regulations targeted tailpipe emissions during 2005–2015. They found a significant reduction in the absolute and relative contribution of tailpipe emissions to the ambient OC level, while the relative contribution of non-tailpipe emissions (road dust resuspension, tire dust, and brake wear particles) increases over the same period, suggesting that the regulations were effective but also underscore the importance of regulating non-tailpipe emissions.

Recent wildfires in California have markedly increased, worsening air quality in much of the region. A warmer and drier climate is expected to lead to more frequent and more intense fires near or within the populated areas, threatening to undo the significant improvement in air quality after decades of implementing the Clean Air Act.^{27–29} Long-term monitoring and reevaluation of forest management strategies will be needed to address the wildfire problem as climate change continues to bring hotter and drier conditions conducive to wildfire activity.¹⁷⁷

Air quality in the Mexico City metropolitan area

Comparing California's air quality with that of other cities (and countries) shows how cities around the world have benefited by adopting strategies and control technologies pioneered in Los Angeles. An example is the Mexico City metropolitan area (MCMA).¹⁷⁸ In late 1980s to early 1990s, all criteria pollutants frequently exceeded the AQ standards, with ozone peaking above 300 ppb 40–50 days a year, leading Mexico City to be ranked as the most polluted megacity in the world at that time.¹⁷⁹ Since the 1990s, the Mexican government has made significant progress in improving the air quality of the MCMA by developing and implementing successive comprehensive air quality management programs that combined regulatory actions with technological change based on scientific, technical, social, and political considerations. Vehicle emissions reduction focused on adapting advanced technology and improved fuel quality that had been successfully implemented in other countries, especially in California, including removal of lead from gasoline, mandatory use of catalytic converters, reduction of sulfur content in diesel fuel, reinforcement of vehicle inspection and maintenance, and mandatory “no driving day” rule. Emissions reduction measures for industry and commercial establishments included closing of an oil refinery, relocating high polluting industries outside the valley, substituting fuel oil in industry and power plants with natural gas, and reformulating liquefied petroleum gas (LPG) for cooking and water heating. As the result of implementing comprehensive air quality improvement programs, the city has significantly reduced the concentrations of all criteria pollutants,¹⁸⁰ as shown in Fig. 6, top left panel. The figure also shows a comparison of the air quality trends (for O₃ and PM) in the MCMA with the SoCAB using the same metrics. Both air basins show similar trends, O₃ and PM₁₀ have decreased significantly in both air basins, but even more rapidly in the MCMA, so that the concentrations in the MCMA have approached those in SoCAB in recent years despite a large difference in the financial and human resources and institutional capacity, which are essential for developing and implementing emission control programs.

Field measurements studies conducted in the MCMA during MCMA-2003 (ref. 112) and MILAGRO-2006 (ref. 81) showed that ozone formation was generally VOC-limited within the urban core, while mostly NO_x-limited in the surrounding area depending on the prevailing meteorology,^{56–58} and that O₃ production might continue in the outflow for several days due to the formation of peroxyacetyl nitrate (PAN), which could regenerate NO_x and contribute to regional O₃ formation.¹⁸¹ A recent study by Zavala *et al.*⁶⁰ shows that there is an overall reduction in the VOC-OH reactivity during the morning hours in the urban area with large spatial variability, implying a large spatial variability in O₃ production, which in turns suggests spatially different O₃ sensitivity regimes to precursor gases. While alkanes (from leakage and unburned LPG used for cooking and water heating) are still key contributors to VOC-OH reactivity, the contribution from aromatic and alkene species has decreased, consistent with reduction of VOCs from mobile sources. Changes in ozone production suggest that increases in the relative contributions from highly oxygenated volatile chemical products, such as consumer and personal care and solvent use, are responsible for sustained high O₃ levels in recent years. The study also found a significant increase in NO₂/NO ratios, suggesting changes in the night-time accumulation of radicals that could

impact the morning photochemistry. The results suggest a need for a new field study of radical budgets in the MCMA, expanding measurements of VOCs to include oxygenated species, and using the data to support modeling studies in the design of new air quality improvement programs.

The MCMA faces additional challenges from regional contributions. Urban expansion of the MCMA has produced the megalopolis, consisting of Mexico City and contiguous municipalities of six surrounding states. The Megalopolis Environmental Commission (CAME, <https://www.gob.mx/comisionambiental>) was created in 2013 to coordinate the regional policies and programs; however, the different administrative and legislative jurisdictions and the available resources have created an ongoing challenge. With the exception of the MCMA, there is limited air quality monitoring and air pollution studies in the other states, making it difficult to evaluate the regional air quality and the impacts of pollutants in the region.⁹

Burning of regional biomass is a major contributor of fine particles to the MCMA during air pollution episodes (<http://www.aire.cdmx.gob.mx>). During the dry season, agricultural and forest fires in the surrounding areas are frequent, the wind transports air masses enriched with organic aerosols, VOCs, as well as other reactive gases to the MCMA, severely impacting the air quality.²⁰ Lei *et al.*¹⁸² evaluated the impact of biomass burning in the MCMA and found that biomass burning contributed significantly to primary organic aerosol (POA), secondary organic aerosol (SOA), and elemental carbon (EC) locally and regionally but has relatively little effect on O₃. Despite the important contribution of biomass burning to local and regional air quality, the authorities did not include fire mitigation in the air quality management strategies. In May 2019, following a severe air pollution episode caused by regional wildfires, the authorities announced new action contingencies, adding PM_{2.5} threshold level, in addition to O₃ and PM₁₀, to the contingency plan.

Air quality in Chinese megacities

Of the 33 megacities in the world in 2018, six are located in the People's Republic of China (Chongqing, Shanghai, Beijing, Tianjin, Guangzhou, and Shenzhen) according to a UN report,³ although according to the China Statistics Bureau, there are 15 cities with more than 10 million inhabitants due to different city boundaries defined in the two datasets.¹⁶⁷ Many of these megacities are suffering from severe air pollution caused by rapid socio-economic development, motorization and industrialization, following the “reform and open-up policy” beginning in the late 1970s, which transformed China into the second-largest economy in the world, after the USA.

As a global hub for manufacturing, the heavy industries, including production of iron and steel, other nonmetal materials and chemical products, play an important role in the Chinese economy, resulting in huge consumption of energy and large emissions of air pollutants. In addition, more and more people are moving from rural to urban areas, leading to a fast expansion of cities and an increasing demand for vehicles, contributing to severe air pollution.

Faced with increasing pressure on the environment in urban development, the Chinese government launched the Action Plan for Air Pollution Prevention and Control (Action Plan) in September 2013 (<http://www.gov.cn/zwggk/2013-09/12/>

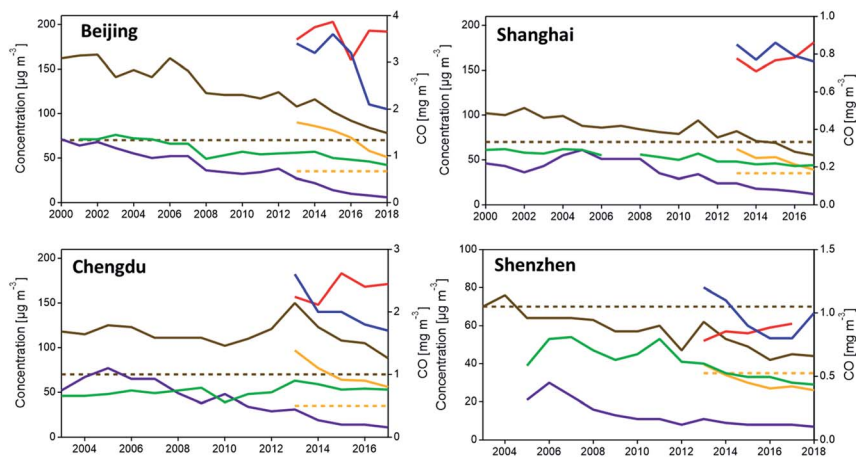

Fig. 7 Air quality trends (annual average) for Beijing, Shanghai, Shenzhen and Chengdu. Red, O_3 ; blue, CO; green, NO_2 ; purple, SO_2 ; brown, PM_{10} (dotted brown line, PM_{10} standard); yellow, $PM_{2.5}$ (dotted yellow line – $PM_{2.5}$ standard). Note O_3 level = annual average of daily 8 h mean concentration. Sources: China Statistics Bureau and Beijing Environmental Protection Bureau; China Statistics Bureau and Shanghai Environmental Protection Bureau; China Statistics Bureau and Shenzhen Environmental Protection Bureau; China Statistics Bureau and Chengdu Environmental Protection Bureau (data compiled by W. Wan¹⁶⁷).

content_2486773.htm), which stated the development targets and roadmap for 2013–2017. The Action Plan provides the framework for air pollution control measures in cities, covering capacity building, emission reduction measures and supporting measures. The implementation of a series of control measures, including coal combustion pollution control, vehicle emission control and VOCs control, have resulted in the reduction of most pollutants and a large decrease in $PM_{2.5}$ concentrations.¹⁶⁷ However, according to a government report,¹⁸³ 74.3% of 74 key cities exceeded the NAAQS of annual mean $PM_{2.5}$ concentrations ($35 \mu\text{g m}^{-3}$) in 2017.

As shown in Fig. 7, while the concentration of most pollutants have decreased for each city, O_3 was not effectively controlled (red line). Also, the annual mean $PM_{2.5}$ concentrations still exceeded the NAAQS of China, except Shenzhen, the first city that met the $PM_{2.5}$ standard. The exceeding of the PM daily average concentration often occurred during the cold winter from November to February, while the maximum daily 8 h average concentration of O_3 is more likely to exceed in the summer during the afternoon, according to the local monitoring data (China National Environmental Monitoring Center, <http://www.cnemc.cn/en/>).

Although the major sources of emissions differ among the four cities, in general, vehicle emissions remain the primary source of air pollution and contribute significantly to VOC, NO_x , CO, and $PM_{2.5}$ (including BC). The primary source of SO_2 is fossil fuel combustion from industry and mobile vehicles; while road and construction dust is the main source of PM_{10} , and agriculture is the primary source of NH_3 .

Vehicle emission control has been a priority of air quality management, and the cities have continuously tightened emission standards for new gasoline and

diesel vehicles; promoting the use of electric vehicles through subsidies.¹⁶⁷ Shenzhen is the first megacity in China and in the world to adopt electric vehicles for the entire public transportation system. However, as a coastal city, diesel trucks carrying large amounts of cargo is the primary source of local emissions and ocean-going vessels, contributing a large portion of SO₂ due to the use of low-quality heavy fuel oil. Emission control policies for the port area and the ocean-going vessels are areas also being implemented. In addition to local sources, pollutants transported from the outskirts have contributed to the pollution levels of the cities.¹⁶⁷

Although the PM levels have decreased significantly due to the stringent measures implemented by the government authorities,^{184–186} summertime O₃ concentrations have increased in the megacity clusters in China.^{187,188} Several studies have investigated the anthropogenic and meteorological factors that are responsible for the O₃ pollution in China.^{189–194} Flat VOCs emissions and reduced NO_x emissions have slightly increased the O₃ concentration in most urban areas of eastern China. A significant anthropogenic driver for the O₃ enhancement is the over 40% reduction of PM_{2.5} in the North China Plain (NCP), which slows down the aerosol sink of hydroperoxyl radicals, thus stimulates the O₃ production.^{61,193} However, meteorological influences have been thought to be comparable to or even more important than the impact of changes in anthropogenic emissions. Increased solar radiation reaching the surface level due to the decrease of cloud cover, cloud optical thickness as well as the aerosol optical depth has promoted photochemical reactions and resulted in O₃ enhancement. Higher temperature, as a result of enhanced solar radiation, has been recognized as an important factor corresponding to the increasingly serious O₃ pollution for enhancing biogenic emissions and decreasing O₃ dry deposition.¹⁹⁵

The dominant cause of increasing O₃ due to changes in anthropogenic emissions was found to vary geographically. In Beijing, NO_x and PM emission reductions were the two main causes of O₃ increase; in Shanghai, NO_x reduction and VOC increase were the major causes; in Guangzhou, NO_x reduction was the primary cause; and in Chengdu, the PM and SO₂ emission reductions contributed most to the O₃ increase.^{195,196} While NO_x reduction in recent years has helped to contain the total O₃ production in China, VOC emission controls should be added to the current NO_x–SO₂–PM policy in order to reduce O₃ levels in major urban and industrial areas.

In addition to O₃, there have been several extreme haze events in China during wintertime in recent years, as a consequence of diverse, high emissions of primary pollutants (*e.g.*, from residential heating) and efficient production of secondary pollutants.^{68,197–201} In particular, the North China Plain (Beijing–Tianjin–Hebei) and Chengdu–Chongqing region have suffered from severe haze pollution.^{68,197,198} Unfavorable meteorological conditions enhancing the air static stability and shallow planetary boundary layer due to aerosol–radiation and aerosol–cloud interactions, could also aggravate severe haze formation.^{68,157,159}

Atmospheric NH₃ plays an important role in fine particle pollution, acid rain, and nitrogen deposition. In contrast to those in developed countries, agricultural NH₃ emissions largely overlap with the industrial emissions of SO₂ and NO₂ in northern China. A model study showed that the average contribution of the agricultural NH₃ emissions in the NCP was ~30% of the PM_{2.5} mass during a severe haze event in December 2015.⁶⁸ Control of NH₃ would mitigate PM

pollution and nitrogen deposition. However, another study²⁰² found that NH₃ control would significantly enhance acid rain pollution and offset the benefit from reducing PM pollution and nitrogen deposition.

The examples of the four Chinese and two North American megacities illustrate the complexity of managing urban pollution. In spite of significant progress in cleaning the air, there are still remaining challenges. While each city has its own unique circumstances – geographical location, meteorology, emission sources, financial and human resources, the need for an integrated, multidisciplinary assessment of the complex urban air pollution problem is the same. In light of the multicomponent nature of air pollution, application of integrated control strategies that address multiple pollutants, supported by ambient monitoring, emissions characterization, air quality modeling, and comprehensive rather than separate strategies for each single pollutant, would be more cost-effective.²⁰³

Impacts of degraded air quality in megacities

Emissions and ambient concentrations of pollutants in megacities can have widespread effects on the health of their populations, urban and regional haze, regional climate and ecosystem degradation. The topic is broad, the following sections will describe the impacts on health and climate.

Health effects

Although there is increasing awareness about the harmful effect of air pollution and more countries are taking action to address it, some regions in the world, notably in megacities in developing countries, are still exposed to high level of harmful ambient air pollutants as well as indoor pollution, such as burning of biomass and fossil fuel for cooking and heating. The World Health Organization (WHO)²⁰⁴ estimates that air pollution was responsible for more than 7 million premature deaths worldwide in 2016, with 4.2 million due to outdoor air pollution. Low income and rapidly industrializing countries are the worst affected. India and China have the largest number of pollution related deaths. However, there is considerable uncertainty in the estimation as scientists are still discovering links between pollution and illnesses and there is a lack of data on many toxic metals and chemicals.²⁰⁵ In the absence of aggressive intervention, the Organisation for Economic Cooperation and Development (OECD)²⁰⁶ projected that outdoor air pollution could cause 6 to 9 million premature deaths by 2060 and annual health costs related to air pollution would increase nearly 10 times relative to 2015 levels. The health and economic benefits of investing in air pollution controls cannot be overestimated; cost-effective options are available for mitigating the impacts. A new report from the Health Effects Institute (HEI)²⁰⁷ stated that air pollution contributed to 6.67 million deaths worldwide in 2019 and is the fourth leading risk factor, with 4.41 million deaths attributable to PM_{2.5} exposure and 2.31 million deaths to household air pollution. Between 2010 and 2019, exposure to PM_{2.5} remained the same, while exposure to O₃ increased. However, there is some encouraging news: exposure to indoor air pollution has declined by about 24% due to a decreasing number of households using solid fuels for cooking.

Over the past few decades, data on air quality has become increasingly available and the science underlying the related health impacts is also evolving rapidly. Effects of air pollution on human health have been investigated with epidemiology, animal studies, and human exposure studies. Populations at greater risk include children and the elderly and those that have pre-existing conditions such as diabetes, or cardiovascular and respiratory diseases. While many countries have established air quality standards for criteria pollutants, or follow WHO guidelines (Table 1), there is an ongoing debate as to the maximum permissible limit of a particular pollutant concentration. As more information becomes available, the standards have been strengthened to protect public health.

It is evidenced from epidemiological and clinical studies that exposure to particulate matter, especially PM_{2.5}, is linked to cardiorespiratory disease and adverse birth outcomes.^{208–211} Although there is a large volume of research on the adverse effects of PM exposure, composition of the particles and the mechanisms causing such association are still not well understood. The physicochemical characteristics of PM vary according to emission sources, secondary atmospheric chemical reactions and meteorological conditions. Other factors can also affect the toxicity of PM, such as the metal content of the particles and their reactivity. For example, some physiological studies of health effects have shown that the causes of cell degradation from exposure to fine particles are most likely from specific toxic compounds, such as polycyclic aromatic hydrocarbons (PAHs) and black carbon.

More recently, ultrafine particles were found to possibly exert higher toxicity than larger particles due to their small size; they generally enter the body through the lungs but are translocated to essentially all organs.^{212,213} Nanoparticles and transition metals, which are also associated with fossil fuel combustion, may also play an important role.^{74–79} Although exposure to UFP is commonly attributed to vehicular exhaust, monitoring in Ghana showed higher exposure from trash burning and domestic cooking.²¹³

Several approaches have been used to elucidate the mechanism of toxicity, one is the use of *in vivo* experimental models to evaluate the effects of PM on the respiratory, cardiovascular and nervous system, another one is *in vitro* models, which has proven useful for investigating mechanistic responses, such as inflammatory/immune alterations and genotoxicity.²¹⁴ Besides the well-documented impacts on respiratory and cardiovascular health, the evidence is accumulating around exposures during pregnancy and adverse birth outcomes, cancer, brain alterations and interactions between infectious agents and air pollution.^{215,216} H. Bové *et al.*²¹⁷ reported the presence of black carbon particles as part of combustion-derived PM in human placenta, suggesting that ambient particulates could be transported towards the fetus, representing a potential mechanism for the adverse health effects of pollution from early life onwards.

Many studies have investigated the association between oxidative potential of air pollutants with adverse health outcomes; however, there are some contradictory results. For example, Quintana *et al.*²¹⁸ reported the oxidative potential correlated with PM₁₀ Cu/Zn content but not with the *in vitro* biological effects from samples collected in Mexico City during the MILAGRO field campaign. Weichenthal *et al.*²¹⁹ examined the relationship between PM_{2.5} oxidation burden and cause-specific mortality; the results suggest that glutathione-related oxidative

burden may be more strongly associated with lung cancer than the mass concentrations. Strak *et al.*²²⁰ examined the role of particle size, composition and oxidative potential; the results suggest that changes in particle number concentrations (PNC), NO₂ and NO_x were associated with acute airway inflammation and impaired lung function, while PM mass concentration and PM₁₀ oxidative potential were not predictive. A study conducted in central London also indicated the association of PNC with cardiovascular effects, while non-primary PM components (nitrate, sulfate, chloride and organic carbon) were associated with adverse respiratory outcomes.²²¹

Results from the various studies and epidemiological evidence suggest that each megacity will have contributing factors that create different air pollution impacts on health,²²² among those could be specific chemical mixtures in the atmosphere, meteorology, socioeconomic conditions/disparities. An important research topic is the health impact related to exposure from smoke from biomass burning (wildfires, burning of agricultural residues and trash, *etc.*). PM_{2.5}, O₃, and other compounds in smoke have clearly demonstrated human health impacts; however, the episodic nature of smoke exposure and the large and variable mix of compounds make health studies even more challenging than traditional air pollution episodes. It is important to better understand the long-term consequences, such as birth outcomes, neurological and cognitive effects, and progression and incidence of chronic disease related to smoke exposure and to establish exposure guidelines.²⁷

To estimate the health impact to be expected from measures affecting air quality, it is important to conduct health risk assessment. An important step is the exposure–response function, such as the exposure–mortality model (EMM) which is based on total concentration of PM_{2.5} and does not consider the unequal toxicity of different components of PM_{2.5}. Xue *et al.* (DOI: 10.1039/D0FD00093K) developed a component-specific EMM (CS-EMM) using the census data, the concentration of ambient PM_{2.5} and satellite-based concentrations simulated by a chemical transport model. The CS-EMM was found to perform better than the EMM. Among the components, although BC contributed only 6.4% of PM_{2.5}, it corresponded to a 46.7% increase in PM_{2.5}-associated deaths. This new approach will allow policy makers to target the toxic source of air pollution and design cost-effective control strategies.

Recently Apte *et al.*⁶⁶ estimated the population-weighted median decrement in life expectancy from PM_{2.5} (Δ LE). If PM_{2.5} concentrations worldwide were limited to the WHO air quality guideline concentration of 10 $\mu\text{g m}^{-3}$, global life expectancy would be on average 0.59 years longer. This benefit would be especially large in countries with the highest current levels of pollution, with approximately 0.8–1.4 years of additional survival in countries such as Egypt, India, Pakistan, Bangladesh, China, and Nigeria. In contrast, many high income countries already nearly meet the WHO guideline and would have much smaller LE benefits; for example, the Δ LE of 0.38 years for the USA is about 3 times lower than that of countries with higher PM_{2.5} concentrations. The result of this study illustrates that reducing air pollution at all levels of economic development could lead to substantial gains in life expectancy, a benefit similar in magnitude to that of eradicating lung and breast cancer.

Regional and global climate impacts

Cities are major emitters of greenhouse gases and contribute about 70% of the world's carbon footprint, according to a study by Moran *et al.*²²³ A relatively few number of urban areas account for a disproportionate share of the world's carbon footprint; the top 100 urban areas contain 11% of the world's population but drive 18% of the global carbon footprint. Population and affluence combine to drive footprints at a scale similar to those of cities in high-income countries, suggesting that concerted action taken by a limited number of city governments can have a disproportionate impact on global emissions. Although the estimated emissions are based only on household consumption, the findings demonstrate the critical impact city dwellers have on overall carbon emissions.

The contributions of megacities to global anthropogenic emissions have been estimated to be 12%, 7% and 4% for CO₂, CH₄ and N₂O respectively for the base year (2005), and are projected to increase significantly in 2050,²²⁴ while the contribution to BC, OC, CO, NO_x and SO₂ are relatively small (3 to 5%). With the exception of CO₂, all the estimated emissions are disproportionately smaller compared to the population. This could be due in part to some of the energy production taking place outside the cities. However, there is a large uncertainty in estimating the emissions and their geographic distributions; further research is needed to better understand the role of megacities in the Earth's environment.

Recently, short-lived climate forcers (SLCFs), also known as short-lived climate pollutants (SLCPs), have received increasing attention due to their relatively short residence time in the atmosphere and the multiple benefits of reducing them using existing available technologies.^{10,225–227} The major SLCFs with lifetimes under a few decades are BC (~days to weeks), CH₄ (~a decade), tropospheric O₃ (weeks to months) and some hydrofluorocarbons (HFCs, average 15 years). Due to their nature, these substances can be rapidly controlled, providing near-time climate benefits and air quality improvement. It is important to emphasize that despite these near-term benefits, reducing warming in the longer term will also require action now to reduce current and future CO₂ emissions.

Anthropogenic CH₄ is emitted into the atmosphere from ruminant livestock, rice cultivation, microbial waste processing (landfills, manure, and waste water), coal mining, and oil and natural gas systems. Methane has about 34 times the Global Warming Potential (GWP) of CO₂ (100 year horizon). Due to its shorter lifetime, it is even more effective over a 20 year time horizon. Methane is included as one of the six greenhouse gases (CO₂, CH₄, N₂O, HFCs, perfluorocarbons (PFCs), and sulfur hexafluoride (SF₆)) controlled under the Kyoto Protocol. Black carbon is emitted directly into the atmosphere in the form of PM_{2.5}; from diesel engines, industrial sources, residential coal and solid biofuels for cooking and heating, and agricultural and forest fires and open burning of solid waste. Black carbon could be the second largest contributor to global warming after CO₂.^{228–229} Although there are large uncertainties about the magnitude of BC climate impacts, it is very likely that mitigating sources with a high proportion of BC, such as diesel engines, will have positive climate benefits, in addition to significant improvement in public health. Many countries have included or are in the process of including BC reduction in their national determined contributions (NDC) to the United Nations Framework Convention for Climate Change (UNFCCC, <https://unfccc.int/>); Mexico was the first country to commit to reducing black carbon.

HFCs are synthetic chemicals produced for use as substitutes for ozone-depleting substances in refrigeration, air-conditioning, insulating foams, aerosols, solvents, and fire protection. However, most HFCs currently in use have high GWP. In 2016, the Parties to the Montreal Protocol agreed to the Kigali Amendment to phase down the production and consumption of HFCs (Ozone Secretariat, <https://ozone.unep.org>).

Many megacities are located along coastal areas, on floodplain and in dry areas, and are increasingly experiencing the effects of extreme weather and climate-related events, such as heat waves, hurricanes, heavy downpours, flooding, droughts, and more frequent and intense wildfires. Despite these risks, many cities have not yet incorporated climate action plans to existing urban planning due to a lack of resources to prepare for the extreme events as well as public awareness on climate change and its impacts. The continued urban expansion and infrastructure development provide an opportunity for cities to manage risks and develop strategies for climate mitigation and adaptation at the local level while at the same time improving the air quality. Organizations such as C40 Cities, a network of the world's megacities, is supporting cities to collaborate and share knowledge to drive measurable and sustainable action on climate change (<http://c40.org>).

Megacities not only influence the environment as large sources of pollutants, but also change the urban landscape and meteorological conditions by replacing vegetation and green areas with asphalt and concrete for roads, buildings and other structures to accommodate the growing population, creating the urban heat island effects.^{230,231} The temperature difference between the urban area and the rural surroundings is usually larger at night than during the day and most apparent when winds are weak. The increased demand for air conditioning to cool buildings and homes relies on power plants to meet the demand, leading to an increase in air pollution and greenhouse gas emissions. Higher air pollution, reduced night-time cooling and increased daytime temperature can adversely affect human health and comfort. Some megacities, such as Mexico City, are using green roofs and vertical gardens to help reduce urban heat island effects by shading building surfaces.

Impact of COVID-19 on megacities' air quality

Since the detection of the novel coronavirus SARS-CoV-2 in Wuhan, China in December 2019,^{232,233} the disease COVID-19, caused by the new virus, has spread rapidly to the rest of China and around the world. The WHO formally declared the COVID-19 outbreak a pandemic in March 2020 after the disease had spread to over 100 countries, and called on countries to take action to contain the disease.^{234,235} As of October 19, 2020, there were 40.6 M reported cases with 27.7 M recoveries and 1.12 M deaths from COVID-19.²³⁶ It is worth noting the limitations in compiling the COVID-19 statistics such as insufficient testing, unreported cases, asymptomatic cases, and the cause of death. The only place in the world that is still free of COVID-19 is the vast continent of Antarctica.²³⁷

Transmission of SARS-CoV-2 is considered to be predominantly by respiratory droplets produced when an infected person coughs, sneezes, or talks. Most public health guidelines have focused on social distancing measures, regular hand-washing, and other precautions to avoid large respiratory droplets.²³⁸ Several

studies have implicated airborne transmission of SARS-CoV-2 *via* respiratory microdroplets as a probable route for the spreading of the disease.^{239–244} Following an open letter from more than 200 scientists appealing to international and national bodies to consider the risk of airborne transmission,²⁴⁵ the WHO revised its guidelines and also recognized the threat of airborne transmission, particularly in inadequately ventilated indoor spaces.²⁴⁶

While national responses to the unprecedented COVID-19 pandemic have been varied, most countries have enacted strict measures to contain the spread of the disease to protect lives and preserve health systems, including lockdowns, quarantines, and travel restrictions, bringing global economic activity, particularly that of developing economies, to a major pause. Thus, in addition to the enormous human toll, the pandemic has led to a deep global recession.^{247,248} The stress from the pandemic and the resulting economic recession have negatively affected the mental health and well-being of people all over the world.²⁴⁹

The response of the scientific community to COVID-19 has resulted in the publication of a large volume of articles at extraordinary speed; with many studies made available in parallel to peer review. In light of the global health emergency of the pandemic, rapid publication ensures that new evidence is shared in a timely manner. However, this also poses a challenge, especially the publicly released preprints that have not been fully evaluated for scientific quality. As noted by Palayew *et al.*,²⁵⁰ it is important for the scientific community to take measures to safeguard the integrity of scientific evidence and avoid the risk of misinterpretation and misleading application in public policy.

The drastic measures implemented around the world to contain the spread of COVID-19 have led to significant reductions in the emissions of air pollutants, notably NO_x and CO₂ emissions from fossil fuel combustion. Many cities have seen dramatic improvement in air quality. Delhi, one of the most polluted megacities, experienced the clearest skies in years as pollution dropped to its lowest level in three decades (<https://earthobservatory.nasa.gov/images/146596/airborne-particle-levels-plummet-in-northern-india>).

The dramatic reduction in air pollution associated with COVID-19 lockdowns and other restrictions imposed by governments in cities around the world has provided an opportunity for atmospheric scientists to conduct a unique natural experiment to gain a better understanding of the complex interactions between emissions, meteorology, and atmospheric processes, as well as the efficiency of control measure surrogates (*e.g.*, reduced gasoline- and diesel-fueled vehicle traffic as a stand-in for large-scale zero emission vehicle deployment, reduced fossil fuel-derived electricity demand for renewable energy) that could lead to long-term emission reductions. Most of the studies have been conducted in China since the first stringent lockdown was enacted by the Chinese authorities in response to the initial outbreak of SARS-CoV-2 in Wuhan.^{251–259} A similar reduction in air pollution levels has been reported in other megacities, for example, Sao Paulo,^{260,261} Barcelona,²⁶² Rio de Janeiro,^{263,264} and Delhi.^{265,266} Sharma *et al.*²⁶⁷ analyzed the air quality of 22 cities in India, including Delhi, Kolkata, Mumbai and Chennai, and found that the concentrations of PM_{2.5} decreased while O₃ increased in most regions during the lockdown period. Jain and Sharma²⁶⁶ assessed the impact of nationwide lockdowns on the air quality in five megacities of India: Delhi, Mumbai, Chennai, Kolkata, and Bangalore. The study evaluated the criteria pollutants PM_{2.5}, PM₁₀, NO₂, CO and O₃ before and during the

lockdown period (March–April 2020) and compared them with air quality in the same period of the previous year. The results showed a statistically significant decline in all the pollutant concentrations except for O₃. The increase in O₃ levels during lockdown may be attributed to more favorable conditions for photochemical reactions due to increased solar insolation (due to the reduced primary pollutant levels) and a decrease in NO₂, which is consistent with the VOC-limited regime of India for O₃ production.²⁶⁸

While the COVID-19 lockdown improved air quality in many regions across the world,²⁶⁹ secondary air pollutant levels in some megacities has not improved due to the complex interplay among emissions, meteorology, and atmospheric chemistry, as illustrated in the following example.^{45,253} Le *et al.*²⁵³ examined the changes in emissions during the COVID-19 lockdown in four megacities in China: Wuhan, Shanghai, Guangzhou, and Beijing. Satellite and ground-based observations revealed up to 90% reductions of NO₂ and SO₂ concentrations. PM_{2.5} concentrations were also reduced in Wuhan, Shanghai and Guangzhou. In contrast, PM_{2.5} concentrations in Beijing–Tianjin–Hebei (BTH) increased substantially during lockdown; the region experienced several severe haze episodes. Ozone followed similar trends to that of PM_{2.5}. Synergistic observation analyses and model simulations show that anomalously high humidity during this period promoted aerosol heterogeneous chemistry, along with stagnant airflow and uninterrupted emissions from power plants and petrochemical facilities, contributing to severe haze formation. Due to nonlinear O₃ production chemistry, reduced NO_x resulted in O₃ enhancement in urban areas, increasing the atmospheric oxidizing capacity and facilitating secondary aerosol formation. The results of this study suggest that it is not sufficient to control emissions from vehicular traffic and manufacturing activities, a comprehensive regulation of precursor gases from all possible emission sources, such as power plants and heavy industries, must be considered for long-term improvement of air quality. The study also highlights the importance of meteorological factors when planning short-term stringent emission controls. Sun *et al.*²⁵⁷ analyzed the responses of primary and secondary aerosols to the changes in emissions during the outbreak in Beijing, along with the effects of emissions reductions during the Chinese New Year holiday of the previous years. The results showed substantial reductions in primary aerosols associated with traffic, cooking, and coal combustion emissions but much smaller decreases in secondary aerosols, suggesting the need for better understanding of the mechanism driving the chemical responses of secondary aerosols to emissions changes under complex meteorological conditions. Zhu *et al.* (DOI: 10.1039/D0FD00091D) conducted hourly measurements of PM_{2.5} and chemical speciation at an urban site in Shanghai before and during the restriction. They observed an overall reduction in PM_{2.5}, with a similar amount from OC, while nitrate accounts for most of the decrease. The reduction was due mostly from the decrease in vehicle traffic volume and fuel consumption; however, this was partially offset by an increase in secondary sources during lockdown, indicating the challenge of predicting PM_{2.5} improvement based on emissions reduction from primary sources.

As noted by the WHO,²⁰⁴ while more countries are taking action to improve the air quality, air pollution levels still remain dangerously high in many regions of the world. Several studies have found that air pollution substantially increases the risk of infection and the severity of COVID-19 symptoms.²⁷⁰ Furthermore, people

with pre-existing conditions from past air pollution exposure are more vulnerable to COVID-19. A study in the USA reported an increase in COVID-19 death rates in areas with higher long-term average PM_{2.5} pollution levels, emphasizing the importance of enforcing existing air pollution regulations during and after the COVID-19 crisis.²⁷¹ High levels of pollution have also been found to be a co-factor in the high lethality risk of COVID-19 disease in Northern Italy.²⁷²

An important consequence of the improvement in air quality during the COVID-19 pandemic is the health benefits in non-COVID-19 illnesses. Chen *et al.*²⁷³ reviewed the daily concentrations of NO₂ and PM_{2.5} in 367 Chinese cities, and estimated that the improved air quality led to substantial cases of avoided death from cardiovascular diseases.

While the unintended consequences of the COVID-19 crisis have brought some temporary non-COVID-19 related health benefits, the drastic measures of shutting down the global economy to clean the air are not sustainable. In fact, as some of the restrictions were lifted and the recovery began, satellite images from NASA show that much of the air pollution has returned (<https://earthobservatory.nasa.gov/images/146741/nitrogen-dioxide-levels-rebound-in-china>). Nevertheless, the unprecedented global pandemic demonstrates that it is possible to achieve better air quality by implementing emission reduction strategies that have been proven to be effective; furthermore, it raises public awareness about the benefits of cleaner air and calls for governments to take actions for the longer term.

Conclusions

Our current understanding of the characteristics of emission sources, their transport, chemical transformations, and their impact on human health, ecosystems, and the climate, have substantially improved in the last seventy years. However, important challenges remain that need to be addressed to substantially improve air quality in megacities and large urban complexes. This includes a better understanding of the atmospheric oxidation mechanisms, the impacts of changes in the emission profiles and atmospheric chemistry due to the implementation of advanced technology in vehicles and industrial processes; the formation and evolution of secondary particles, and the interactions between climate change and air quality. Regional and international scientific collaboration will be needed to address these issues through a combination of laboratory experiments, field measurements, and modeling studies.

Pollutant emissions from vehicles and industrial activities have reduced in many megacities by applying technology-forcing policies. However, establishing stringent regulations and their enforcement is more difficult in megacities with limited economic and human resources. International collaboration and cooperation are strongly encouraged, including strengthening local capacity in air quality monitoring and emissions inventory development, so that megacities confronting severe air pollution challenges will have the opportunity to learn from the experience of those cities that have successfully addressed them.

Conflicts of interest
