9, 11772Approximate models for the lattice thermal
conductivity of alloy thermoelectrics†Jonathan M. Skelton 

Thermoelectric generators (TEGs) convert waste heat to electricity and are a leading contender for improving energy efficiency at a range of scales. Ideal TE materials show a large Seebeck effect, high electrical conductivity, and low thermal conductivity. Alloying is a widely-used approach to engineering the heat transport in TEs, but despite many successes the underlying mechanisms are poorly understood. In previous work, first-principles modelling has successfully been used to study the thermodynamics of alloy formation and to investigate its effect on the electronic structure and phonon spectrum. However, it has so far only been possible to examine qualitatively the impact of alloying on the lattice thermal conductivity. In this work, we develop and test two new approaches to addressing this. The constant relaxation-time approximation (CRTA) assumes the primary effect of alloying is on the phonon group velocities, and allows the thermal conductivity to be calculated assuming a suitable constant lifetime. Alternatively, setting the three-phonon interaction strengths to a constant further enables an assessment of how changes to the phonon frequency spectrum influence the lifetimes. We test both approaches for the *Pnma* Sn(S_{1-x}Se_x) alloy system and are able to account for the substantially-reduced thermal conductivity measured in experiments.

1. Introduction

Reducing greenhouse gas emissions to mitigate rising global temperatures is among the most pressing scientific and technological challenges of our time. Efforts to phase out coal- and gas-fired power plants in favour of nuclear power and renewables mean an increasingly large proportion of emissions are due to industry and transportation.¹ Around two thirds of the energy consumed in these sectors is wasted as heat, and thus strategies to improve energy efficiency are an important part of the fight against climate change.² Thermoelectric generators (TEGs), which harness the Seebeck effect in a thermoelectric material to extract electrical energy from a temperature gradient, are among the most promising solutions. TEGs are widely used in the aerospace industry^{3,4} and have potential applications at scales from low-power Internet of Things (IoT) devices such as wireless sensors,^{5,6} to heat recovery in automobile engines,^{7,8} to augmenting the power output of nuclear reactors and repurposing decommissioned offshore oil platforms for geothermal power.¹

The performance of a thermoelectric material is typically expressed by the dimensionless figure of merit ZT :²

$$ZT = \frac{S^2 \sigma T}{\kappa_{\text{latt}} + \kappa_{\text{el}}} \quad (1)$$

Department of Chemistry, University of Manchester, Oxford Road,
Manchester M13 9PL, UK. E-mail: jonathan.skelton@manchester.ac.uk

† Electronic supplementary information (ESI) available. See DOI: 10.1039/d1tc02026a

where $S = -\frac{dV}{dT}$ is the Seebeck coefficient, σ is the electrical conductivity, $S^2 \sigma$ is the power factor, and κ_{latt} and κ_{el} are the lattice (phonon) and electronic components of the thermal conductivity κ . The electrical properties S , σ and κ_{el} are interdependent through the carrier concentration n such that the best ZT are typically found in doped semiconductors,² and the figure of merit can be tuned to a target operating temperature by chemical doping. In most high-performance TEs the electronic thermal conductivity is negligible and thus the κ_{latt} represents the bulk of the denominator. κ_{latt} is independent of n , and most high-performance TEs are materials with large intrinsic phonon anharmonicity and naturally low thermal conductivity. As for the electrical properties, the κ_{latt} can also be tuned to some extent by alloying,^{9–11} chemical doping¹² and hierarchical nanostructuring.¹³

Commercial TEGs are currently based on doped Bi₂Te₃, which shows a ZT of ~ 1 at room temperature corresponding to a 2–3% heat recovery.¹ PbTe is also a well-established standard for high-temperature TEGs,¹⁴ and endotaxial nanostructuring with SrTe has been shown to yield a $ZT > 2$ above 800 K.¹³ However, both materials are unsuitable for widespread application for a number of reasons, chief among them the low natural abundance of Te and the environmental toxicity of Pb.¹ This has prompted interest in a range of alternative material systems including oxides and other chalcogenides,¹⁵ half-Heuslers,¹⁶ Zintl compounds,¹⁷ and “phonon-glass electron-crystal” framework materials such as clathrates¹⁸ and skutterudites.¹⁹

Reports of a high-temperature ZT up to 2.6 in $\text{SnSe}^{20,21}$ have led to considerable interest in this system for thermoelectric applications. Despite its relatively simple structure and the low atomic masses of its constituent atoms, SnSe has unusually low thermal conductivity due to the strongly-anharmonic lattice dynamics associated with its high-temperature $Pnma$ -to- $Cmcm$ phase transition.^{22–24} However, despite a low κ_{latt} and similar anharmonic lattice dynamics,^{25,26} the isostructural SnS has much lower performance than SnSe .^{27,28} Various studies have therefore looked at $\text{Sn}(\text{S,Se})$ alloys and reported that the ZT is optimised for 80–85% Se content, due in part to a reduction in the κ_{latt} .^{9–11}

Since the terms in eqn (1) are amenable to calculation, first-principles modelling *e.g.* with density-functional theory has played an instrumental role in our current understanding of the material features that favour high thermoelectric performance. In particular, it has recently become feasible to accurately model lattice dynamics²⁹ and thermal transport,^{30–32} and insight from studying highly-anharmonic materials is helping to establish structure/property relationships for identifying new high-performance TEs and optimising the performance of existing materials.^{23,24,33,34} More recently, high-throughput modelling studies have been applied to identify potentially promising but previously-overlooked TEs from known materials.^{35–37} However, the inherent difficulty of modelling solid solutions means that comparatively little modelling work has been done to understand the impact of alloying on thermoelectric properties.

In our previous work, we developed first-principles models for four $\text{Sn}_n(\text{S}_{1-x}\text{Se}_x)_m$ solid solutions and investigated the effect of alloying on the optoelectronic properties.³⁸ This was subsequently extended to investigate the effect of alloying on the lattice dynamics of the $Pnma$ $\text{Sn}(\text{S}_{1-x}\text{Se}_x)$ system and to obtain qualitative insight into the impact of alloying on the thermal transport.³⁹ In this work, we extend these studies to quantify the thermal transport in the Se-rich $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ alloy. Using analysis techniques developed in our previous work,³⁴ we show that the difference in the κ_{latt} of the SnS and SnSe endpoints is a balance of reduced phonon group velocities and longer lifetimes. We find that $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ shows near-ideal mixing behaviour, with the mixing free energy dominated by entropy and a near-homogenous distribution of chalcogen atoms over the lattice sites. We investigate several models for calculating the thermal transport of the solid solution and demonstrate that alloying reduces the κ_{latt} by 40–60% compared to SnSe , due to a large reduction in the group velocity of the heat-carrying modes and a small secondary reduction in the phonon lifetimes. These results lay a foundation for future theoretical studies to improve our fundamental understanding of the impact of alloying on lattice thermal conductivity, and thereby design new high-performance alloys for future thermoelectric applications.

2. Methods

The starting point for this work was our previous calculations on the $Pnma$ $\text{Sn}(\text{S}_{1-x}\text{Se}_x)$ alloy system.^{38,39} The alloy model is

based on a 32-atom $2 \times 1 \times 2$ supercell of the eight-atom $Pnma$ unit cell, which has 2446 unique configurations in 17 compositions between the $x = 0$ (SnS) and $x = 1$ (SnSe) endpoints. A set of optimised structures and lattice energies were taken from the dataset published with ref. 38 (ref. 40) and new phonon and thermal-transport calculations were performed on the SnS and SnSe endpoints together with the 23 unique structures with composition $x = 0.8125$ (*i.e.* $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$). We note that this composition was not included in our previous study on the structural dynamics of the $Pnma$ $\text{Sn}(\text{S}_{1-x}\text{Se}_x)$ system.³⁹

Our calculations were performed using periodic pseudopotential plane-wave density-functional theory (DFT) as implemented in the Vienna *Ab initio* Simulation Package (VASP) code.⁴¹ The technical parameters used were as in our previous work.^{38,39} The PBEsol functional⁴² with the DFT-D3 dispersion correction⁴³ (*i.e.* PBE+D3) was used to model electron exchange and correlation. A plane-wave basis with a 600 eV kinetic-energy cutoff and a $4 \times 4 \times 4$ Monkhorst–Pack k -point sampling mesh⁴⁴ were used to represent the electronic structure of the alloy supercell. Projector augmented-wave (PAW) pseudopotentials^{45,46} were used to treat the core electrons, with the Sn 5s, 5p and 4d, the S 3s and 3p, and the Se 4s and 4p electrons in the valence region. The electronic wavefunctions were optimised to a tight tolerance of 10^{-8} eV on the total energy. The precision of the charge-density grids was set automatically to avoid aliasing errors, and a support grid with $8 \times$ the number of points was used to evaluate the augmentation charges. The PAW projection was performed in reciprocal space, and non-spherical contributions to the gradient corrections inside the PAW spheres were accounted for. These settings minimise the numerical noise in the forces, which is required to compute accurate force constants.

Lattice-dynamics and thermal-conductivity calculations were carried out using the Phonopy²⁹ and Phono3py³¹ codes with VASP as the force calculator. The second- and third-order interatomic force constants were computed using the supercell finite-displacement approach with step sizes of 10^{-2} and 3×10^{-2} Å respectively. $2 \times 2 \times 2$ supercells of the 32-atom alloy cells (256 atoms) were used to calculate the second-order interatomic force constants (IFCs), while the single alloy cells were used to compute the third-order IFCs. These are equivalent respectively to $4 \times 2 \times 4$ and $2 \times 1 \times 2$ supercells of the eight-atom $Pnma$ unit cell. Explicit testing showed that with this setup the calculated 300 K κ_{latt} of SnS and SnSe are both converged to within 6% of the values obtained using larger $3 \times 2 \times 3$ and $2 \times 1 \times 2$ second- and third-order expansions of the alloy cell, with 576 and 128 atoms. The k -point meshes used for the alloy cells were reduced proportionally for the supercell calculations.

Phonon density of states (DoS) curves were computed by interpolating the phonon frequencies onto uniform Γ -centered q -point meshes with $16 \times 8 \times 16$ and $8 \times 8 \times 8$ subdivisions for the primitive and alloy supercells respectively. The DoS curves were generated using a Gaussian smearing with a width $\sigma = 0.032$ THz, corresponding to a full-width at half-maximum of 2.5 cm^{-1} . To calculate the vibrational

contributions to the free energy, phonon frequencies were computed on denser $32 \times 16 \times 32$ or $16 \times 16 \times 16$ grids. Dispersions of *Pnma* SnS and SnSe were obtained by interpolating frequencies along a path passing through all the high-symmetry wavevectors in the *Pnma* Brillouin zone. Dispersions of the alloy model were computed by using the band-unfolding algorithm in ref. 47 to project the dispersions back to the *Pnma* primitive cell. To compute the thermal conductivity, the modal properties were computed on the same grids as used for the DoS, which were found by testing to be sufficient to converge the 300 K κ_{latt} of SnS and SnSe to within 1% of the values obtained using denser $24 \times 12 \times 24$ meshes with $\sim 3 \times$ as many mesh points. In these calculations, the linear tetrahedron method was used for the Brillouin zone integration.

3. Results and discussion

a. Structure and lattice dynamics of SnS and SnSe

The orthorhombic *Pnma* structure (Fig. 1) is the ground state phase of SnS and SnSe under ambient conditions.^{48,49} The Sn(II) oxidation state favours a distorted tetrahedral coordination environment in which each Sn atom forms three bonds to chalcogen atoms and the fourth coordination site is occupied by a stereochemically-active $5s^2$ lone pair of electrons. This results in a layered structure composed of 2D sheets held together with dispersion interactions facilitated by the Sn lone pairs projecting into the interlayer spacing. The layers stack along the long crystallographic axis (here the *b* direction), with stronger but anisotropic covalent bonding along the perpendicular in-plane (*a/c*) directions.

The optimised lattice constants of the two models are listed and compared to experimental neutron-scattering measurements⁵¹ in Table 1. As found in our previous work, the PBEsol+D3 functional gives a good description of the structure, with lattice constants and cell volumes within 0.4–2.7% and $\sim 4.5\%$ of the experimental measurements. The calculations parameters are technically athermal (0 K) values, whereas the experimental structures were collected at 295 K and are therefore expected to include some degree of thermal expansion, so we consider these discrepancies to be reasonable.

The calculated phonon dispersion and density of states (DoS) curves of SnS and SnSe are shown in Fig. 2. The eight atoms in the *Pnma* primitive cell result in $3n_a = 24$ phonon bands at each wavevector \mathbf{q} . The phonon spectra of SnS and SnSe can be partitioned into lower- and upper-frequency regions with equal numbers of modes, which the atom-projected DoS (PDOs) curves indicate can be assigned predominantly to motions of the Sn and chalcogen atoms respectively. These two groups of modes are separated by a so-called “phonon bandgap”, which is more prominent in SnS. Due to the heavier chalcogen and weaker chemical bonding, the phonon spectrum of SnSe spans a smaller frequency range of 0–6 THz compared to the 0–9 THz frequency range of the SnS spectrum. In both systems, the acoustic mode frequencies range from ~ 0 –1.5 THz and overlap with some of the optic modes in the low-frequency region of the spectrum. Finally, the comparatively

Fig. 1 Structure of *Pnma* SnS shown through the *ab* (a) and *bc* (b) planes, illustrating the layering along the *b* axis and the anisotropic chemical bonding along the perpendicular in-plane *a* and *c* axes. S and Sn atoms are shown in yellow and grey, respectively. These images were prepared using the VESTA software (ref. 50).

flat dispersion along the X–S and R–U segments of the dispersion, which correspond to the *b* direction in real space, highlights the weaker interlayer interactions along this direction.

b. Lattice thermal conductivity of SnS and SnSe

Using the single-mode relaxation-time approximation (RTA) solution to the phonon Boltzmann transport equations, the κ_{latt} is computed according to:³¹

$$\kappa_{\text{latt}} = \frac{1}{NV_0} \sum_{\lambda} \kappa_{\lambda} = \frac{1}{NV_0} \sum_{\lambda} C_{\lambda} v_{\lambda} \otimes v_{\lambda} \tau_{\lambda} \quad (2)$$

where the sum runs over phonon modes λ with wavevector \mathbf{q} and band index j , each of which have a modal thermal conductivity κ_{λ} , heat capacity C_{λ} , group velocity v_{λ} and lifetime τ_{λ} . V_0 is the unit-cell volume, and N is the number of phonon wavevectors \mathbf{q} included in the summation. In the RTA model, the C_{λ} and v_{λ} are calculated within the harmonic approximation, using the second-order interatomic force constants (IFCs), while the τ_{λ} are obtained perturbatively using the second- and third-order IFCs. We refer readers to ref. 31 for full details of the method.

Fig. 3a and b show the calculated κ_{latt} of SnS and SnSe as a function of temperature. The thermal transport of the orthorhombic *Pnma* structure is anisotropic, so we consider separately the three diagonal elements of the tensor κ_{xx} , κ_{yy} , and κ_{zz} , which correspond to transport along the *a*, *b* and *c* axes respectively, together with the average $\kappa_{\text{ave}} = \frac{1}{3} \text{Tr}[\kappa_{\text{latt}}] = \frac{1}{3} (\kappa_{xx} + \kappa_{yy} + \kappa_{zz})$. Calculated values at $T = 300$ K are listed in Table 2.

For SnS we calculate room-temperature conductivities of 1.88, 1.36 and 3.22 $\text{W m}^{-1} \text{K}^{-1}$ along the crystallographic *a*, *b* and *c* axes, giving an average value of $\kappa_{\text{ave}} = 2.15 \text{ W m}^{-1} \text{K}^{-1}$. In our model, the *b* and *c* axes correspond respectively to the

Table 1 Comparison of the calculated lattice parameters and cell volume of *Pnma* SnS and SnSe obtained in these calculations to the 295 K neutron-scattering measurements in ref. 51. The % difference between the calculated and measured values are given in parentheses

	Expt.				Calc. (this work)			
	<i>a</i> [Å]	<i>b</i> [Å]	<i>c</i> [Å]	<i>V</i> [Å ³]	<i>a</i> [Å]	<i>b</i> [Å]	<i>c</i> [Å]	<i>V</i> [Å ³]
SnS	4.336	11.143	3.971	192	4.218 (−2.7%)	10.974 (−1.5%)	3.957 (−0.35%)	183 (−4.5%)
SnSe	4.445	11.501	4.153	212	4.342 (−2.3%)	11.338 (−1.4%)	4.121 (−0.77%)	203 (−4.4%)

layering direction and the direction of strongest in-plane bonding (*cf.* Fig. 1), and thus have the smallest and largest κ_{latt} . We note that these values are considerably higher than in our previous calculations,⁵² where we obtained values of $\kappa_{xx} = 0.74$, $\kappa_{yy} = 0.36$, $\kappa_{zz} = 1.10$ and $\kappa_{\text{ave}} = 0.73 \text{ W m}^{-1} \text{ K}^{-1}$. This discrepancy can be attributed to differences in the supercells used to compute the second- and third-order force constants, to the inclusion of the DFT-D3 dispersion correction in the present calculations, and also to some convergence issues in the previous calculations. From a technical perspective, we expect the present results to be more accurate.

For SnSe we calculate room-temperature conductivities of 1.62, 0.94 and 2.16 $\text{W m}^{-1} \text{ K}^{-1}$ along the *a*, *b* and *c* axes and an average of 1.58 $\text{W m}^{-1} \text{ K}^{-1}$. As for SnS, the κ_{latt} is strongly anisotropic with the smallest and largest components along the *b* and *c* axes respectively. These are also larger than, albeit similar to, the values we obtained in our previous calculations,²³ *viz.* 1.44, 0.53 and 1.88 $\text{W m}^{-1} \text{ K}^{-1}$ along the three axes and an average of 1.28 $\text{W m}^{-1} \text{ K}^{-1}$. This discrepancy can again be attributed to differences in the technical parameters used in the two sets of calculations. The dispersion correction reduces the lattice constants and cell volume by ~ 0.7 and 2.1%, respectively, and is likely to result in stronger

non-bonded interactions along the *b* axis where the discrepancy with previous calculations is largest. As for SnS, we again expect the present results to be technically more accurate.

Ref. 20 reports single-crystal κ_{latt} measurements on SnSe of 0.67, 0.46 and 0.70 $\text{W m}^{-1} \text{ K}^{-1}$ along the equivalent directions to the *a*, *b* and *c* axes in our calculations. It was subsequently noted however that the density of these crystals was $\sim 10\%$ lower than the expected theoretical value.⁵³ The aggregated room-temperature κ_{latt} measurements in ref. 53 span a range of ~ 0.7 – $1.4 \text{ W m}^{-1} \text{ K}^{-1}$ along the in-plane *a* and *c* directions and ~ 0.5 – $0.9 \text{ W m}^{-1} \text{ K}^{-1}$ along the layered *b* axis. This $\sim 2 \times$ spread in measured results clearly highlights the sensitivity of the κ_{latt} to the material preparation and handling. However, the upper range of these values are reasonably comparable to our calculations. Possible origins of the discrepancy between different measurements are a typical 15–20% error in measurements of the thermal diffusivity,²¹ the presence of vacancies and interstitials,⁵³ microcracks caused by the high-temperature phase transition,⁵⁴ and oxidation at high temperatures.⁵⁵ It is also likely that the RTA calculations we perform here will overestimate the κ_{latt} to some extent due to a neglect of thermal expansion at finite temperature, higher-order (*e.g.* 4th order) phonon-phonon interactions,⁵⁶ and non-perturbative anharmonicity associated with the high-temperature phase transition.^{22–24}

We were unable to find any reports of single-crystal κ_{latt} measurements on SnS. Ref. 10,27 report polycrystalline values of ~ 1.25 and 1.15–1.30 $\text{W m}^{-1} \text{ K}^{-1}$ at 300 K, which are again lower than but reasonably comparable to our calculations. It is of course likely that the two sets of experimental measurements would be subject to the same issues as measurements on SnSe. In the same vein, SnS also shows a high-temperature *Pnma* \rightarrow *Cmcm* phase transition and the same non-perturbative anharmonicity as SnSe,^{26,48} which may result in our calculations overestimating the κ_{latt} .

The effect of grain boundaries in polycrystalline samples (or present as defects in single crystals) can be investigated using a simple boundary-scattering model to limit the mean-free paths of the long-wavelength phonon modes (see ESI†). We find that the lower range of experimental values on SnSe can be recovered by imposing a boundary limit of ~ 10 nm, while a κ_{ave} comparable to measurements on SnS can be recovered with a limit of around 10–20 nm.

To investigate the difference in the κ_{latt} of SnS and SnSe, we used the constant relaxation-time approximation (CRTA) model developed in ref. 34 in which the τ_{λ} are replaced with a constant τ^{CRTA} such that the κ_{latt} can be written:

$$\kappa_{\text{latt}} \approx \tau^{\text{CRTA}} \times \frac{1}{NV_0} \sum_{\lambda} \frac{\kappa_{\lambda}}{\tau_{\lambda}} = \tau^{\text{CRTA}} \times \frac{1}{NV_0} \sum_{\lambda} C_{\lambda} \mathbf{v}_{\lambda} \otimes \mathbf{v}_{\lambda} \quad (3)$$

Fig. 3 Calculated thermal conductivity of SnS (left) and SnSe (right) as a function of temperature analysed using the constant relaxation time approximation (CRTA) model defined in eqn (3) and (4). (a) and (b) Thermal conductivity κ_{latt} . (c) and (d) Harmonic component $\kappa_{\text{latt}}/\tau^{\text{CRTA}}$. (e) and (f) Lifetime component τ^{CRTA} . On each subplot, the tensor components along the a (xx, blue), b (yy, red) and c (zz, green) directions are shown together with the average $\frac{1}{3}(xx + yy + zz)$ (ave, black).

We further modify eqn (3) to replace the scalar τ^{CRTA} with a tensor so that individual components of κ_{latt} are computed as follows:

$$\begin{aligned} \kappa_{\text{latt}}(\alpha\beta) &\approx \tau^{\text{CRTA}}(\alpha\beta) \times \frac{1}{NV_0} \sum_{\lambda} \frac{\kappa_{\lambda}(\alpha\beta)}{\tau_{\lambda}} \\ &= \tau^{\text{CRTA}}(\alpha\beta) \times \frac{1}{NV_0} \sum_{\lambda} C_{\lambda} v_{\lambda}(\alpha) v_{\lambda}(\beta) \end{aligned} \quad (4)$$

where the indices α and β label the Cartesian x , y and z directions. While this formulation is perhaps counter-intuitive since the τ_{λ} in

eqn (2) are scalars, in an anisotropic system such as *Pnma* SnS/SnSe we might expect some variation in the lifetimes of modes responsible for transport along different directions.

The temperature dependence of the harmonic component $\kappa_{\text{latt}}/\tau^{\text{CRTA}}$ on the right-hand side of eqn (3) and (4) and the lifetime component τ^{CRTA} are shown in Fig. 3c, d and e, f respectively. This analysis clearly shows that the harmonic term is much smaller in SnSe than SnS, which can be attributed to the weaker bonding and heavier chalcogen and hence lower group velocities. Interestingly, this is offset by longer τ^{CRTA} in SnSe. Comparing the values at $T = 300$ K (Table 2) shows the

Table 2 Analysis of the 300 K lattice thermal conductivity κ_{latt} of SnS and SnSe. Rows 1–3 compare the κ_{latt} components and the $\kappa_{\text{latt}}/\tau^{\text{CRTA}}$ and τ^{CRTA} values defined in eqn (3) and (4). Row 4 lists the (scalar) phonon lifetimes $\bar{\tau}_\lambda$ averaged over all modes for comparison to the τ^{CRTA} . Row 5 lists the average phonon–phonon interactions strengths \bar{P} that reproduce the κ_{latt} components when used with the model in eqn (8), and Row 6 lists the interaction strengths \bar{P}_λ averaged over all modes, which are again scalar values

	SnS				SnSe			
	xx	yy	zz	ave	xx	yy	zz	ave
κ_{latt} [$\text{W m}^{-1} \text{K}^{-1}$]	1.88	1.36	3.22	2.15	1.62	0.94	2.16	1.58
$\kappa_{\text{latt}}/\tau^{\text{CRTA}}$ [$\text{W m}^{-1} \text{K}^{-1} \text{ps}^{-1}$]	0.786	0.442	0.925	0.718	0.415	0.212	0.490	0.372
τ^{CRTA} [ps]	2.40	3.07	3.48	3.00	3.91	4.42	4.42	4.23

\bar{P} [10^{-11}eV^2]	4.87	4.60	3.99	4.37	1.92	1.98	1.85	1.90
\bar{P}_λ [10^{-11}eV^2]	24.6				9.81			

harmonic terms along the three principal directions are reduced by 47–52% in SnSe while the lifetimes are increased by 27–63%, which leads to an overall decrease of 14–33% in the κ_{latt} components. We made a similar qualitative conclusion in our previous work³⁹ based on data from previous calculations.^{23,52} Although the longer τ^{CRTA} in SnSe indicate it to be less anharmonic than SnS, the τ^{CRTA} in both are on the order of ps and are very short in comparison to other systems – for example, a similar CRTA analysis on CoSb₃ yields an order-of-magnitude larger τ^{CRTA} of 36.6 ps.³⁴ Fig. 3c and d also show that the anisotropy in the thermal transport is again largely due to differences in the harmonic term, as there is a 2.1–2.3 \times variation in the $\kappa_{\text{latt}}/\tau^{\text{CRTA}}$ but a much smaller 1.1–1.5 \times variation in the τ^{CRTA} . This confirms that the anisotropy in the chemical bonding has a large effect on the group velocities and hence the thermal transport.

We note that a similar constant relaxation-time model is often used to model the electronic transport properties of thermoelectric materials (as implemented in *e.g.* the BoltzTraP code⁵⁷), but there are few if any examples of its application to modelling lattice thermal conductivity. However, a key difference is that whereas the relaxation time in electronic transport calculations is often assumed to be independent of temperature and energy, in the present model the τ^{CRTA} are independent of energy (*i.e.* phonon frequency) but not temperature. Comparison of Fig. 3a, b and e, f clearly shows that the temperature dependence of the κ_{latt} is strongly linked to the temperature dependence of the phonon lifetimes, particularly above the Dulong–Petit limit where the C_λ and hence the $\kappa_{\text{latt}}/\tau^{\text{CRTA}}$ saturate, and thus a temperature-dependent τ^{CRTA} is required for this model to be reasonable.

While the origin of the differences in the harmonic components $\kappa_{\text{latt}}/\tau^{\text{CRTA}}$ can be understood by the differences in chalcogen mass and chemical bonding, the origin of the longer phonon lifetimes in SnSe require further investigation. As outlined in ref. 31, the lifetimes are computed from the inverse of the phonon linewidths Γ_λ according to:

$$\tau_\lambda = \frac{1}{2\Gamma_\lambda} \quad (5)$$

The Γ_λ are computed as a sum of contributions from three-phonon interactions using the expression:

$$\begin{aligned} \Gamma_\lambda = & \frac{18\pi}{\hbar^2} \sum_{\lambda'\lambda''} |\Phi_{-\lambda\lambda'\lambda''}|^2 \times \{ (n_{\lambda'} + n_{\lambda''} + 1) \delta(\omega_\lambda - \omega_{\lambda'} - \omega_{\lambda''}) \\ & + (n_{\lambda'} - n_{\lambda''}) [\delta(\omega_\lambda + \omega_{\lambda'} - \omega_{\lambda''}) - \delta(\omega_\lambda - \omega_{\lambda'} + \omega_{\lambda''})] \} \end{aligned} \quad (6)$$

where $\Phi_{\lambda\lambda'\lambda''}$ are the three-phonon interaction strengths, which enforce conservation of (crystal) momentum, the δ functions in the summand enforce conservation of energy, and n_λ are the phonon occupation numbers given by the Bose–Einstein distribution:

$$n_\lambda = \frac{1}{\exp(\hbar\omega_\lambda/k_B T) - 1} \quad (7)$$

Following ref. 31, an approximate linewidth Γ_λ can be written as:

$$\tilde{\Gamma}_\lambda = \frac{18\pi}{\hbar^2} P_\lambda N_2(\mathbf{q}, \omega_\lambda) \quad (8)$$

where P_λ is the averaged phonon–phonon interaction strength for mode λ and $N_2(\mathbf{q}, \omega)$ is a weighted two-phonon joint density of states (w-JDoS) that counts the number of energy-conserving scattering pathways available to a phonon with wavevector \mathbf{q} and frequency ω :

$$P_\lambda = \frac{1}{(3n_a)^2} \sum_{\lambda'\lambda''} |\Phi_{-\lambda\lambda'\lambda''}|^2 \quad (9)$$

$$N_2(\mathbf{q}, \omega) = N_2^{(1)}(\mathbf{q}, \omega) + N_2^{(2)}(\mathbf{q}, \omega) \quad (10)$$

The $N_2(\mathbf{q}, \omega)$ is the sum of separate functions for collision (Type 1) and decay (Type 2) events:

$$\begin{aligned} N_2^{(1)}(\mathbf{q}, \omega) = & \frac{1}{N} \sum_{\lambda'\lambda''} \Delta(-\mathbf{q} + \mathbf{q}_{\lambda'} + \mathbf{q}_{\lambda''}) \\ & \times (n_{\lambda'} - n_{\lambda''}) [\delta(\omega + \omega_{\lambda'} - \omega_{\lambda''}) - \delta(\omega - \omega_{\lambda'} + \omega_{\lambda''})] \end{aligned} \quad (11)$$

$$N_2^{(2)}(\mathbf{q}, \omega) = \frac{1}{N} \sum_{\lambda'\lambda''} \Delta(-\mathbf{q} + \mathbf{q}_{\lambda'} + \mathbf{q}_{\lambda''}) \quad (12)$$

$$\times (n_{\lambda'} + n_{\lambda''} + 1) \delta(\omega - \omega_{\lambda'} - \omega_{\lambda''})$$

Collisions correspond to phonon absorption through the coalescence of two modes, *i.e.* $\lambda + \lambda' \rightarrow \lambda''$ or $\lambda + \lambda'' \rightarrow \lambda'$, while decay processes correspond to emission, *i.e.* $\lambda \rightarrow \lambda' + \lambda''$. For comparing between materials it is convenient to average the $N_2(\mathbf{q}, \omega)$ over wavevectors to obtain a function of frequency only, which we denote $\bar{N}_2(\omega)$ with corresponding components $\bar{N}_2^{(1)}(\omega)$ and $\bar{N}_2^{(2)}(\omega)$:

$$\begin{aligned} \bar{N}_2(\omega) = & \bar{N}_2^{(1)}(\omega) + \bar{N}_2^{(2)}(\omega) \\ = & \frac{1}{N} \sum_{\mathbf{q}} N_2^{(1)}(\mathbf{q}, \omega) + \frac{1}{N} \sum_{\mathbf{q}} N_2^{(2)}(\mathbf{q}, \omega) \end{aligned} \quad (13)$$

Fig. 4a, b and c, d compare respectively the $\bar{N}_2(\omega)$ and spectra of P_λ for SnS and SnSe. At frequencies below ~ 2 THz

in both systems there are very few decay (emission) pathways and the phonon scattering is dominated by collisions (absorption). At higher frequencies, decay pathways become available and become the dominant scattering mechanism from around 3 THz. Across most of the frequency spectrum the $\bar{N}_2(\omega)$ are 1.5–2× higher in SnSe than in SnS, indicating that the smaller range of frequencies in the former leads to a higher density of energy-conserving scattering pathways. The P_λ of SnS and SnSe

both form two clear groups, spanning a range of 10^{-11} – 10^{-10} eV² at low frequency and 10^{-10} – 10^{-9} eV² at high frequency, indicating that the high-frequency modes interact an order of magnitude more strongly with other phonons than the low-frequency modes. This analysis also clearly shows that the phonon–phonon interaction strengths for both groups of modes are considerably weaker in SnSe than in SnS. Given the longer τ^{CRTA} in SnSe, the weaker P_λ therefore counteract the

Fig. 4 Analysis of the phonon lifetimes/linewidths in SnS (left) and SnSe (right). (a) and (b) Two-phonon weighted joint density-of-states (w-JDoS) functions $\bar{N}_2(\omega)$ defined in eqn (13). (c) and (d) Spectra of modal phonon–phonon interaction strengths P_λ defined in eqn (9). The constant phonon–phonon interaction strengths \tilde{P} that reproduce the average thermal conductivity κ_{ave} at $T = 300$ K are indicated by dashed black lines. (e) and (f) Dependence of the principal thermal conductivity components $\kappa_{xx}/\kappa_{yy}/\kappa_{zz}$ and κ_{ave} at 300 K on the averaged phonon–phonon interaction strength \tilde{P} . The values of \tilde{P} that reproduce the calculated κ_{xx} , κ_{yy} and κ_{zz} and κ_{ave} are indicated by dashed lines.

larger $\bar{N}_2(\omega)$ and lead to longer lifetimes, at least for the dominant heat-carrying modes. This analysis is again in line with our previous work.³⁹

We previously demonstrated that finding a constant value \bar{P} such that replacing the P_λ in eqn (8) reproduces the κ_{latt} provides a useful metric for comparing the relative phonon-phonon interaction strengths in different materials.³⁴ From the relationships in eqn (2), (5) and (8), the κ_{latt} is inversely proportional to \bar{P} , and a suitable value can be estimated from a simple linear fit (Fig. 4e, f and Table 2). For SnS and SnSe, we obtain values of $3.99\text{--}4.87 \times 10^{11}$ and $1.85\text{--}1.98 \times 10^{11}$ eV², respectively. These are heavily weighted toward the P_λ of the lower-frequency modes (cf. Fig. 4c and d), which can be understood from the fact that the majority of the heat transport in semiconductors is typically through acoustic and low-lying optic modes. This analysis thus reaffirms that the phonon-phonon interactions in SnSe are weaker than in SnS.

Overall, our calculations indicate that the κ_{latt} of SnS and SnSe are similar and both ultra-low. A comparison of the room-temperature κ_{latt} of SnS and SnSe using the CRTA model shows that SnSe has lower group velocities but longer lifetimes than SnS, resulting in an overall decrease in the thermal transport of 14, 31 and 33% along the *a*, *b* and *c* directions, respectively. Considering the w-JDoS and P_λ/\bar{P} we can further attribute the differences in lifetimes to the larger number of energy-conserving scattering pathways enabled by the smaller range of phonon frequencies in the SnSe spectrum being counteracted by weaker phonon-phonon interaction strengths. The fact that SnS and SnSe have similar κ_{latt} and that the difference arises from a balance of two opposing effects means it would not be entirely unexpected if the qualitative ordering was sensitive to the theoretical methodology employed. Certainly, the spread in experimental measurements highlighted for SnSe in ref. 53 suggests that it is difficult to make a conclusive ordering on the basis of experiments alone.

c. Statistical thermodynamics of the Sn(S_{0.1875}Se_{0.8125}) solid solution

We previously developed a structural model for the *Pnma* Sn(S_{1-x}Se_x) alloy following the approach in ref. 58.³⁸ The model comprises a set of 17 compositions between the SnS (*x* = 0) and SnSe (*x* = 1) endpoints, where each composition is a set of n_x symmetry-inequivalent chalcogen arrangements in a 32-atom $2 \times 1 \times 2$ supercell expansion of the eight-atom *Pnma* unit cell. In this work, we examine the Sn(S_{0.1875}Se_{0.8125}) composition (i.e. *x* = 0.8125), for which there are $n_x = 23$ independent configurations. This is a manageable number for performing accurate phonon calculations, and the composition is within the 80–85% Se range where the κ_{latt} is reported to reach a minimum.^{9–11}

For each of the structures we calculate a lattice internal energy U^{latt} , which we equate to the DFT total energy *E*, and a temperature-dependent constant-volume (Helmholtz) free energy *A*(*T*) including contributions from the phonons:

$$A_i(T) = U_i^{\text{latt}} + A_i^{\text{vib}}(T) = U_i^{\text{latt}} + U_i^{\text{vib}}(T) - TS_i^{\text{vib}}(T) \quad (14)$$

where $A^{\text{vib}}(T) = U^{\text{vib}}(T) - TS^{\text{vib}}(T)$ is the vibrational contribution to the Helmholtz energy and U^{vib} and S^{vib} are the vibrational internal energy and entropy respectively. A^{vib} is computed directly from the vibrational partition function $Z^{\text{vib}}(T)$ using the bridge relation from statistical mechanics:

$$Z^{\text{vib}}(T) = \prod_{\lambda} \frac{\exp[-\hbar\omega_{\lambda}/2k_{\text{B}}T]}{1 - \exp[-\hbar\omega_{\lambda}/k_{\text{B}}T]} \quad (15)$$

$$A^{\text{vib}}(T) = -\frac{1}{N}k_{\text{B}}T \ln Z^{\text{vib}}(T) \quad (16)$$

where as in eqn (2) the product runs over phonon modes λ with wavevector **q** and band index *j*, *N* is the number of phonon wavevectors **q** included in the product, and k_{B} is the Boltzmann constant.

Given the lattice internal or Helmholtz energies for each of the n_x structures for composition *x*, analogous thermodynamic partition functions *Z*(*x*; *T*) and free energies *A*(*x*; *T*) can be computed as:

$$Z(x; T) = \sum_{i=1}^{n_x} g_i \exp[-U_i^{\text{latt}}/k_{\text{B}}T] \quad (17)$$

$$A(x; T) = -k_{\text{B}}T \ln Z(x; T) = \bar{U}^{\text{latt}}(x; T) - TS^{\text{conf}}(x; T) \quad (18)$$

$$Z(x; T) = \sum_{i=1}^{n_x} g_i \exp[-A_i/k_{\text{B}}T] \quad (19)$$

$$A(x; T) = -k_{\text{B}}T \ln Z(x; T) = \bar{A}(x; T) - TS^{\text{conf}}(x; T) = \bar{U}^{\text{latt}}(x; T) + \bar{U}^{\text{vib}}(x; T) - T[\bar{S}^{\text{vib}}(x; T) + S^{\text{conf}}(x; T)] \quad (20)$$

In these expressions, the degeneracies g_i are the number of alternative chalcogen arrangements that are equivalent under the symmetry operations of the parent *Pnma* structure, $\bar{U}^{\text{latt}}/\bar{A}$ are the weighted average lattice/Helmholtz energies of the structures for the composition *x*, and S^{conf} is the vibrational entropy.

Once the *A*(*x*; *T*) has been calculated, a mixing free energy $A_{\text{mix}}(x; T)$ can be computed with reference to the free energies of the endpoints $A(x = 0; T)$ and $A(x = 1; T)$ according to:

$$A_{\text{mix}}(x; T) = A(x; T) - [(1 - x)A(x = 0; T) + xA(x = 1; T)] \quad (21)$$

Given a *Z*(*x*; *T*), the occurrence probabilities P_i of each of the n_x structures can also be computed from:

$$P_i(x; T) = \frac{1}{Z(x; T)} g_i \exp[-U_i^{\text{latt}}/k_{\text{B}}T] \quad (22)$$

$$P_i(x; T) = \frac{1}{Z(x; T)} g_i \exp[-A_i/k_{\text{B}}T] \quad (23)$$

These weights can then be used to compute the thermodynamic average \bar{X} of a general physical property *X* as:

$$\bar{X}(x; T) = \sum_{i=1}^{n_x} P_i(x; T) \times X_i \quad (24)$$

For example, the \bar{U}^{latt} and \bar{A} in eqn (18) and (19) are computed by averaging the U_i^{latt} and A_i using eqn 24 and the

appropriate P_i from eqn (22) or (23). It is typically assumed that the distribution of configurations is kinetically trapped when the alloy is formed, and the P_i are therefore computed at the formation temperature T_F .⁵⁸ In our previous work, we used a value of $T_F = 900$ K.^{38,39}

We previously compared the $A_{\text{mix}}(x;T)$ and $P_i(x;T)$ obtained using the U_i^{latt} and $A_i(T)$ for several compositions of the $\text{Sn}(\text{S}_{1-x}\text{Se}_x)$ alloy and found that differences in phonon frequencies both disfavoured the mixing (*i.e.* predicted more positive A_{mix}) and resulted in substantially different distributions of occurrence probabilities.³⁹ However, the A_i^{vib} were determined from force constants obtained in the 32-atom alloy supercells, as the number of configurations made this a necessary approximation. Given that a larger 256-atom supercell expansion is required to converge the κ_{latt} of the endpoints, we investigated the extent to which the supercell used to compute the force constants influences the free energies.

Fig. 5a compares the calculated mixing energy of $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ as a function of temperature based on $A(x;T)$ computed from the lattice energies and Helmholtz energies with phonon frequencies obtained using the 32-atom alloy supercells and 256-atom expansions. We find that the Helmholtz energies calculated using the larger supercell yield very similar mixing energies to the lattice energies, whereas the Helmholtz energies calculated using the alloy supercell result in a very different temperature dependence.

For the SnS and SnSe endpoints, calculations using the 32-atom alloy supercell underestimate the 900 K A^{vib} by 0.3 and 0.15 $\text{kJ mol}^{-1} \text{atom}^{-1}$, respectively, compared to larger 256-atom supercells. Among the 23 configurations in the alloy model, the range of U_i^{latt} is 0.07 $\text{kJ mol}^{-1} \text{atom}^{-1}$, whereas the ranges in the A_i^{vib} computed using the small and large supercell are 1.13 and 0.06 $\text{kJ mol}^{-1} \text{atom}^{-1}$ respectively. This suggests the error associated with the small supercell is even larger for structures in the mixed-composition model.

We also compared the individual contributions to the mixing free energy at $T_F = 900$ K from the lattice and vibrational

internal energy, $U_{\text{mix}}^{\text{latt}}/U_{\text{mix}}^{\text{vib}}$, and from the configurational and vibrational entropy, $S_{\text{mix}}^{\text{config}}/S_{\text{mix}}^{\text{vib}}$ (Table 3). Using the U_i^{latt} , the $U_{\text{mix}}^{\text{latt}}$ and $-TS_{\text{mix}}^{\text{config}}$ terms are 0.28 and -1.48 $\text{kJ mol}^{-1} \text{atom}^{-1}$, respectively, and the small increase in internal energy is compensated by the much larger configurational entropy to produce an overall negative A_{mix} of -1.20 $\text{kJ mol}^{-1} \text{atom}^{-1}$. Using the A_i from the smaller alloy supercell predicts that differences in the $U_{\text{mix}}^{\text{vib}}$ and $S_{\text{mix}}^{\text{vib}}$ combine to disfavour the mixing by 0.64 $\text{kJ mol}^{-1} \text{atom}^{-1}$, while the contribution from configurational entropy is also reduced by around 13% presumably due to the more skewed distribution of P_i in Fig. 5b. Together, these result in a much less negative predicted A_{mix} of -0.37 $\text{kJ mol}^{-1} \text{atom}^{-1}$. On the other hand, when the A_i are computed using the larger phonon supercell expansions, the P_i and thus the $S_{\text{mix}}^{\text{config}}$ are very close to the result obtained using the lattice energies, and the vibrational contributions to the mixing are very small, with differences in vibrational entropy favouring mixing by an additional 0.06 $\text{kJ mol}^{-1} \text{atom}^{-1}$.

The clear implication of this result is that the force constants obtained using the 32-atom alloy supercell do not yield sufficiently accurate frequencies to compute accurate Helmholtz energies. As a result, our previous conclusion that differences in vibrational frequencies disfavour the mixing and skew the distribution of occurrence probabilities in the *Pnma* $\text{Sn}(\text{S}_{1-x}\text{Se}_x)$ alloy may not be correct. Indeed, the present finding suggests that it is not necessary to consider the phonon contributions to the free energy in order to obtain a reasonable thermodynamic model for this system. However, we previously found that the full range of $\text{Sn}_m(\text{S}_{1-x}\text{Se}_x)_n$ systems form near-ideal solid solutions, based on alloy models using the lattice energies, and it is entirely possible the lattice dynamics would have a more significant impact on the thermodynamics of less ideal systems. Either way, our findings clearly highlight the need carefully to check the convergence of the free energies with respect to the accuracy of the force constants.

Fig. 5 Thermodynamics of the $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ solid solution: (a) mixing free energy A_{mix} as a function of temperature computed from eqn (21); and (b) cumulative distribution of occurrence probabilities P_n as a function of the percentage of structures in the alloy model at a formation temperature $T_F = 900$ K computed using eqn (22) and (23). Each plot compares calculations using the lattice energies U_i^{latt} and the constant-volume (Helmholtz) free energies $A_i(T)$, which include vibrational contributions to the internal energy and entropy calculated using force constants obtained with the 32-atom alloy supercells and 256-atom supercell expansions.

Table 3 Comparison of the calculated mixing free energy A_{mix} of $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ at $T_{\text{F}} = 900$ K obtained using the lattice energies U_i^{latt} and the constant-volume (Helmholtz) free energies A_i calculated with force constants obtained in the 32-atom alloy cells and 256-atom supercell expansions. Also shown are the separate contributions to A_{mix} from the lattice and vibrational internal energy, $U_{\text{mix}}^{\text{latt}}/U_{\text{mix}}^{\text{vib}}$, and the configurational and vibrational entropy, $S_{\text{mix}}^{\text{config}}/S_{\text{mix}}^{\text{vib}}$

[kJ mol ⁻¹ atom ⁻¹]	U_i^{latt}	A_i

d. Thermal conductivity of $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$

We now consider the thermal conductivity of the $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ alloy model. Fig. 6 shows the unfolded dispersion and atom-projected DoS of $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$, computed as a thermodynamic average using eqn (24) at a formation temperature $T_{\text{F}} = 900$ K.

The PDOS is similar to that of SnSe but with an additional feature above ~6 THz comprising modes predominantly associated with S vibrations. The lower-frequency part of the unfolded dispersion, which consists predominantly of Sn-based modes, retains considerable structure, albeit with some smearing, suggesting that the Sn sublattice is largely unaffected by the alloying. On the other hand, the mid-frequency Se-based bands show considerably more broadening, and the dispersion of the high-frequency S bands has very little structure. Since the low-frequency modes are the dominant heat carriers, and the corresponding part of the dispersion remains similar to SnSe, it is not clear from this analysis to what extent the alloying will affect the thermal conductivity through changes to the group velocities.

We also note that, unlike in our previous work, we see no evidence of imaginary modes in the unfolded dispersion, which we also confirmed by inspecting of the phonon frequencies at the commensurate wavevectors for each of the alloy configurations. This again highlights the importance of using a sufficiently large supercell for computing the force constants.

Since $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ is close to the SnSe endpoint, a very simple reference point for the κ_{latt} is to use the SnSe force constants and adjust the mass of the chalcogen atoms to a weighted average:

$$m_{\text{ave}} = \sum_i a_i \times m_i \quad (25)$$

where a_i are the site occupations and $m_i = m_{\text{S}}/m_{\text{Se}}$ are the masses of the occupying atoms. The change in mass affects the $C_{\lambda}^{\nu}/\nu_{\lambda}$ in eqn (2) directly, and also indirectly affects the τ_{λ} via the three-phonon interaction strengths and conservation of energy expression in eqn (6). In addition, the increased mass variance at the chalcogen site also affects the κ_{latt} , and this can

be modelled as an isotope effect using the approach in ref. 59 and a mass variance parameter calculated as:

$$m_{\text{var}} = \sum_i a_i \times \left(1 - \frac{m_i}{m_{\text{ave}}}\right)^2 \quad (26)$$

We previously used this technique to investigate the thermal conductivity of the $\text{Li}(\text{Ni,Mn,Co})\text{O}_2$ (NMC) alloy system.⁶⁰

Fig. 7 compares the κ_{latt} obtained from this model with the thermal conductivity of SnSe computed in the alloy supercell, the latter of which gives a thermal conductivity within 5% of the value computed using the primitive cell. Instead of considering transport along the a , b , and c directions separately, as we did for the endpoints, we discuss the in-plane and out-of-plane thermal conductivity perpendicular and parallel to the layering direction, respectively, which we denote $\kappa_{\perp} = \frac{1}{2}(\kappa_{xx} + \kappa_{zz})$ and $\kappa_{\parallel} = \kappa_{yy}$, as well as the average $\kappa_{\text{ave}} = \frac{1}{3}(2\kappa_{\perp} + \kappa_{\parallel}) = \frac{1}{3}(\kappa_{xx} + \kappa_{yy} + \kappa_{zz})$. This is because we would not necessarily expect the bonding anisotropy along the a and c axes to be retained in the alloy models.

Decreasing the average mass to $m_{\text{ave}} = 0.1875m_{\text{S}} + 0.8125m_{\text{Se}}$ predicts a ~2–4% increase in the κ_{latt} compared to SnSe. This is readily understood given the larger group velocities in SnS (*cf.* Fig. 3). Including the isotope scattering, on the other hand, predicts a surprisingly large 40% reduction in the κ_{latt} of the alloy, with the κ_{\perp} , κ_{\parallel} and κ_{ave} reduced from 1.82, 0.93 and 1.53 W m⁻¹ K⁻¹ in SnSe to 1.11, 0.55 and 0.93 W m⁻¹ K⁻¹ at $T = 300$ K (Table 4). The isotope scattering model in ref. 59 is usually used to model the effect of natural isotope variation on the κ_{latt} . For Sn, S and Se, the natural m_{var} computed using eqn (26) are 3.34, 1.65 and 4.63 × 10⁻⁴, respectively, and we previously found that isotope scattering has very little effect on the thermal conductivity of SnS.²⁵ On the other hand, the m_{var} parameter computed for $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ is 6.85 × 10⁻², *i.e.* two orders of magnitude larger (Table 4).

To obtain the calculated κ_{latt} in Fig. 3 required a total of 16 accurate force calculations on 256-atom cells and 2580 calculations on 32-atom cells to obtain the second- and third-order force constants, respectively, using the supercell finite-displacement

Fig. 6 Unfolded dispersion and atom-projected density of states (PDOS) of $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$. The colour scale in the unfolded dispersion represents the spectral weight and runs from blue (low weight) to yellow (high weight).

Fig. 7 Impact of mass variation at the chalcogen site in SnSe on the thermal conductivity κ_{latt} . The solid lines show the in-plane (κ_{\perp} , blue), out-of-plane (κ_{\parallel} , red) and average κ_{latt} (κ_{ave} , black) of SnSe. The corresponding values obtained by changing the average mass m_{ave} at the chalcogen site to mimic the $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ solid solution are shown by dashed lines, and the values obtained by additionally including isotope scattering due to the change in mass variance m_{var} are shown by dotted lines.

method. For the 23 configurations in our $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ model, obtaining the second-order force constants required 3536 calculations on 256-atom cells, which was challenging but possible. To obtain the third-order force constants, however, would require 649 096 calculations on 32-atom cells, which is not feasible.

Returning to the CRTA model defined in eqn (3) and (4), we can use the second-order force constants to compute an averaged $\kappa_{\text{latt}}/\tau^{\text{CRTA}}$ for the alloy and thereby quantify the impact of changes to the frequencies and group velocities on the κ_{latt} . As shown in Fig. 8a and b, the alloying is predicted to reduce the harmonic term by 2–2.5 \times compared to SnSe, with the in-plane and out-of-plane values falling from 0.433 and 0.212 to 0.215 and 0.088 $\text{W m}^{-1} \text{K}^{-1} \text{ps}^{-1}$ at $T = 300 \text{ K}$ (Table 4). The estimates of the spread of values, given by the weighted standard deviations, are on the order of 5%. If we assume that the lifetime term τ^{CRTA} can be interpolated between the SnS and SnSe endpoints, we obtain the temperature dependence in Fig. 8c

and hence the predicted κ_{latt} in Fig. 8e, which can be compared to the corresponding reference calculations on SnSe shown in Fig. 8d and f. The reduced harmonic terms of the alloy models, coupled with the 5% shorter interpolated lifetime, yield a predicted 300 K κ_{\perp} , κ_{\parallel} and κ_{ave} of 0.85, 0.37 and 0.70 $\text{W m}^{-1} \text{K}^{-1}$, which are overall 50–60% reductions compared to SnSe. These reductions are larger than predicted using the isotope-scattering model and suggest substantial changes in the phonon group velocities of the alloys due to the local variation in atomic masses and chemical bonding/force constants.

A third possible model is to note that the w-JDoS functions $N_2(\mathbf{q}, \omega)$ in eqn (10) can be computed using the second-order force constants, and to use the model in eqn (8) with the interaction strengths P_{λ} substituted by a constant \tilde{P} interpolated between the endpoints. It is perhaps more physically intuitive to assume the weighted average interaction strength can be interpolated between the endpoints than it is to assume the averaged lifetime in the CRTA model can be interpolated.

For the 32-atom alloy models of SnS and SnSe the \tilde{P} that reproduce the κ_{ave} at $T = 300 \text{ K}$ are 2.705×10^{-12} and $1.184 \times 10^{-12} \text{ eV}^2$ respectively (see ESI†). These are 16 \times larger than the values obtained by analysing the eight-atom primitive cells as they are computed over $(3n_a)^2 = 9216$ instead of 576 pairwise interactions. We therefore calculate an interpolated \tilde{P} of $1.469 \times 10^{-12} \text{ eV}^2$ for $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$.

We note in passing that although the P_{λ} are temperature independent, it is unlikely to be possible to choose a single \tilde{P} that reproduces the κ_{latt} at all temperatures. However, the temperature variation in the \tilde{P} obtained by fitting, as in Fig. 4, was found to be on the order of 1% between 300 and 600 K in CoSb_3 ,³⁴ so we do not expect this to be a large source of error.

Fig. 9 compares the averaged $\tilde{N}_2(\omega)$ of $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ and the averaged κ_{latt} computed using the interpolated \tilde{P} to the corresponding data for the SnSe alloy cell.

Two of the 23 structures were each calculated to have one unphysically large κ_{latt} component ($\kappa_{xx} = 6.13$ and $\kappa_{yy} = 1.89 \text{ W m}^{-1} \text{K}^{-1}$, respectively), which had a disproportionate effect on the calculated average and standard deviation. We put this down to numerical issues, but we were unable to correct for them and therefore opted instead to omit these structures from our

Table 4 Model parameters and calculated thermal conductivity κ_{latt} at $T = 300 \text{ K}$ for the $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ alloy for the three models discussed in the text. Where appropriate, values are given for the in-plane (\perp), out-of-plane (\parallel) and average (ave) thermal transport. Note that some of these values differ from those in Table 2 as these SnSe calculations were performed using an equivalent alloy supercell to $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ instead of the eight-atom primitive cell

		$\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$			SnSe

Fig. 8 Thermal conductivity of $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ (left) and SnSe (right) predicted using the constant relaxation-time approximation (CRTA) model defined in eqn (3) and (4). (a) and (b) Harmonic component $\kappa_{\text{latt}}/\tau^{\text{CRTA}}$. (c) and (d) Lifetime component τ^{CRTA} . (e) and (f) Thermal conductivity κ_{latt} . On each subplot, the in-plane (\perp , red), out-of-plane (\parallel , blue) and average values (ave, black) are shown. The shaded area in plots (a) and (e) mark \pm one weighted standard deviation. The τ^{CRTA} in (c) are obtained by interpolating between the SnS and SnSe endpoints.

analysis. A version of Fig. 9 including these two structures is provided as ESL[†]

The $\bar{N}_2(\omega)$ of $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ is very similar to the SnSe endpoint, and suggests a reduction in the number of scattering channels in some parts of the frequency spectrum. We note, however, that the averaging over wavevectors may of course mask stronger variations in the individual $N_2(\mathbf{q},\omega)$. Combined with the interpolated \bar{P} in Table 4, we obtain a 300 K κ_{\perp} , κ_{\parallel} and κ_{ave} of 0.73, 0.39 and 0.62 $\text{W m}^{-1} \text{K}^{-1}$, which are a $\sim 60\%$ smaller than those calculated for SnSe . Excluding the obvious outliers, as noted above, the weighted standard deviations

indicate a spread of $\sim 5\%$ in the calculated κ_{latt} . Alongside the results from the CRTA, this model suggests changes in the number of energy-conserving scattering channels and a small increase in the phonon-phonon interaction strengths may have a small secondary effect on thermal transport in addition to the reduced group velocity.

To complete our discussion, we compare the predicted κ_{ave} obtained from the three methods tested above with SnSe in Fig. 10. At $T = 300$ K, the calculated κ_{ave} of SnSe is 1.53 $\text{W m}^{-1} \text{K}^{-1}$, and the values calculated for $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ using the three models are 0.93, 0.70 ± 0.04 and 0.62 ± 0.02 $\text{W m}^{-1} \text{K}^{-1}$. All three models

Fig. 9 Thermal conductivity of $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ predicted using the model defined in eqn (8) with the phonon–phonon interaction strengths replaced by a constant value $\tilde{P} = 1.469 \times 10^{-12} \text{ eV}^2$. (a) and (b) Two-phonon weighted joint density-of-states functions $\tilde{N}_2(\omega)$ defined in eqn (13). (c) and (d) Predicted in-plane (κ_{\perp} , blue), out-of-plane (κ_{\parallel} , red) and average thermal conductivity (κ_{ave} , black). Plots (a) and (c) show calculations on the $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ alloy model, and the shaded areas indicate \pm one standard deviation. Plots (b) and (d) show calculations on SnSe for comparison.

predict a large reduction in the thermal conductivity due to alloying. The experimental measurements in ref. 11 on $\text{Ag}_{0.01}\text{Sn}_{0.99}\text{Se}_{1-x}\text{S}_x$ reported a large drop from ~ 0.55 to $0.2 \text{ W m}^{-1} \text{ K}^{-1}$ at room temperature at 15–20% S content, which suggests that the magnitude of the reduction predicted by the calculations is reasonable. (We note that this study used pressed pellets, and thus we would likely expect a reduced κ_{latt} due to defects, as discussed for SnS and SnSe in a previous section.)

Within the CRTA model, the majority of the reduction in the κ_{latt} is due to a reduced harmonic term which, to the extent that thermodynamic model for the alloy is reasonable, is not approximated in this work. The small difference between the CRTA and constant \tilde{P} then points to a small potential secondary effect from changes in the phonon lifetimes due to changes in the phonon frequency spectrum. While we cannot rule out changes in the phonon–phonon interaction strengths in the alloy, for a near-ideal solid solution like $\text{Sn}(\text{S}_{1-x}\text{Se}_x)$ it seems reasonable to assume that the averaged \tilde{P} can be interpolated. The performance of the simple mass-variance model is remarkable given that it is much less computationally demanding than either of the other two approaches, and suggests it may be a good initial approach to predicting the κ_{latt} of alloy systems.

Fig. 10 Predicted averaged thermal conductivity κ_{ave} of SnSe (black) and the κ_{ave} of $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ obtained using the three models considered in this section: the mass-variance model (blue), the CRTA model defined in eqn (3) and (4) with an interpolated lifetime τ^{CRTA} (red), and the model defined in eqn (8) with the interaction strengths P_{λ} replaced by an interpolated constant \tilde{P} (orange).

Finally, we should also note that the virtual crystal approximation (VCA) might be a useful “middle ground” between the simple mass-variance model and the more sophisticated CRTA and constant interaction-strength models. In the VCA, the force constants for an alloy are built from appropriate linear combinations of the force constants of the endpoints, which in principle improves on the average mass model by accounting for changes in the second- and third-order force constants.³² Unfortunately, this technique is presently not implemented in the Phono3py software, so we were not able to test it alongside the other methods.

4. Conclusions

In summary, we have performed a detailed characterisation of the thermal conductivity of SnS and SnSe and of the $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ alloy.

In these calculations, we find that SnS and SnSe have similar, ultra-low κ_{latt} , and the difference between them is down to a subtle balance of decreased group velocities but longer lifetimes in the selenide. The longer lifetimes are due to weaker phonon–phonon interaction strengths, and negate an increase in the number of energy- and momentum-conserving scattering pathways due to the smaller range of phonon frequencies.

Our thermodynamic model of $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$ indicates near-ideal behaviour, with the mixing free energy dominated by entropy and a close-to homogenous distribution of occurrence probabilities over the 23 independent chalcogen arrangements in our 32-atom alloy supercell. In contrast to our previous work, we find that vibrational contributions to the free energy have a relatively small impact on the thermodynamics. While this result may be taken as an indication that vibrational effects need not be taken into account in alloy models, further work is required to determine whether this generalises to less ideal solid solutions.

By performing harmonic phonon calculations on the alloy model, we investigated three possible approaches to quantifying the impact of alloying on the thermal transport and predicted a substantial 40–60% drop in the κ_{latt} compared to the SnSe endpoint. Our analysis suggests the majority of this is due to a reduction in the group velocities, which also manifests as a “smearing” of the phonon dispersion, together with a small additional effect from a reduction in the phonon lifetimes. We also found that a simple isotope-scattering model provided a good reproduction of the results obtained using more sophisticated – and more computationally-demanding – models, and it is therefore of interest to investigate whether this is more generally applicable.

Overall, this study has provided useful insight into how alloying reduces the thermal conductivity of SnS and SnSe, and we hope these theoretical models will be of use to modelling studies on other widely-used thermoelectrics in the future. Ultimately, we hope that microscopic insight from first-principles calculations such as these will be able to inform

the future selection of alloy systems to optimise the thermoelectric performance of existing and novel TEs. With regard to the SnS/SnSe system, the preservation of the structure in the low-frequency dispersion of $\text{Sn}(\text{S}_{0.1875}\text{Se}_{0.8125})$, together with the large impact of changes in group velocity in reducing the κ_{latt} , suggests that it may be of interest to consider $(\text{Ge}_{1-x}\text{Sn}_x)\text{S}$ or $(\text{Ge}_{1-x}\text{Sn}_x)\text{Se}$ alloys as alternatives.

Data-access statement

Raw data from our previous studies on the $\text{Sn}_n(\text{S}_{1-x}\text{Se}_x)_m$ and *Pnma* $\text{Sn}(\text{S}_{1-x}\text{Se}_x)$ solid solutions is available free of charge in online repositories (ref. 40 and 61). Raw data from this study is also available free of charge online at: <http://dx.doi.org/10.17632/hrzkm56zw7.1>. A set of utilities and analysis codes for Phonopy and Phono3py calculations are available in a GitHub repository: <https://github.com/skelton-group/Phono3py-PowerTools>. Any data not included in the data repositories is available from the authors on reasonable request.

Conflicts of interest

There are no conflicts to declare.
