2024, 12, 19671**Abnormal anti-thermal quenching of Mn<sup>2+</sup> and reverse thermal response of Mn<sup>2+</sup>/Mn<sup>4+</sup> luminescence in garnet phosphor for wide-range temperature sensing†**Annu Balhara,<sup>ab</sup> Santosh K. Gupta,<sup>id</sup> \*<sup>ab</sup> G. D. Patra,<sup>id</sup> <sup>c</sup> Boddu S. Naidu<sup>id</sup> <sup>d</sup> and Kathi Sudarshan<sup>id</sup> <sup>ab</sup>

Herein, we explored the diverse temperature-dependent luminescence, thermal quenching, and decay kinetics of Mn<sup>2+</sup>/Mn<sup>4+</sup> emission centers in a Y<sub>3</sub>Al<sub>2</sub>Ga<sub>3</sub>O<sub>12</sub> garnet host. Emission color tuning was achieved from red to deep red region as a function of the Mn doping amount. The tuning of the Mn valence state as a function of doping concentration in Y<sub>3</sub>Al<sub>2</sub>Ga<sub>3</sub>O<sub>12</sub> was investigated in detail, and the mechanism of self-reduction of Mn<sup>4+</sup> has been discussed. Interestingly, the temperature-dependent photoluminescence study of Y<sub>3</sub>Al<sub>2</sub>Ga<sub>3</sub>O<sub>12</sub>:Mn<sup>2+/4+</sup> revealed the abnormal anti-thermal quenching of the Mn<sup>2+</sup> emission band with increasing temperature. In contrast, Mn<sup>4+</sup> emission displayed thermal quenching with increase in temperature. The interplay of self-reduction and defects in the anti-thermal quenching of Mn<sup>2+</sup> has been discussed. Benefiting from the reverse temperature-dependent luminescence behaviour of Mn<sup>2+/4+</sup>, luminescence ratiometric and lifetime thermometry have demonstrated a promising wide temperature sensing range, from cryogenic conditions (10 K) to 490 K. A high relative sensitivity of 2.35% K<sup>-1</sup> (190 K) and 3.10% K<sup>-1</sup> (390 K) could be achieved for ratiometric and lifetime thermometry, respectively. The lifetime thermometer based on the lifetime of Mn<sup>2+</sup> and Mn<sup>4+</sup> ions offered good temperature resolution (<0.30 K). This work proposed the use of dual-emitting single-doped materials for highly sensitive wide sensing range thermometry and offers meaningful advancement in the design of orange–red emitting phosphors.

## 1. Introduction

Phosphor materials have emerged as potential sources of solid-state lighting technology for indoor/outdoor illumination, displays, optoelectronics, and light-emitting diodes (LEDs) applications.<sup>1–6</sup> The transition metal manganese (Mn<sup>2+/4+</sup> ions) is a well-known photoluminescence activator for various inorganic luminescent materials used in modern lighting sources owing to red emission with high luminous efficiency, low cost and non-rare earth-based red phosphors.<sup>7–11</sup> Mn<sup>2+</sup>-based phosphors have been widely investigated to achieve multimode fluorescence for the design of white LEDs, thermal sensing, and anti-counterfeiting applications.<sup>12,13</sup> Garnet phosphors (A<sub>3</sub>B<sub>2</sub>C<sub>3</sub>O<sub>12</sub>) are popular candidates for achieving

the strong red to deep red emission of Mn<sup>2+/4+</sup> ions as they can be stabilized in octahedral Al<sup>3+</sup>/Ga<sup>3+</sup> sites.<sup>14,15</sup> The high temperature solid-state synthesis of the garnet structure may result in the coexistence of Mn<sup>2+/4+</sup> ions due to the defect-induced self-reduction of Mn<sup>4+</sup> ions. The design of Mn<sup>2+/4+</sup>-activated materials offers the potential optimization of emission from red light (Mn<sup>2+</sup>) to deep red light (Mn<sup>4+</sup>) by controlling the composition and tuning the emission for indoor plant growth. Since the control of the Mn valence state is a great challenge for developing Mn-activated luminescent materials, few studies have reported dual-emitting Mn<sup>2+/4+</sup> phosphors for suitable applications.<sup>14–20</sup> Therefore, understanding the photophysical properties, defect-induced self-reduction, charge transfer dynamics, decay kinetics and thermal behaviour is essential for designing Mn-based phosphors for targeted applications utilizing the multiple valence states of Mn. The mixed valence of Mn offers the development of multifunctional phosphors with emission tunability, which is promising for the development of phosphors for indoor plant lighting, anti-counterfeiting, optoelectronics and temperature sensing applications.

See DOI: <https://doi.org/10.1039/d4tc03650f>

Benefitting from the multifunctionality of phosphor materials, optical temperature sensors based on the thermal response of luminescence intensity ratio (LIR), lifetime, and bandwidth have attracted scientific attention due to their high accuracy, non-contact thermometry, and fast response.<sup>21–26</sup> Lifetime-based thermometers have gained popularity due to the low chances of erroneous temperature readout.<sup>22</sup> Recently, dual-wavelength emission materials have emerged as perfect candidates for ratiometric or lifetime-based temperature sensing, which utilize temperature-dependent energy transfer between the dopant ions and charge transfer (CT) between the host matrix and dopant ions.<sup>27–29</sup> Interestingly, the dual-wavelength emitting  $\text{Mn}^{2+/4+}$ -activated phosphors can be studied for ratiometric and lifetime thermometry based on the diverse temperature-dependent photoluminescence (PL) properties and thermal quenching (TQ) of  $\text{Mn}^{2+/4+}$  ions.

Herein, we synthesized a series of  $\text{Mn}^{2+/4+}$ -activated  $\text{Y}_3\text{Al}_2\text{Ga}_3\text{O}_{12}$  (YAGG) phosphors using solid-state synthesis reported in our earlier work,<sup>3</sup> which is detailed in the ESI†. We reported the stabilization of mixed valent states of Mn in the YAGG lattice and studied the photoluminescence properties of the dual-emitting  $\text{Y}_3\text{Al}_2\text{Ga}_3\text{O}_{12}:\text{Mn}^{2+/4+}$  phosphor at different excitation energies, doping amounts and temperature. The luminescence and application prospects of the dual-emitting  $\text{Y}_3\text{Al}_2\text{Ga}_3\text{O}_{12}:\text{Mn}^{2+/4+}$  phosphor have not been studied before to the best of our knowledge. The changes in the defects and oxidation state of Mn ions with composition were probed using positron annihilation lifetime spectroscopy (PALS) and electron paramagnetic resonance (EPR) spectroscopy. We investigated the temperature-dependent luminescence behaviour of  $\text{Mn}^{2+/4+}$  ions in a wide temperature range of 10 K to 490 K. The evolution of the  $\text{Mn}^{2+}$  emission band with temperature is discussed in detail with respect to temperature-dependent CT and defect-induced self-reduction of  $\text{Mn}^{4+} \rightarrow \text{Mn}^{2+}$ . The excitation wavelength-dependent decay kinetics was studied as a function of temperature to understand the depopulation mechanism and charge transfer dynamics in  $\text{Mn}^{2+/4+}$ -activated YAGG system. We demonstrate that the dual-wavelength emitting YAGG:Mn phosphor (620 nm/675 nm) can be utilized for ratiometric and lifetime thermometry based on the diverse thermal response of luminescence and decay of  $\text{Mn}^{2+/4+}$  ions. The characterization details are provided in the ESI† file (Section S1.2).

## 2. Results and discussion

### 2.1 Structural and morphological analysis

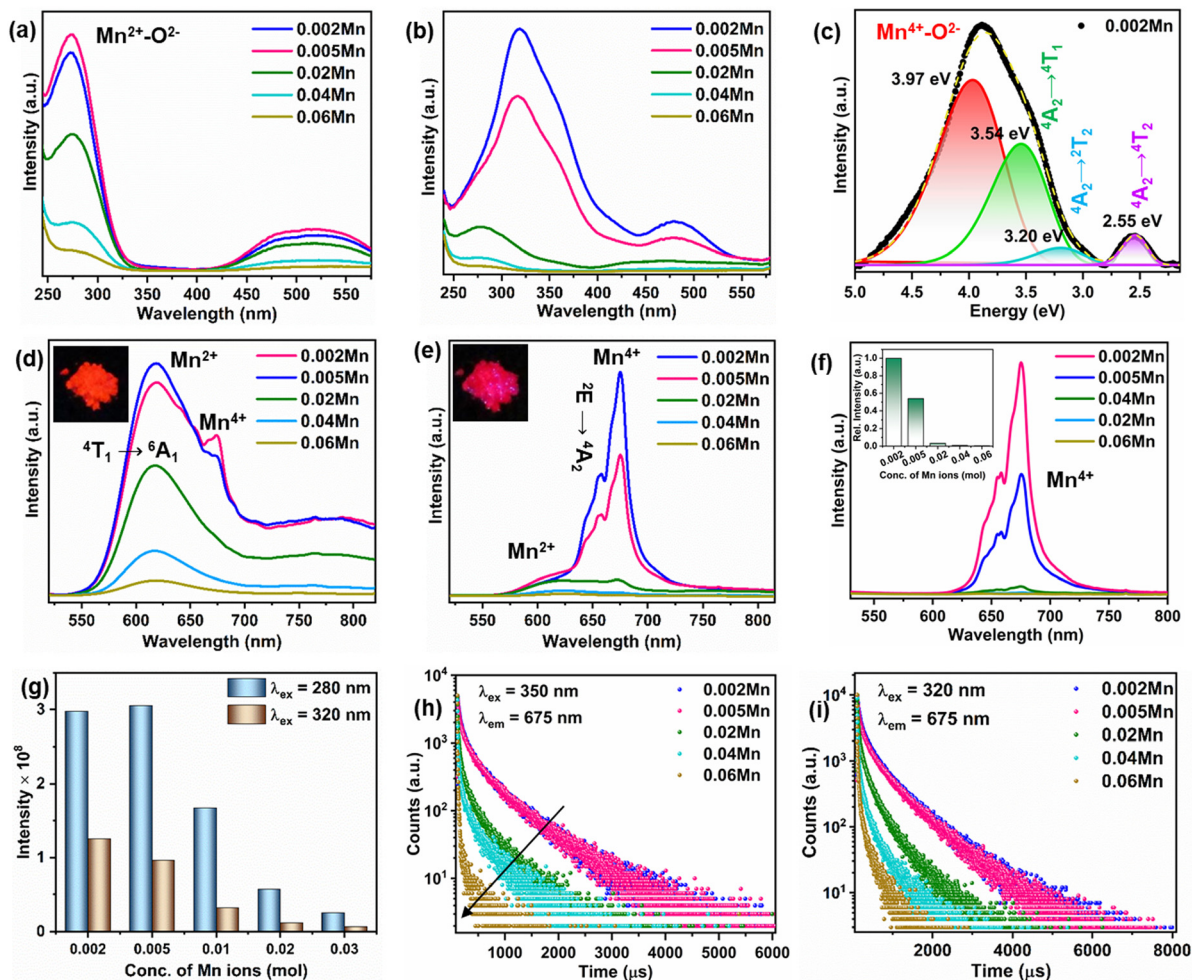

The XRD diffraction patterns of all the Mn-doped YAGG samples confirmed the phase purity and YAGG crystallized in a cubic system ( $Ia\bar{3}d$  space group) (Fig. S1, ESI†). The garnet structure YAGG is composed of  $\text{YO}_8$  dodecahedron,  $\text{AlO}_6/\text{GaO}_6$  octahedron, and  $\text{AlO}_4/\text{GaO}_4$  tetrahedron (Fig. S2, ESI†). Based on the ionic size, the  $\text{Mn}^{2+}/\text{Mn}^{4+}$  ions (0.67 Å/0.53 Å) preferably occupy the octahedral  $\text{Al}^{3+}/\text{Ga}^{3+}$  (0.535 Å/0.62 Å) sites to form  $\text{Mn}^{2+}/\text{Mn}^{4+}$  color centers.<sup>27</sup> The FTIR spectra show the

characteristic bands of Ga–O and Al–O stretching frequencies in the 580–850  $\text{cm}^{-1}$  region (Fig. S3, ESI†).<sup>3</sup> The TEM image of YAGG:0.02Mn shows that the sample crystallized as particles with irregular morphology and size  $\sim 1 \mu\text{m}$  (Fig. S4, ESI†). The EDS spectra confirmed the presence of Y, Al, Ga, Mn, and O elements in the YAGG:0.02Mn sample (Fig. S5, ESI†).

### 2.2 Photoluminescence study

The photoluminescence excitation (PLE) spectra show different profiles for 620 nm and 675 nm emissions (Fig. 1(a) and (b)). When excited at 280 nm, the emission spectra (Fig. 1(d)) show a broad red emission peaking at 620 nm along with weak sharp bands at 675 nm, which can be ascribed to the  ${}^4\text{T}_1 \rightarrow {}^6\text{A}_1$  transition of  $\text{Mn}^{2+}$  ions and the  ${}^2\text{E} \rightarrow {}^4\text{A}_2$  transition of  $\text{Mn}^{4+}$  ions located in the  $\text{AlO}_6/\text{GaO}_6$  octahedra, respectively.<sup>21,23</sup>  $\text{Mn}^{2+}$  emission depends on the crystal field strength and red emission of  $\text{Mn}^{2+}$  ions in the YAGG lattice is in accordance with the octahedral coordination of  $\text{Mn}^{2+}$  ions.<sup>6,30</sup>  $\text{Mn}^{4+}$  ions with  $3\text{d}^3$  electronic configuration occupy the octahedral sites due to the preferred octahedral coordination and size.<sup>18,24</sup> The absence of green emission of  $\text{Mn}^{2+}$  ions in the emission spectra negated the possible occupation of tetrahedral  $\text{Al}^{3+}/\text{Ga}^{3+}$  sites. This suggested the presence of  $\text{Mn}^{2+/4+}$  ions in the YAGG:Mn samples, which was confirmed by EPR measurements. The presence of sextet EPR lines due to both  $\text{Mn}^{2+/4+}$  ions are marked in the EPR spectra (Fig. S6 and S7, ESI†). To further confirm the presence of  $\text{Mn}^{2+}$  and  $\text{Mn}^{4+}$  ions and investigate the relative amounts of  $\text{Mn}^{2+/4+}$  ions in the samples with different Mn doping contents, X-ray photoelectron spectroscopy (XPS) measurements were performed on two samples, *i.e.*, YAGG:0.02Mn and YAGG:0.06Mn. The XPS survey spectra of the two samples and Mn  $2\text{p}_{3/2}$  spectra are presented in Fig. S8a–c (ESI†). The Mn  $2\text{p}_{3/2}$  spectra for YAGG:0.02Mn and YAGG:0.06Mn can be deconvoluted into two peaks of  $\text{Mn}^{2+}$  at 640.9 eV and  $\text{Mn}^{4+}$  at 644.9 eV.<sup>18,31</sup> Though the peak positions remained similar, the relative peak areas of  $\text{Mn}^{2+}$  and  $\text{Mn}^{4+}$  show different order. In YAGG:0.02Mn, the area of the  $\text{Mn}^{2+}$  peak is much smaller than that of  $\text{Mn}^{4+}$ , while in the YAGG:0.06Mn sample, the area of the  $\text{Mn}^{2+}$  peak is relatively higher than that of YAGG:0.02Mn. This indicated that the  $\text{Mn}^{2+}$  concentration increased compared to  $\text{Mn}^{4+}$  with the increase in the doping amounts of Mn ions in the YAGG matrix, which can be explained by the self-reduction of  $\text{Mn}^{4+}$  ions to  $\text{Mn}^{2+}$  at higher doping concentrations, as discussed later.

The color tunability from the red emission of  $\text{Mn}^{2+}$  in YAGG:0.002Mn to the deep red emission of  $\text{Mn}^{4+}$  ions under different excitation wavelengths is depicted by the emission photographs captured by a camera (see inset of Fig. 1(d) and (e)). The emission spectra ( $\lambda_{\text{ex}} = 320 \text{ nm}$ ) show the typical sharp band emission of  $\text{Mn}^{4+}$  ions with less intense  $\text{Mn}^{2+}$  emission (Fig. 1(e)). Interestingly, upon excitation at 280 and 320 nm, which can be ascribed to  $\text{O}^{2-} \rightarrow \text{Mn}^{2+}$  and  $\text{O}^{2-} \rightarrow \text{Mn}^{4+}$  CT transitions, the dual-band emission bands of both  $\text{Mn}^{2+}$  and  $\text{Mn}^{4+}$  were observed in the PL emission spectra of the samples at 620 nm ( ${}^4\text{T}_1 \rightarrow {}^6\text{A}_1$ ) and 675 nm ( ${}^2\text{E} \rightarrow {}^4\text{A}_2$ ), respectively.  $\text{Mn}^{4+}$  emission dominates at  $\lambda_{\text{ex}} = 320 \text{ nm}$ , and  $\text{Mn}^{2+}$  emission

**Fig. 1** PLE spectra of YAGG:*x*Mn (*x* = 0.002–0.06 mol) phosphors monitored at (a)  $\lambda_{\text{em}} = 620$  nm and (b)  $\lambda_{\text{em}} = 675$  nm. (c) Deconvolution of the PLE spectrum of YAGG:0.002Mn monitored at 675 nm. PL emission spectra for (d)  $\lambda_{\text{ex}} = 280$  nm and (e)  $\lambda_{\text{ex}} = 320$  nm (emission photograph of YAGG:0.002Mn in inset). (f) PL emission spectra for  $\lambda_{\text{ex}} = 350$  nm (inset showing the relative intensity with increasing Mn doping amounts). (g) Integral intensity as a function of Mn ions concentration. (h) Decay curves of  $\text{Mn}^{4+}$  ions at  $\lambda_{\text{ex}} = 350$  nm and  $\lambda_{\text{em}} = 675$  nm. (i) Decay curves of Mn ions at  $\lambda_{\text{ex}} = 320$  nm and  $\lambda_{\text{em}} = 675$  nm.

is more intense at  $\lambda_{\text{ex}} = 280$  nm. The broad PLE spectrum ( $\lambda_{\text{em}} = 675$  nm) of YAGG:0.002Mn is composed of four Gaussian bands centered at 312 nm ( $32\,051\text{ cm}^{-1}$ ), 350 nm ( $28\,571\text{ cm}^{-1}$ ), 388 nm ( $25\,839\text{ cm}^{-1}$ ) and 487 nm ( $20\,533\text{ cm}^{-1}$ ) due to the  $\text{O}^{2-} \rightarrow \text{Mn}^{4+}$  CT,  ${}^4\text{A}_2 \rightarrow {}^4\text{T}_1$ ,  ${}^4\text{A}_2 \rightarrow {}^2\text{T}_2$  and  ${}^4\text{A}_2 \rightarrow {}^4\text{T}_2$  transitions of  $\text{Mn}^{4+}$  ions, respectively (Fig. 1(c)).<sup>5</sup> The PL emission spectra of the samples under 350 nm excitation, *i.e.*, the  ${}^4\text{A}_2 \rightarrow {}^4\text{T}_1$  transition of  $\text{Mn}^{4+}$  ions, showed single emission of  $\text{Mn}^{4+}$  ions at 675 nm only due to the  ${}^2\text{E} \rightarrow {}^4\text{A}_2$  transition (Fig. 1(f)). The presence of dual-band emission and single-band emission under 320 and 350 nm excitations can be observed in Fig. S9 (ESI<sup>†</sup>). We evaluated the crystal field strength ( $D_q$ ) and Racah parameter ( $B$ ) of the  $\text{Mn}^{4+}$  sites in the YAGG:0.002Mn<sup>4+</sup> sample using the following equations.

$$D_q/B = 15(x - 8)/x^2 - 10x \quad (1)$$

$$D_q = E({}^4\text{A}_2 - {}^4\text{T}_2)/10 \quad (2)$$

$$x = E({}^4\text{A}_2 - {}^4\text{T}_1) - E({}^4\text{A}_2 - {}^4\text{T}_2)/D_q \quad (3)$$

The crystal field strength ( $D_q$ ), Racah parameters ( $B$ ), and crystal field strength ( $D_q/B$ ) for  $\text{Mn}^{4+}$  were calculated as  $2053\text{ cm}^{-1}$ ,  $798\text{ cm}^{-1}$ , and 2.57, respectively.

The variation of emission intensity as a function of Mn concentration is displayed in Fig. 1(f) and (g) where the optimal concentration is 0.002 mol and 0.005 mol for 320/350 nm and 280 nm excitation, respectively. The tuning of Mn emission color with doping amounts can be visualized from the CIE diagram (Fig. S10 and S11, ESI<sup>†</sup>). The excitation wavelength-dependent color tunability of Mn emission is achieved due to the different absorption efficiency of  $\text{Mn}^{2+/4+}$  ions in the UV and near-UV regions (Fig. S12, ESI<sup>†</sup>). The concentration quenching resulted in the reduced emission intensity of both  $\text{Mn}^{2+/4+}$  ions at higher Mn doping amounts.<sup>32</sup> The concentration quenching of both  $\text{Mn}^{2+/4+}$  ions is caused by electric dipole–dipole interactions as  $\theta = 5.76$  and 6.36 (close to 6) were obtained from the  $\log(I/x)$  versus  $\log(x)$  plot shown in Fig. S13a and b (discussion in ESI<sup>†</sup>), respectively.<sup>32</sup>

With the increase in the Mn ions content,  $\text{Mn}^{4+}$  emission is quenched significantly and the broad emission of  $\text{Mn}^{2+}$  is

dominant in the YAGG samples with higher Mn content (Fig. S14 and S15, ESI†). This suggested the defect-induced self-reduction of  $\text{Mn}^{4+} \rightarrow \text{Mn}^{2+}$  at higher Mn doping amounts.<sup>33</sup> Due to charge imbalance, the substitution of  $\text{Al}^{3+}/\text{Ga}^{3+}$  sites by  $\text{Mn}^{4+}$  ions will induce the formation of cation vacancies ( $V_{\text{Al/Ga}}$ ). The nature of defects with changing doping amount of Mn ions was probed using PALS technique (Fig. S16, ESI†). Typical positron annihilation lifetime spectra are shown in Fig. S16a (ESI†). All the lifetime spectra could be fitted as the sum of three exponentials or three positron annihilation lifetimes with longest lifetime of 1.5 to 2 ns with intensity <0.5%. The typical fitting of the lifetime spectra is given as inset of Fig. S16a (ESI†). The long-lived component of <0.5% intensity is due to positronium formation on the surface of the powder particles. The other two positron lifetimes ( $\tau_1$  and  $\tau_2$ ), intensity of the second positron lifetime ( $I_2$  and  $I_1 \sim 100 - I_2$ ) and the intensity-weighted average positron lifetime ( $\tau_{\text{avg}}$ ) are given in Fig. S16b (ESI†).

The first positron lifetime ( $\tau_1$ ) is from the delocalised positron annihilation in the bulk of the sample while the second positron lifetime ( $\tau_2$ ) is from defects. The first positron lifetime in all the samples is in the range from 167 to 173 ps and is close to the lifetimes of 147–160 ps reported for the YAG samples in the literature.<sup>34</sup> With the doping of Mn, the first positron lifetime varied only marginally. A significant change is observed as a continuous reduction in the second positron lifetime, with the intensity of this component initially reducing and reaching a minimum at about 0.25–1% Mn doping and then increasing. Theoretical positron lifetimes for positron annihilations from various possible vacancies in YAG are reported.<sup>35</sup> As per the calculations, Y vacancies are expected to give positron lifetime of 341 ps, Al vacancy gives a lifetime of 275–279 ps, and oxygen vacancies about 238 ps. The second positron lifetime suggested that cation vacancies are formed initially at low Mn doping amount and finally lead to oxygen vacancies at higher Mn doping. Mn can be doped in variable oxidation states. It is expected that the doping of  $\text{Mn}^{4+}$  would lead to the formation of cation vacancies while  $\text{Mn}^{2+}$  would enhance the formation of oxygen vacancies for charge compensation. These results indicated that Mn might be doped as  $\text{Mn}^{4+}$  at lower concentrations while  $\text{Mn}^{2+}$  is favoured at higher concentrations. This result is in line with the XPS analysis; hence, it can be concluded that more  $\text{Mn}^{4+}$  ions get reduced to  $\text{Mn}^{2+}$  with the increase in the Mn doping amounts.

The presence of both  $\text{Mn}^{4+}$  and  $\text{Mn}^{2+}$  emission indicated abnormal self-reduction in the YAGG lattice. The charge compensation model has been used in earlier reports to explain the abnormal self-reduction from  $\text{Mn}^{4+} \rightarrow \text{Mn}^{2+}$  ions.<sup>15</sup> The substitution of trivalent  $\text{Al}^{3+}/\text{Ga}^{3+}$  sites by tetravalent  $\text{Mn}^{4+}$  ions in YAGG will induce the formation of positively charged  $[\text{Mn}^{4+}]_{\text{Al/Ga}}^{\bullet}$  and negatively charged  $V_{\text{Al/Ga}}'''$  defects. To neutralize the excess positive charge, four  $\text{Al}^{3+}/\text{Ga}^{3+}$  ions will be replaced by three  $\text{Mn}^{4+}$  ions (eqn (1)). The generated  $V_{\text{Al/Ga}}'''$  can act as electron donors, and the released electrons from the  $V_{\text{Al/Ga}}'''$  defects can be captured by the electron acceptor

$[\text{Mn}^{4+}]_{\text{Al/Ga}}^{\bullet}$  -defects. As a result, some of the  $\text{Mn}^{4+}$  ions are reduced to  $\text{Mn}^{2+}$ . The above processes can be explained by the following equations.

In addition, the YAGG:0.02Mn samples were synthesized under air atmosphere using  $\text{MnCO}_3$  and  $\text{MnO}_2$  as raw Mn source. The PLE and emission spectra (Fig. S17, ESI†) show similar spectral profiles, which confirm the self-reduction of  $\text{Mn}^{4+}$  to  $\text{Mn}^{2+}$  ions in the YAGG matrix.

The luminescence decay profiles for the Mn-doped YAGG phosphors for emission at 675 nm and 620 nm ( $\lambda_{\text{ex}} = 320/350$  nm and 280 nm) are presented in Fig. 1(h), (i) and Fig. S18 (ESI†), respectively. The average lifetimes ( $\tau_{\text{avg}}$ ) of Mn ions were calculated using a bi-exponential decay function.

$$I(t) = I_0 + A_1 e^{-t/\tau_1} + A_2 e^{-t/\tau_2} \quad (7)$$

where  $I_0$  and  $I(t)$  represent the emission intensities at zero offset and at 't' time,  $\tau_1$  and  $\tau_2$  are the two lifetime components, while  $A_1$  and  $A_2$  are constants, respectively. The lifetime values for the Mn-doped YAGG phosphors are summarized in Tables S1 and S2 (ESI†). The average lifetimes of the 675 nm emission ( $\lambda_{\text{ex}} = 320$  nm) peak decreased from 652  $\mu\text{s}$  to 276  $\mu\text{s}$  on higher Mn doping ( $x = 0.002$  to 0.06), which is consistent with the PL intensity trend due to non-radiative energy migration between  $\text{Mn}^{4+}$  ions.<sup>36</sup> Similarly, the lifetime value of  $\text{Mn}^{4+}$  ions decreased from 500  $\mu\text{s}$  to 200  $\mu\text{s}$  on higher Mn doping at  $\lambda_{\text{ex}} = 350$  nm. The lifetime values of 620 nm emission ( $\lambda_{\text{ex}} = 280$  nm) firstly increased from 354  $\mu\text{s}$  to 360  $\mu\text{s}$  and then decreased to 160  $\mu\text{s}$  at higher Mn doping. Time-resolved emission spectroscopy (TRES) was performed for 280 nm excitation (Fig. S19, ESI†). With an increase in the delay times, both  $\text{Mn}^{2+}$  and  $\text{Mn}^{4+}$  emissions can be observed while only  $\text{Mn}^{2+}$  emissions are dominant at lower delay times.

### 2.3 Temperature-dependent PL study

Since the excitations at 280 and 320 nm fall in the excitation range of both  $\text{Mn}^{4+}$  and  $\text{Mn}^{2+}$  ions, the temperature-dependent luminescence behaviour of the dual-emission bands of  $\text{Mn}^{2+/4+}$  ions can be investigated effectively using these two CT transitions. To understand the thermal behaviour of  $\text{Mn}^{2+/4+}$  luminescence, the temperature-dependent PLE and emission spectra of  $\text{Mn}^{2+/4+}$  under CT band excitation were recorded from 10 K to 490 K (Fig. 2(a)–(f)). The PLE spectra ( $\lambda_{\text{em}} = 620$  nm) in Fig. 2(a) display an increase in the  $\text{O}^{2-} \rightarrow \text{Mn}^{2+}$  CT band intensity initially up to 290 K, followed by decreased intensity at elevated temperatures (Fig. 3(a)). On the contrary, the PLE spectra ( $\lambda_{\text{em}} = 675$  nm) shows a continuous decrease in the intensity of the  $\text{O}^{2-} \rightarrow \text{Mn}^{4+}$  CT band with temperature (Fig. 3(a)). The temperature-dependent PL emission

Fig. 2 Temperature-dependent PLE spectra of YAGG:0.002Mn in the range from 10 to 490 K at (a)  $\lambda_{\text{em}} = 620$  nm and (b)  $\lambda_{\text{em}} = 675$  nm. Temperature-dependent PL spectra at (c)  $\lambda_{\text{ex}} = 280$  nm and (d)  $\lambda_{\text{ex}} = 320$  nm (inset shows the zoomed-in emission spectra). Temperature-dependent normalized PL spectra at 675 nm under (e)  $\lambda_{\text{ex}} = 280$  nm and (f)  $\lambda_{\text{ex}} = 320$  nm. (g)–(i) Contour plots for the normalized intensity of the CT band ( $\lambda_{\text{em}} = 675$  nm) and emission spectra ( $\lambda_{\text{ex}} = 320$  and 280 nm), respectively.

spectra ( $\lambda_{\text{ex}} = 320$  nm and 280 nm) demonstrated an abnormal trend in integral intensity change with temperature (Fig. 2(c) and (d)). The normalized emission spectra with respect to 675 nm emission shows that the spectral profile changes with temperature, where the  $\text{Mn}^{2+}$  emission becomes dominant at elevated temperatures (Fig. 2(e) and (f)). The broad emission at 620 nm ( $\lambda_{\text{ex}} = 280$  nm) due to  $\text{Mn}^{2+}$  ions increased with temperature till 290 K and shows TQ above 310 K; however,  $\text{Mn}^{4+}$  emission at 675 nm undergoes continuous TQ (Fig. 2(g) and 3(a)). The above observations can be visualized from the contour plots (Fig. 2(g)–(i)). The TQ in the  $\text{Mn}^{4+}$  ions can be caused by the crossover of  $^2\text{E}$  and  $^4\text{T}_2$  parabolas ( $\Delta E_1$ ) or  $^4\text{T}_2$  and  $^4\text{A}_2$  parabolas ( $\Delta E_2$ ), which results in non-radiative relaxation.<sup>37</sup> The phonon-assisted crossover of  $^4\text{T}_1$  and  $^6\text{A}_1$  parabolas in the case of  $\text{Mn}^{2+}$  ions can result in non-radiative relaxation to the ground state ( $\Delta E$ ).<sup>38</sup>

The trend of total integral intensity under different excitation wavelengths is shown in Fig. S20 (ESI†). The trend of the

$\text{O}^{2-} \rightarrow \text{Mn}^{2+}$  CT band is similar to the 620 nm peak intensity variation with temperature. This indicated that the release of electrons from the traps with increasing temperature may strengthen the  $\text{O}^{2-} \rightarrow \text{Mn}^{2+}$  CT, which led to the anti-TQ of  $\text{Mn}^{2+}$  emission ( $< 290$  K). The temperature dependence of the  $\text{Mn}^{2+}$  ion showing both anti-TQ and normal TQ can be fitted by the Shibata *et al.* model discussed in the ESI† (Fig. S21).<sup>39</sup> The values of activation energies for the anti-TQ of  $\text{Mn}^{2+}$  emission below 290 K is  $686 \text{ cm}^{-1}$ , normal TQ of  $\text{Mn}^{2+}$  emission after 310 K is  $1955 \text{ cm}^{-1}$ , and energy barrier for TQ of  $\text{Mn}^{4+}$  ions is  $774 \text{ cm}^{-1}$ . This suggested that the anti-TQ of  $\text{Mn}^{2+}$  ions and TQ of  $\text{Mn}^{4+}$  ions may be controlled by the thermal population of the  $^4\text{T}_1$  state of  $\text{Mn}^{2+}$  ions and the simultaneous depopulation of the  $^2\text{E}$  state of  $\text{Mn}^{4+}$  ions, respectively.

To get better insights into the depopulation and thermal quenching mechanisms, temperature-dependent decay curves were recorded at  $\text{Mn}^{2+/4+}$  emission wavelengths in the temperature range from 10 K to 490 K. The lifetime values of  $\text{Mn}^{2+}$

Fig. 3 (a) Variation in the peak intensity at 620 nm and 675 nm with temperature ( $\lambda_{ex} = 280$  nm) and the CT band intensity for  $\lambda_{em} = 620$  nm and 675 nm. (b) Luminescence decay profiles as a function of temperature at  $\lambda_{ex} = 280$  nm and  $\lambda_{em} = 620$  nm. (c) Temperature variation of lifetime for  $\lambda_{ex} = 280$  nm. (d) TL spectra of YAGG:0.02Mn when irradiated with 280 nm light. (e) Schematic illustration of radiative transitions and possible thermal quenching mechanisms for  $Mn^{4+}$  emission in octahedral coordination. (f) Schematic illustration of electron release from the traps and enhanced  $Mn^{2+}$  emission with the increase in temperature.

emission at 620 nm increases initially, which can be attributed to the thermal population of the  $4T_1$  state of  $Mn^{2+}$  ions, which modulates the PL intensity of  $Mn^{2+}$  emission (Fig. 3(b) and (c) and Fig. S22, S23, ESI†).<sup>40</sup> The lifetime increase indicated that with increasing temperature, the excited state population is increased by some thermally-activated processes. At higher temperature, the increased non-radiative pathways may result in the observed decrease in the lifetime values. In contrast, the lifetime values of 675 nm emission show a continuous decrease with temperature due to the increased non-radiative processes for the  $Mn^{4+}$  excited states (Fig. 3(c) and Fig. S22–S24, ESI†). The normal TQ of  $Mn^{4+}$  emission can be explained by the thermal cross-over of the excited states with the ground state of  $Mn^{4+}$  ions (Fig. 3(e)).

#### 2.4 Mechanism of thermal quenching behaviour of $Mn^{2+/4+}$ ions

To investigate the nature of defects, the thermoluminescence (TL) spectrum for the YAGG:0.002 $Mn^{2+/4+}$  was recorded sample upon irradiation with 280 nm light for 100 s. The TL spectra (Fig. 3(d)) shows two peaks at 364 K and 482 K, which can be attributed to the presence of  $V_O$  and  $[Mn^{4+}]_{Al/Ga}^\bullet$  defects, respectively.<sup>33</sup> The trap depths of these defects were calculated as 0.73 eV and 0.96 eV, using the equation  $E = T/500$  (eV). Fig. 3(f) shows the proposed mechanism for the anti-TQ of  $Mn^{2+}$  emission. The shallow traps can capture the electrons during UV excitation, which can be released to the conduction

band (CB) on increasing the temperature. The electrons in the CB can populate the excited  $4T_1$  state of  $Mn^{2+}$ . The increased thermal vibrations can also induce electron tunneling to the excited  $4T_1$  level of  $Mn^{2+}$  ions from the trap levels around the excited energy levels of  $Mn^{2+}$ . The above thermally-induced population of  $Mn^{2+}$  excited levels resulted in the enhancement of  $Mn^{2+}$  emission with temperature increase to 290 K. However, thermal quenching dominates at higher temperatures due to the thermal crossover of the  $4T_1$  and  $6A_1$  states. The observed trend can also be explained by the thermally-induced self-reduction of  $Mn^{4+} \rightarrow Mn^{2+}$  ions as  $V_{Ga/Al}$  can act as electron donors.<sup>30,33</sup> With the increase in temperature, the electrons are released from  $V_{Ga/Al}$  and transferred to the nearby  $Mn^{4+}$  ions.<sup>18</sup>

#### 2.5 Temperature sensing application

The diverse temperature-dependent behaviour of  $Mn^{2+/4+}$  emission upon 280 nm excitation can be utilized for LIR-based ratiometric and lifetime thermometry. The LIR (620 nm/675 nm) (Fig. 4(a)) from 10 K to 330 K can be fitted with the following exponential equation.<sup>41</sup>

$$LIR_{(620/675)} = A + B \exp(-\Delta E/kT) \quad (8)$$

Here,  $\Delta E$  is the activation energy for thermal quenching,  $T$  is temperature (Kelvin),  $k$  is the Boltzmann constant, and  $A$  and  $B$  are constants. The absolute sensitivity ( $S_a$ ) and relative sensitivity ( $S_r$ ) values can be evaluated by the following

Fig. 4 (a) Temperature dependence of  $LIR_{(620/675)}$  and the fitting curve. Temperature dependence of relative  $\tau$  values for (b)  $\lambda_{ex} = 280$  nm and  $\lambda_{em} = 675$  nm, (c)  $\lambda_{ex} = 280$  nm and  $\lambda_{em} = 620$  nm, (d)  $\lambda_{ex} = 320$  nm and  $\lambda_{em} = 620$  nm. (e) Corresponding  $S_a$  values as a function of temperature. (f) Corresponding  $S_r$  values as a function of temperature.

relations.

$$S_a \text{ (K}^{-1}\text{)} = \left| \frac{dLIR}{dT} \right| \quad (9)$$

$$S_r \text{ (% K}^{-1}\text{)} = \frac{1}{LIR} \left| \frac{dLIR}{dT} \right| \times 100 \quad (10)$$

The  $S_a$  and  $S_r$  values as a function of temperature are shown in Fig. 4(e) and (f), respectively. The maximum  $S_a$  value of  $0.018 \text{ K}^{-1}$  (at 330 K) and high  $S_r$  of  $2.35\% \text{ K}^{-1}$  (190 K) could be achieved for the  $Mn^{2+/4+}$  LIR-based thermometer. An  $S_r$  value higher than  $1.0\% \text{ K}^{-1}$  was retained up to 330 K. The temperature uncertainty ( $\delta T$ ) can be evaluated using the following expression.

$$\delta T \text{ (K)} = \frac{1}{S_r} \frac{\delta LIR}{LIR} \quad (11)$$

where  $\delta LIR/LIR$  can be evaluated as the uncertainty of the measured LIR values.<sup>40</sup> The  $\delta T$  values in the range of 0.15–0.01 K were obtained for ratiometric thermometry.

The thermal dependence of the lifetime values of 675 nm emission under 280 nm excitation wavelength can be utilized for wide-range temperature sensing from 10 to 310 K. The sigmoidal temperature dependences of the relative lifetime ( $\tau_{(t)}/\tau_0$ ) of  $Mn^{4+}$  ions can be fitted using the Boltzmann function as follows.

$$A_\tau = \frac{\tau_{(t)}}{\tau_0} = \frac{1}{1 + A \exp(T - T_0/dT)} \quad (12)$$

where  $\tau_0$  and  $\tau_{(t)}$  are the lifetime values at initial temperature  $T_0$  and at ' $T$ ', respectively.

The temperature dependences of  $Mn^{2+}$  lifetime ( $\lambda_{ex} = 280$  nm/320 nm) can be fitted in the temperature range from 330 K to 490 K using an equation derived from the Mott-Seitz model.<sup>27</sup>

$$A_\tau = \tau_{(t)} = \frac{\tau_0}{1 + A \exp(-\Delta E/kT)} \quad (13)$$

where  $k$  is Boltzmann constant, and  $\Delta E$  is the activation energy for non-radiative processes.

The  $S_a$  and  $S_r$  values for lifetime thermometry can be evaluated by the following relations.

$$S_a \text{ (K}^{-1}\text{)} = \left| \frac{dA_\tau}{dT} \right| \quad (14)$$

$$S_r \text{ (% K}^{-1}\text{)} = \frac{1}{A_\tau} \left| \frac{dA_\tau}{dT} \right| \times 100 \quad (15)$$

Lifetime thermometry based on the Boltzmann function using  $Mn^{4+}$  emission offers the maximum  $S_a$  value of  $0.0045 \text{ K}^{-1}$  (at 310 K), and  $S_r$  of  $1.05\% \text{ K}^{-1}$  was attained at 310 K (Fig. 4(f)). Lifetime thermometry based on  $Mn^{2+}$  emission ( $\lambda_{ex} = 280$  nm) displays the maximum  $S_a$  value of  $0.009 \text{ K}^{-1}$  (at 330 K) and  $S_r$  of  $2.29\% \text{ K}^{-1}$  (390 K). Lifetime thermometry based on  $Mn^{2+}$  emission ( $\lambda_{ex} = 320$  nm) displays the maximum  $S_a$  value of  $0.012 \text{ K}^{-1}$  (at 350 K) and  $S_r$  of  $3.10\% \text{ K}^{-1}$  (390 K). The temperature uncertainty ( $\delta T$ ) for lifetime thermometry can be

evaluated using the following expression

$$\delta T \text{ (K)} = \frac{1}{S_r} \frac{\delta \tau}{\tau} \quad (16)$$

where  $\delta \tau / \tau$  can be evaluated as uncertainty in lifetime measurements, which was determined as 0.4% for repeated decay measurements. The  $\delta T$  values within 0.12–0.30 K indicated high resolution for temperature sensing in the range from 330 K to 490 K for lifetime thermometry using Mn<sup>2+</sup> emission (Fig. S25, ESI†). Temperature sensing with high precision can be achieved in this work based on LIR and the lifetime of Mn<sup>2+/4+</sup> ions in the YAGG matrix.

The thermometric performance of our thermometer was compared with similar thermometers in Table 1. Hence, the lifetime thermometry displayed by the YAGG:Mn<sup>2+/4+</sup> phosphor is relatively higher than the earlier reported lifetime thermometers, and  $S_r$  greater than 1.0% K<sup>-1</sup> can be achieved above 150 K. The reverse thermal response of Mn<sup>2+/4+</sup> ions can be utilized for temperature sensing at low temperatures. The lifetime of the two valence states can be used in different temperature ranges for temperature detection with high precision. Hence, the mixed valence state YAGG:Mn<sup>2+/4+</sup> phosphor is a potential candidate for a dual-mode temperature sensor. This work discussed the abnormal reverse thermal response of two ions, which can be utilized for targeted applications and provide useful insights into such mixed valent Mn<sup>2+/4+</sup> orange-red emitting phosphors.

### 3. Conclusion

In conclusion, YAGG:Mn<sup>2+/4+</sup> phosphors display different emission from red to deep red under different excitation wavelengths (280 and 320 nm). The luminescence tuning of orange-red emitting phosphors with doping concentration of Mn ions and excitation wavelength can be promising for designing orange-red emitting materials. The Mn<sup>2+/Mn<sup>4+</sup></sup> ions display distinctive luminescence and decay time behaviour, which can be utilized for potential wide range optical thermometry with high temperature

sensitivity. The ratiometric thermometer offers a high maximum  $S_r$  value of 2.35% K<sup>-1</sup> (190 K). Lifetime thermometry at two different excitation wavelengths, namely, 280 nm and 320 nm, presents temperature read-out with a high maximum  $S_r$  value of 3.10% K<sup>-1</sup> (390 K) and 1.05% K<sup>-1</sup> (310 K), respectively. This work reports a single metal (two oxidation states)-based dual emitting ratiometric and lifetime thermometer with wide sensing range. Additionally, this work demonstrated the self-reduction of Mn ions in Mn-doped garnet materials and abnormal temperature-dependent luminescence properties of Mn<sup>2+/4+</sup> ions.
