# Dual kinetic effect from confined iron nanoparticles in zeolite modulates high-temperature catalytic NO reduction and NH<sub>3</sub> oxidation

Xinlin Xie, Jibin Yuan, Lei Liu, Hanzi Liu\* and Zhiqiang Sun \*

The selective catalytic reduction of ammonia (NH<sub>3</sub>-SCR) is a promising technology for abating nitrogen oxides (NO<sub>x</sub>), yet its application at high temperatures is severely hampered by the over-oxidation of ammonia, leading to a trade-off between NO<sub>x</sub> conversion and N<sub>2</sub> selectivity. Herein, we construct a series of Fe-exchanged ZSM-5 catalysts with controlled Fe loadings (0.05–0.5 wt%) to decouple the competing reaction pathways. The optimized 0.1Fe@ZSM-5 catalyst achieves 83.0% NO<sub>x</sub> conversion at 700 °C and maintains exceptional stability for over 120 h under harsh conditions, representing a significant performance enhancement. Mechanistic investigations combining kinetic modeling and *in situ* spectroscopy reveal a dual kinetic regime, governed by the size of the Fe species. Catalysts with low Fe loadings favor the standard SCR pathway *via* stable NH<sub>4</sub><sup>+</sup> and NH<sub>2</sub><sup>\*</sup> intermediates, whereas catalysts with higher loadings and larger Fe nanoparticles promote the undesirable oxidation of ammonia to NO<sub>x</sub>. The result identifies that the optimal catalytic sites for high-temperature SCR rely on a delicate balance, activating ammonia for the desired reaction while suppressing its subsequent over-oxidation. These findings provide new implications for advanced catalyst design by tuning the active site structure to navigate competing reaction kinetics.

## 1 Introduction

The abatement of nitrogen oxides (NO<sub>x</sub>) from high-temperature exhaust streams is a critical challenge in emerging industrial scenarios, including the after-treatment of diesel engine emissions, end-of-pipe control for ammonia–hydrogen co-firing, and the management of emissions from coal-fired boilers under rapid load changes.<sup>1,2</sup> The selective catalytic reduction of NO<sub>x</sub> with ammonia (NH<sub>3</sub>-SCR) over Fe-based zeolites represents a promising technology due to its exceptional efficacy in promoting NH<sub>3</sub> dehydrogenation and N–N bond formation.<sup>3</sup> However, the catalysts are susceptible to deactivation by sulfur poisoning and hydrothermal aging.<sup>4</sup> More critically, the over-oxidation of ammonia at elevated temperatures severely suppresses the overall NO<sub>x</sub> reduction activity.<sup>5–8</sup> Our previous work has shown that incorporating transition metals can enhance thermal-sulfur stability

through synergistic effects;<sup>9</sup> however, a fundamental understanding of the NH<sub>3</sub> oxidation mechanism and its kinetics at high temperatures remains elusive. Specifically, suppressing ammonia over-oxidation above 700 °C with sufficient deNO<sub>x</sub> efficiency shows a significant yet challenging task.

The catalytic oxidation of ammonia over metal-based catalysts has been studied extensively, both for its abatement as a toxic pollutant and for its potential in chemical synthesis, yielding products such as N<sub>2</sub>, NO, and N<sub>2</sub>O.<sup>10–12</sup> The ammonia activation is facilitated by metal–oxygen sites *via* abstraction of a H<sup>+</sup> proton, where the stronger oxidizability of the metal–oxygen bonds plays a crucial role. For instance, iron oxides possess a relatively low Fe–O bond energy, enabling the activation of NH<sub>3</sub>. In the case of NH<sub>3</sub>-SCR, rational ammonia oxidation is beneficial, as it accelerates the initial dehydrogenation to form the NH<sub>2</sub><sup>\*</sup> intermediate, which couples with NO to produce N<sub>2</sub>. However, under excessively oxidizing conditions, lattice oxygen can drive the progressive dehydrogenation of adsorbed NH<sub>2</sub><sup>\*</sup>. This process leads to the formation of highly reactive NH<sup>\*</sup> or N<sup>\*</sup> radicals, which are subsequently oxidized to NO<sub>x</sub>, thereby lowering

the  $N_2$  selectivity and suppressing the catalytic performance for the desired  $NO_x$  reduction.<sup>13,14</sup> This inherent trade-off between  $NH_3$  conversion and  $N_2$  selectivity poses a challenge for  $NH_3$ -SCR reactions on activated metal oxide surfaces.

Fe-based zeolites are energetically favored for stable NO reduction and high  $N_2$  selectivity, owing to their inherent spatial confinement and shape-selective properties.<sup>7</sup> Previous studies have focused on the kinetics and mechanisms of the interaction between  $NO_x$  and  $NH_3$ .<sup>15,16</sup> According to acid-base principles, the exchange of Fe ions into the zeolite framework generates Brønsted acid sites associated with Fe–OH moieties, which are recognized as critical for the initial adsorption and activation of  $NH_3$ , thereby facilitating N–N bond coupling.<sup>17,18</sup> However, an excessive concentration of these exposed acid sites can trigger the over-oxidation of ammonia. Current research often investigates how the catalyst's lattice structure, oxidation state, and acid site distribution influence NO conversion and  $N_2$  selectivity, with the reaction pathway of  $NH_2NO^*$  being a key intermediate.<sup>19–22</sup> Recent work has demonstrated the local coordination structure of the metal sites in dictating the diffusion pathways of dehydrogenated species, where van der Waals forces can create a barrier effect that suppresses the egress of intermediates leading to side reactions.<sup>23</sup> The disparity between Fe–O and Si–O bond lengths makes the Fe catalytic center particularly sensitive to local defects, which in turn alters the Fe–Fe and Fe–O coordination environments and the structure of the Fe–OH acid sites. By tailoring the oxidative properties and coordination environment of the catalytic Fe centers, one can modulate the product selectivity and reaction network through synergistic kinetics. Therefore, establishing a quantitative descriptor that correlates Fe–Fe/O coordination numbers and acid properties helps to fundamentally decouple the competing pathways of NO reduction and  $NH_3$  oxidation.

In this study, we report the synthesis and robust catalytic performance of a series of Fe-exchanged ZSM-5 catalysts. By developing a comprehensive kinetic model that couples the primary SCR reaction with parasitic  $NH_3$  oxidation, we demonstrate that the ion-exchanged Fe loading directly affects the high-temperature  $NH_3$ –NO– $O_2$  reaction system. Among the catalysts studied, 0.1Fe@ZSM-5 achieved a NO conversion of 83.0% and maintained exceptional stability for over 120 h at 700 °C in the presence of  $SO_2$  and water vapor. This performance represents a 15.2% enhancement in high-temperature de- $NO_x$  activity at 850 °C compared to our previous work. Mechanistically, we reveal that the exposed Fe nanoparticles facilitate the consumption of  $NH_3$ -coordinated Lewis acid sites, promoting  $NH_3$  adsorption and activation on the Brønsted acid sites for the SCR reaction. Simultaneously, these nanoparticles catalyze further dehydrogenation of  $NH_2^*$  intermediates at elevated temperatures, which leads to the undesired over-oxidation of ammonia to NO.

## 2 Results and discussion

### 2.1 Characterization of Fe@ZSM-5

The Fe@ZSM-5 catalysts were synthesized *via* a facile ion-exchange method, schematically depicted in Fig. 1a. A series of catalysts with different iron mass loadings were prepared and are denoted as 0.05Fe@ZSM-5, 0.08Fe@ZSM-5, 0.1Fe@ZSM-5, and 0.5Fe@ZSM-5, based on the calculated Fe content during synthesis. The loading of Fe was determined by ICP-OES and the results are summarized in Table S1. Detailed synthesis procedures are provided in the Experimental and computational section. Unless otherwise specified, HZSM-5 in this work refers to the zeolite with a Si/Al ratio of 27. X-ray diffraction (XRD) patterns confirmed the retention of the MFI framework, showing characteristic reflections at  $8.1^\circ$  (101) and  $23.2^\circ$  (332) (Fig. 1b). Notably, no diffraction peaks corresponding to  $Fe_2O_3$  (*e.g.*, at  $33.2^\circ$ ,  $35.7^\circ$ , or  $53.6^\circ$ ) or other crystalline iron-containing phases were detected,<sup>24,25</sup> indicating the dispersed state of iron species on the ZSM-5 lattice.

Transmission electron microscopy (TEM) revealed the microstructural features of 0.5Fe@ZSM-5 (Fig. 1c, S1 and S2). The large-scale image displays the characteristic morphology of the MFI framework. High-resolution TEM (HR-TEM) reveals distinct  $Fe_2O_3$  nanoparticles anchored on the zeolite framework, evidenced by clear lattice fringes corresponding to the (110) and (104) planes (Fig. 1e and f). Furthermore, energy-dispersive X-ray spectroscopy (EDS) elemental maps (Fig. 1g) show a homogeneous distribution of the framework elements (Si, Al, and O), whereas Fe is concentrated in discrete locations, consistent with the presence of nanoparticles.

Atomic-resolution scanning transmission electron microscopy (AC-STEM) was used to probe the iron species in 0.1Fe@ZSM-5 at the atomic scale. The images (Fig. 1h–j and S3) revealed numerous distinct bright dots and  $\sim 1.5$  nm particles, demonstrating that 0.1Fe@ZSM-5 is composed of both dispersed Fe atoms and nanoparticles (NPs). Electron energy loss spectroscopy (EELS) was subsequently conducted to analyze the oxidation state of the Fe species. The Fe L3 and L2 edges from three EELS line scans exhibited identical positions at 708.7 and 721.5 eV, respectively, consistent with the  $Fe^{3+}$  reference (Fig. 1k).<sup>26</sup> The combined results confirm the presence of small nanoparticles containing  $Fe^{3+}$  species on 0.1Fe@ZSM-5.

### 2.2 Coordination environment of Fe@ZSM-5

The physicochemical properties of the Fe@ZSM-5 catalysts were characterized by X-ray photoelectron spectroscopy (XPS), where the Fe 2p spectra varied significantly with iron loading (Fig. 2a). For samples with low iron content (0.05Fe@ZSM-5 and 0.08Fe@ZSM-5), distinct iron peaks were not resolved. In contrast, the 0.1Fe@ZSM-5 and 0.5Fe@ZSM-5 catalysts displayed well-defined peaks for  $Fe^{2+}$  ( $2p_{3/2}$  at 710.8 eV) and  $Fe^{3+}$  ( $2p_{3/2}$  and  $2p_{1/2}$ ).<sup>27–31</sup> The presence of  $Fe^{3+}$  was further confirmed by satellite peaks at 718.8 eV and 733.0 eV.<sup>32,33</sup>

**Fig. 1** Synthesis and structural characterization of Fe@ZSM-5 catalysts. (a) Schematic illustration of the synthesis of Fe@ZSM-5; (b) XRD patterns of the as-prepared Fe@ZSM-5 catalysts with different iron loadings; (c) TEM image of 0.5Fe@ZSM-5; (d–f) high-resolution TEM images of 0.5Fe@ZSM-5, showing Fe<sub>2</sub>O<sub>3</sub> nanoparticles with resolved lattice fringes corresponding to the (110) and (104) planes; (g) HAADF-STEM image and the EDS elemental maps for Fe, Al, Si, and O in 0.5Fe@ZSM-5; (h–j) aberration-corrected STEM images of 0.1Fe@ZSM-5. Isolated single Fe atoms are marked by yellow circles, and Fe nanoclusters are highlighted by white squares; (k) Fe L-edge EELS spectra of 0.1Fe@ZSM-5.

Therefore, iron exists as a mixture of Fe<sup>2+</sup> and Fe<sup>3+</sup> in the higher-loading samples, with Fe<sup>3+</sup> being the predominant species. The larger Fe<sup>3+</sup> peak area for 0.5Fe@ZSM-5 is consistent with its higher total iron content.

The O 1s XPS spectra (Fig. 2b) were deconvoluted into three distinct components, corresponding to lattice oxygen (O<sub>lattice</sub>) at a binding energy of 530.2 eV, surface-adsorbed oxygen (O<sub>surface-adsorbed</sub>) at 531.7 eV, and adsorbed hydroxyl groups (O<sub>hydro</sub>) at 532.6 eV.<sup>34,35</sup> It is worth noting that the parent HZSM-5 exhibits a large proportion of O<sub>surface-adsorbed</sub> which is associated with –Al/Si bonds.<sup>36</sup> While surface-adsorbed oxygen was the predominant species across all

samples (49–54%) from parent HZSM-5 or metal oxides,<sup>36–38</sup> the concentration of lattice oxygen exhibited a notable, non-monotonic trend with increasing Fe content. For 0.1Fe@ZSM-5, it has the highest value of lattice oxygen of about 33.1%, and concurrently displayed the lowest concentration of adsorbed hydroxyl groups (14.9%). However, 0.5Fe@ZSM-5 shared the equivalent amount of lattice oxygen and adsorbed hydroxyl groups (both 20.7%). The variation suggests that moderate Fe incorporation promotes the generation of lattice oxygen while excessive Fe loading may bring hydroxyl enrichment, which enables the catalyst to obtain higher N<sub>2</sub> selectivity.

X-ray absorption fine structure (XAFS) was employed to probe the coordination environment of iron within the synthesized Fe@ZSM-5 catalysts. The normalized Fe K-edge X-ray absorption near-edge structure (XANES) spectra are presented in Fig. 2e. The absorption threshold ( $E_0$ ) for all samples is shifted to a higher energy relative to that of Fe foil, indicating that iron predominantly exists in an oxidized state.<sup>45</sup> As the iron loading decreases, the XANES spectra exhibit a further shift toward higher energy and a broadening of the normalized peak. These features are characteristic of the oxidation of Fe to Fe<sup>3+</sup>, suggesting a higher average oxidation state in catalysts with lower iron content,<sup>46</sup> aligning with the fitting results in the XANES spectra.

The Fourier-transformed (FT) EXAFS spectra of the Fe@ZSM-5 catalysts (Fig. 2f) exhibit a prominent peak at  $\sim 2.5$  Å, corresponding to the Fe–Fe scattering path. The intensity of this peak strengthens with increasing iron loading, while the intensity of the Fe–O scattering path at 1.8 Å concurrently diminishes. These trends indicate that higher iron loadings promote the formation of Fe nanoclusters. In contrast, lower loadings favor a coexistence of atomically dispersed Fe species and small nanoclusters. This structural model is corroborated by wavelet transform (WT) analysis (Fig. 2g), which clearly resolves the distinct scattering contributions from Fe–O and Fe–Fe paths. Quantitative EXAFS fitting provides

further validation (Table S3). As the iron loading increases from 0.05 to 0.5 wt%, the Fe–Fe coordination number rises from 0.9 to 5.4, while the Fe–O coordination number decreases from 4.1 to 1.8. These results are in agreement with the structural evolution inferred from our XANES and WT analyses.

### 2.3 Dual kinetic effect of NH<sub>3</sub>-SCR over Fe@ZSM-5

To identify the optimal support, we first evaluated the catalytic performance of the parent HZSM-5 zeolites with various Si/Al ratios (10, 27, 85, 130, and 240), as shown in Fig. 3a. The zeolite with a Si/Al ratio of 27 exhibited the highest activity. The catalytic performance of the Fe@ZSM-5 series in the SCR of NO with NH<sub>3</sub> was evaluated (Fig. 3b). By varying the Fe loading amount during ion exchange from 0.05 to 0.5 wt%, two distinct kinetic regimes were observed in catalytic tests over the 400–850 °C temperature range. In the low-temperature regime (400–700 °C), the NO conversion increased with both temperature and iron loading. The 0.5Fe@ZSM-5 catalyst achieved the highest performance, with an average NO conversion of 95.1%. In contrast, the parent HZSM-5 support showed poor activity (9.3–65.3% conversion), confirming that the iron species are the primary sites for activating NH<sub>3</sub>-SCR, which improved the redox properties of the catalyst thereby accelerating the

**Fig. 3** NO catalytic reduction and NH<sub>3</sub> oxidation. NO conversion over (a) HZSM-5 with various Si/Al ratios and (b) Fe@ZSM-5 at different reaction temperatures; (c) effect of NO<sub>x</sub> concentration on catalytic NH<sub>3</sub> oxidation at 700–850 °C; (d) effect of gas hourly space velocity on NO conversion; (e) time-on-line NO conversion and outlet concentration of N<sub>2</sub>O and NO<sub>2</sub> over 0.1Fe@ZSM-5 at 700 °C. Conditions: 1000 ppm NH<sub>3</sub>, 6.0 vol% O<sub>2</sub>, 1000 ppm NO, and balance N<sub>2</sub>.

reaction rates and catalytic performance.<sup>47</sup> However, at temperatures above 700 °C, this trend reversed. The NO conversion began to decrease with increasing temperature and iron loading, indicating a loss of activity and N<sub>2</sub> selectivity (Fig. S5).

To investigate this high-temperature inactivation, we performed separate catalytic oxidation of NH<sub>3</sub> in the presence of O<sub>2</sub>. The concentration of NO<sub>x</sub> produced from NH<sub>3</sub> oxidation increased with both temperature and iron loading (Fig. 3c). This result shows that at high temperatures, NH<sub>3</sub> oxidation becomes a dominant competing side reaction, consuming the reducing agent and thereby lowering the efficiency of NO reduction. Moreover, the lower NO concentration of pristine HZSM-5 further confirms this side reaction to the iron species. Combining the TEM and XAS results, we preliminary conclude that the iron nanoparticle size is an important factor in modulating the trade-off between NH<sub>3</sub>-SCR activity and NH<sub>3</sub> oxidation.

The effect of gas hourly space velocity on the catalytic performance was explored (Fig. 3d). Increasing the space

velocity led to a decrease in NO conversion. This was accompanied by a rise in unconverted NH<sub>3</sub> at the outlet, while the concentrations of NO<sub>2</sub> and N<sub>2</sub>O by-products did not change significantly. These results indicate that the drop in NO conversion at higher space velocities is due to the reduced NH<sub>3</sub> conversion rather than the enhanced NH<sub>3</sub> over-oxidation.

In addition, the long-term stability of the 0.1Fe@ZSM-5 catalyst was tested at 700 °C (Fig. 3e). The catalyst demonstrated robust performance over a 50 hour run, with NO conversion showing only a slight decrease from 79.5% to 77.0%. During this period, the outlet NO<sub>2</sub> concentration increased from 4.1 to 7.5 ppm, while the N<sub>2</sub>O concentration remained stable. This suggests that the minor drop in NO conversion is linked to a slow side reaction where some NO is oxidized to NO<sub>2</sub>, which does not efficiently enter the fast SCR pathway.

Regarding practical application, we evaluated the long-term catalytic performance of synthesized 0.1Fe@ZSM-5 and HZSM-5 under exposure to 300 ppm SO<sub>2</sub> and 8.3

**Fig. 4** The long-term stability test on synthesized (a) 0.1Fe@ZSM-5 and (b) HZSM-5 catalysts in the presence of SO<sub>2</sub> and H<sub>2</sub>O; (c) magnified HAADF-STEM image and corresponding EDS maps of the reacted 0.1Fe@ZSM-5; (d) <sup>27</sup>Al MAS NMR spectra; (e) pyridine FTIR spectra; (f) O<sub>2</sub>-TPD patterns of the as-prepared and reacted 0.1Fe@ZSM-5. Reaction conditions: 700 °C, 1000 ppm NH<sub>3</sub>, 6.0 vol.% O<sub>2</sub>, 1000 ppm NO, 300 ppm SO<sub>2</sub>, 8.3 vol% H<sub>2</sub>O and balance N<sub>2</sub> at a space velocity of 30 533 ml g<sub>cat.</sub><sup>-1</sup> h<sup>-1</sup>.

vol% H<sub>2</sub>O at 700 °C. Under 300 ppm SO<sub>2</sub>, 0.1Fe@ZSM-5 deactivated gradually, with NO conversion decreasing from 83.0% to 78.5% over 50 h as shown in Fig. 4a. Introducing 8.3 vol% H<sub>2</sub>O accelerated deactivation and the conversion dropped to 60.1%. After both poisons were removed at 110 h, the catalyst partially recovered to 71.5%. For comparison, HZSM-5 showed a similar slight decline under SO<sub>2</sub> alone, from 77.3% to 72.1% NO conversion. With both SO<sub>2</sub> and H<sub>2</sub>O, the conversion decreased to 60.8% and did not recover after poison removal, indicating irreversible deactivation.

Further physicochemical analyses were performed after 120 h continuous reaction to probe the deactivation mechanism of 0.1Fe@ZSM-5. HAADF-STEM and EDS reveal dispersed Fe nanoparticles. Sulfur deposits distribute

broadly on ZSM-5 with partial co-localization on Fe nanoparticles, while remaining overall dispersed. The <sup>27</sup>Al MAS NMR spectra were used to track the evolution of the framework Al throughout the long-term hydrothermal ageing. As can be seen in Fig. 4d, the broad peak signal of dehydrated 0.1Fe@ZSM-5 is 4-coordinated corresponding to the Brønsted acidic Al(IV) site at 58 ppm. After SO<sub>2</sub> + H<sub>2</sub>O ageing for 120 h, the signal intensity of the framework Al decreases, suggesting a dealumination process.<sup>48</sup> The significant decline of the L<sub>NH<sub>3</sub></sub> peak from Py-IR clearly indicates the loss of Lewis acid sites after long-term poisoning (Fig. 4e). The O<sub>2</sub>-TPD patterns (Fig. 4f) of the as-prepared catalyst and after 120 h in SO<sub>2</sub> and H<sub>2</sub>O confirm a severe loss of lattice oxygen (over 400 °C)<sup>49,50</sup> and diminished oxygen mobility after exposure to SO<sub>2</sub> and H<sub>2</sub>O.

**Fig. 5** Identification of the dual kinetic effect on 0.1Fe@ZSM-5. (a) Comparison of the conventional SCR kinetic model with experimental data under a NO + NH<sub>3</sub> + O<sub>2</sub> atmosphere; effect of reaction temperature on (b) NH<sub>3</sub> concentration and (c) NO<sub>x</sub> selectivity under NH<sub>3</sub> + O<sub>2</sub> oxidation conditions; (d) comparison of the dual kinetic model and experimental data; *in situ* DRIFT spectra for (e) NO + NH<sub>3</sub> + O<sub>2</sub> reduction and (f) NH<sub>3</sub> + O<sub>2</sub> oxidation; (g) evolution of DRIFT spectra on intermediates; (h) schematic illustrating the proposed dual kinetic pathway for high-temperature SCR.

These observations indicate that sulfur deposition blocks active oxygen sites and suppresses lattice oxygen participation in the long-term test.

#### 2.4 Kinetics of NO reduction and NH<sub>3</sub> oxidation

Catalytic experiments revealed that NH<sub>3</sub> oxidation significantly influences the overall reaction kinetics at high temperatures, with its rate being dependent on the Fe loading. Consequently, a conventional kinetic model for standard SCR fails to accurately describe the system at 700 °C (Fig. 5a). We therefore developed a dual-pathway kinetic model that considers both the NH<sub>3</sub> oxidation and NO reduction reactions. The model parameters, governing equations, and diffusion criteria are detailed in the SI.

Under NH<sub>3</sub> + O<sub>2</sub> atmospheric conditions, NH<sub>3</sub> oxidation products on the catalyst surface can be primarily classified as N<sub>2</sub> and NO, with selectivity varying as the temperature increases. Higher temperatures favor higher NO selectivity.

The NO generation rate due to NH<sub>3</sub> oxidation,  $S_{\text{NH}_3\text{-NO}}$ , is considered as shown

$$\frac{dC_{\text{NH}_3}}{dt} = -\rho_{\text{catal}} S_{\text{catal}} \eta_{\text{NH}_3} k_{\text{NH}_3} \theta_{\text{NH}_3} C_{\text{O}_2} \quad (3)$$

$$S_{\text{NH}_3\text{-NO}} = \frac{k_{\text{NH}_3\text{-NO}} \theta_{\text{NH}_3} C_{\text{O}_2}}{k_{\text{NH}_3\text{-NO}} \theta_{\text{NH}_3} C_{\text{O}_2} + k_{\text{NH}_3\text{-N}_2} \theta_{\text{NH}_3} C_{\text{O}_2}} \quad (4)$$

$$\frac{dC_{\text{NO}}}{dt} = -\frac{dC_{\text{NH}_3}}{dt} S_{\text{NH}_3\text{-NO}} = -\frac{dC_{\text{NH}_3}}{dt} \frac{k_{\text{NH}_3\text{-NO}}}{k_{\text{NH}_3\text{-NO}} + k_{\text{NH}_3\text{-N}_2}} \quad (5)$$

Experimental measurement data under NH<sub>3</sub> + O<sub>2</sub> conditions were analyzed by selecting data points where NH<sub>3</sub> conversion remained below 15% to minimize diffusion effects on fitting accuracy. Here,  $\theta_{\text{NH}_3} = \frac{k_{\text{ad}} C_{\text{NH}_3}}{k_{\text{ad}} C_{\text{NH}_3} + 1}$  represents the NH<sub>3</sub> surface coverage. After optimization, the rate constants for NH<sub>3</sub> oxidation reactions at various temperatures yielded an activation energy of 98.3 kJ mol<sup>-1</sup>. The pre-exponential factor  $A$  and activation energy  $E_a$  for the NH<sub>3</sub> oxidation process were subsequently determined by fitting the  $\ln k_x$  vs.  $1/T$  relationship according to the Arrhenius equation. We compare the experimental measurements and model calculations for NH<sub>3</sub> conversion and NH<sub>3</sub>-to-NO oxidation selectivity under NH<sub>3</sub> + O<sub>2</sub> atmospheric conditions. The calculated results demonstrate good agreement with experimental data over the 500–850 °C temperature range (Fig. 5b and c).

Under NH<sub>3</sub> + NO + O<sub>2</sub> atmospheric conditions, the reaction rate of NO is governed by the synergistic interplay between the catalytic reduction of NO by NH<sub>3</sub> and the

concurrent catalytic oxidation of NH<sub>3</sub> to form NO. This dual mechanism significantly influences the overall reaction kinetics, as demonstrated below:

The NO reaction rate can be expressed by the following equation:

$$\frac{dC_{\text{NH}_3}}{dt} = -\rho_{\text{catal}} S_{\text{catal}} \eta_{\text{NH}_3} k_{\text{NH}_3} \theta_{\text{NH}_3} C_{\text{O}_2} \quad (9)$$

$$\frac{dC_{\text{NO}}}{dt} = -\rho_{\text{catal}} S_{\text{catal}} \eta_{\text{NO}} k_{\text{re}} \theta_{\text{NH}_3} C_{\text{NO}} + \frac{dC_{\text{NH}_3}}{dt} S_{\text{NH}_3\text{-NO}} \quad (10)$$

Subsequently, the experimental data obtained under NH<sub>3</sub> + NO + O<sub>2</sub> conditions were systematically analyzed. Given the relatively low SNCR efficiency observed below 850 °C, gas-phase NH<sub>3</sub> + NO + O<sub>2</sub> reactions were excluded from consideration in this temperature range. To minimize the influence of mass transfer limitations on fitting accuracy, experimental data points with NO conversion rates below 15% were specifically selected for kinetic analysis. Through optimization procedures, the rate constants for NO catalytic reduction reactions were determined at various temperatures. The pre-exponential factor ( $A$ ) and activation energy ( $E_a$ ) for the NH<sub>3</sub> oxidation process were subsequently derived by fitting the  $\ln(k_x)$  versus  $1/T$  relationship according to the Arrhenius equation, as presented in Table S4.

Compared to conventional SCR kinetic models, this work introduces a dual kinetic framework that explicitly incorporates NH<sub>3</sub> surface oxidation as a competing reaction under high-temperature conditions. A key feature of this framework is the inclusion of the selectivity of NH<sub>3</sub> toward NO formation as a temperature-dependent parameter, which allows quantitative evaluation of how the NH<sub>3</sub> over-oxidation pathway influences the overall SCR performance. This integration provides a more accurate description of the experimental results (Fig. 5d). As the temperature rises, the model successfully captures the transition where the NO formation rate surpasses the N<sub>2</sub> formation rate, revealing the increasing contribution of NH<sub>3</sub> oxidation in determining overall selectivity. By incorporating this temperature-dependent selectivity, the dual kinetic model addresses a gap in prior SCR kinetic frameworks, which typically treat NH<sub>3</sub> oxidation as a parallel but independent side reaction.

To explore the effect of NH<sub>3</sub> catalytic oxidation on SCR-related intermediates, *in situ* DRIFT measurements combined with TPSR were performed on 0.1Fe@ZSM-5 from 400 to 850 °C (Fig. 5e). Following NH<sub>3</sub> adsorption, broad N–H vibration peaks at 3259 and 2936 cm<sup>-1</sup> are ascribed to

intensity of the band corresponding to  $\text{NH}_3$  coordinated to Lewis acid sites decreased, while the band assigned to  $\text{NH}_4^+$  ions at  $1471\text{ cm}^{-1}$  grew substantially. This shift indicates that  $\text{NH}_3$  preferentially adsorbs at Brønsted acid sites in the presence of metallic Fe species, where it forms more stable  $\text{NH}_4^+$  species. The enhanced stability at Brønsted sites suppresses the excessive oxidation of  $\text{NH}_3$  at high temperatures, thereby improving the selectivity toward  $\text{N}_2$  formation.<sup>54</sup> Furthermore, the band at  $3259\text{ cm}^{-1}$ , attributed to  $\text{NH}_4^+$  ions interacting with Brønsted acid sites of the zeolite, was attenuated, indicating a weaker interaction between the agglomerated iron species and the zeolite framework.

As the temperature was increased (Fig. 6d–f), the intensity of all ammonia-related bands decreased, indicating the progressive desorption of  $\text{NH}_3$  from the acid sites. Notably, the evolution of the surface species differed significantly with iron loading. For the low-loading  $0.05\text{Fe@ZSM-5}$  and  $0.08\text{Fe@ZSM-5}$  catalysts, the bands for  $\text{NH}_3$  adsorbed on Lewis acid sites were almost completely consumed by  $700\text{--}850\text{ }^\circ\text{C}$ , whereas the signals for  $\text{NH}_4^+$  and  $\text{NH}_2^*$  species persisted. This suggests that the latter are more thermally stable and likely serve as key intermediates in the redox reaction. In contrast, for the  $0.5\text{Fe@ZSM-5}$  catalyst, the bands corresponding to nitrosyl species at  $1846\text{ cm}^{-1}$  were significantly more intense.<sup>55</sup> Concurrently, the consumption of the  $\text{NH}_4^+$  band at  $3259\text{ cm}^{-1}$  was more pronounced, indicating that the larger iron nanoparticles promote the undesirable over-oxidation of ammonia to NO at high temperatures, which is in agreement with the observed SCR performance.

### 3 Conclusions

In summary, we have developed a sinter-resistant  $0.1\text{Fe@ZSM-5}$  catalyst whose exceptional stability in high-temperature  $\text{NH}_3\text{-SCR}$  is attributed to the confinement of ultrasmall Fe nanoclusters within the zeolite framework. Its structural integrity was confirmed, with minor long-term deactivation resulting from sulfur deposition rather than framework collapse or Fe sintering. Through a combination of *in situ* DRIFTS and kinetic analysis, we have established a dual-pathway mechanism that accurately captures the transition from the conventional NO-reduction route to the high-temperature  $\text{NH}_3$ -oxidation-dominated regime. Unlike traditional SCR kinetic models, which assume independent or single-pathway behavior, the dual-pathway model explicitly incorporates the competing oxidation of  $\text{NH}_3$  by treating the selectivity of  $\text{NH}_3$  toward NO formation as a temperature-dependent parameter. This approach reveals how the interplay between  $\text{NH}_3$  consumption by oxidation and its availability for SCR modifies apparent activation energies and selectivity trends, providing improved predictive capability across the entire temperature range. These studies identified the distinct roles of key surface intermediates, providing direct evidence for  $\text{NH}_2^*$  as a critical species in the NO reduction pathway, which competes with the  $\text{NH}_3$  oxidation route. These findings

offer a new strategy for the rational design of robust catalysts for challenging industrial applications. The development of a stable catalyst structure, coupled with a more accurate kinetic model, paves the way for advancing high-performance de $\text{NO}_x$  technologies to meet stringent emission regulations.

## 4 Experimental and computational section

### 4.1 Catalyst synthesis and activity measurement

The HZSM-5 zeolite was prepared *via* a hydrothermal synthesis route. A precursor gel was formed by dissolving ethylenediamine (EDA, 1.20 g), tetraethyl orthosilicate (TEOS, 8.32 g), NaOH (0.3 g), and  $\text{NaAlO}_2$  (1.02 g) in an aqueous solution containing distilled water (15 g) and the structure-directing agent (SDA), tetramethylammonium hydroxide ( $\text{TMADa}^+$ , 13 g). After stirring for 6 h at room temperature, the gel was transferred to a 100 mL Teflon-lined autoclave and crystallized at  $170\text{ }^\circ\text{C}$  for 3 days. The resulting solid product was calcined at  $800\text{ }^\circ\text{C}$  for 5 h (with a heating ramp of  $5\text{ }^\circ\text{C min}^{-1}$ ) to remove the SDA. To produce the final parent material, the calcined powder was ion-exchanged by washing three times with a 0.2 M  $\text{NH}_4\text{NO}_3$  solution at  $70\text{ }^\circ\text{C}$ , followed by drying at  $110\text{ }^\circ\text{C}$  for 12 h.

For the fabrication of  $\text{Fe@ZSM-5}$ , a suspension was created by mixing 10 g of HZSM-5 in 100 ml of distilled water, under intense stirring. The necessary quantity of iron acetylacetonate ( $\text{Fe}(\text{C}_5\text{H}_7\text{O}_2)_3$ ) was dissolved in this mixture. Ensuing continuous magnetic agitation at  $80\text{ }^\circ\text{C}$  for 3 h facilitated the homogenization of the solution, which was then subjected to filtration and thrice rinsed with distilled water. The filtrate was air-dried at  $110\text{ }^\circ\text{C}$  for 12 h, followed by calcination in a muffle furnace at  $800\text{ }^\circ\text{C}$  for 5 h under ambient air conditions. The resultant catalyst particles were sieved to obtain a granule size range between 0.18 and 0.25 mm.

The catalytic performance for the  $\text{NH}_3\text{-SCR}$  of  $\text{NO}_x$  was evaluated in a continuous-flow quartz fixed-bed reactor over a temperature range of  $400\text{--}850\text{ }^\circ\text{C}$ . The standard feed gas consisted of 1000 ppm  $\text{NH}_3$ , 1000 ppm NO, and 6 vol%  $\text{O}_2$ , with  $\text{N}_2$  as the balance gas. The total flow rate was maintained at  $2\text{ L min}^{-1}$  using mass flow controllers, corresponding to a gas hourly space velocity (GHSV) of  $30\,000\text{ h}^{-1}$ . The effluent gas concentrations (NO,  $\text{NH}_3$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}_2$ , and  $\text{O}_2$ ) were continuously monitored using an online infrared (IR) gas analyzer. To comprehensively assess the catalyst, several experiments were conducted: (i) the effect of GHSV on NO reduction was systematically investigated; (ii) long-term stability tests were performed under standard reaction conditions; (iii) the catalyst's resistance to poisoning was evaluated in the presence of 300 ppm  $\text{SO}_2$  and/or 8.3 vol%  $\text{H}_2\text{O}$ . Prior to data acquisition for each point, the system was allowed to reach a steady state, and the reported values represent the average of

measurements taken over a 20 minute period. The NO reduction efficiency, N<sub>2</sub> selectivity, and apparent reaction kinetics were calculated using the following equations:

$$X_{\text{NO}} = \left( \frac{[\text{NO}]_{\text{inlet}} - [\text{NO}]_{\text{outlet}}}{[\text{NO}]_{\text{inlet}}} \right) \times 100\% \quad (11)$$

$$\begin{aligned} & \text{N}_2 \text{ selectivity (\%)} \\ & = \left( 1 - \frac{[\text{NO}_2]_{\text{outlet}} + 2[\text{N}_2\text{O}]_{\text{outlet}}}{[\text{NH}_3]_{\text{inlet}} + [\text{NO}]_{\text{inlet}} - [\text{NH}_3]_{\text{outlet}} - [\text{NO}]_{\text{outlet}}} \right) \times 100\% \end{aligned} \quad (12)$$

$$k [\text{mol g}^{-1} \text{s}^{-1}] = \frac{X_{\text{NO}} [\%] \times F_{\text{NO}} [\text{L min}^{-1}]}{m [\text{g}] \times 60 [\text{s min}^{-1}] \times 22.4 [\text{L min}^{-1}] \times 100} \quad (13)$$

where  $X_{\text{NO}}$  denotes the conversion efficiency of NO,  $k$  represents the catalyst's reaction rate,  $F_{\text{NO}}$  is the initial flow rate of NO through the system, and  $m$  indicates the mass of the catalyst utilized.

#### 4.2 Characterization and computational methods

The loading of Fe was determined by inductively coupled plasma (ICP, Agilent ICP-OES 725 ES). The crystallinity was assessed by X-ray diffraction (XRD) using a D8 Advance instrument with a scanning angle range (2-theta) from 5° to 90°. X-ray photoelectron spectroscopy (XPS) was conducted on a Thermo Scientific Nexsa. The obtained binding energy was externally calibrated by the carbonaceous C 1s of 284.6 eV. Surface areas and pore size distributions were quantified *via* the Brunauer–Emmett–Teller (BET) analysis and Barrett–Joyner–Halenda (BJH) method, determined by N<sub>2</sub> physisorption performed on an ASAP 2460 (Micromeritics) by degassing at 150 °C for 8 h. The morphologies were investigated using scanning electron microscopy (SEM) and scanning-transmission electron microscopy (STEM) *via* an FEI, Tecnai F20. Electron energy loss spectroscopy (EELS) was conducted with a Gatan Model 977 Enfinitum ER EELS spectrometer. *In situ* infrared spectroscopy and diffuse reflectance UV-vis spectroscopy (UV-3600i Plus, Shimadzu) were employed to explore the dynamics of the catalytic processes. Nuclear magnetic resonance (NMR, Bruker 400 M) and K-edge X-ray absorption fine structure (XAFS) analyses were performed with Si (111) crystal monochromators at the BL14W beam line at the Shanghai Synchrotron Radiation Facility (SSRF) (Shanghai, China). Before the analysis at the beamline, samples were placed into aluminum sample holders and sealed using Kapton tape film. The XAFS spectra were recorded at room temperature using a 4-channel silicon drift detector (SDD) Bruker 5040. The obtained spectra were refined and analyzed using Athena. Athena and Artemis software programs were employed to perform the EXAFS fitting.<sup>56</sup> The software developed by Funke and Chukalina was applied to execute wavelet transformation using the Morlet wavelet with  $\kappa = 5$  and  $\sigma = 1$ .<sup>57</sup>

Hydrogen temperature-programmed reduction (H<sub>2</sub>-TPR) was conducted on an AutoChem II 2920 instrument to

evaluate the reducibility of the catalysts. In a typical measurement, 100 mg of the sample was loaded into a U-shaped quartz tube. The catalyst was pretreated at 300 °C for 1 h under a flowing He atmosphere (heated at 10 °C min<sup>-1</sup>) to remove adsorbed water. After the sample was cooled to 50 °C, the gas flow was switched to a 10 vol% H<sub>2</sub>/He mixture (30 mL min<sup>-1</sup>). The temperature was then ramped to 800 °C at a rate of 10 °C min<sup>-1</sup>, and H<sub>2</sub> consumption was continuously monitored with a thermal conductivity detector (TCD).

The acidic properties of the catalysts were characterized by ammonia temperature-programmed desorption (NH<sub>3</sub>-TPD) and oxygen storage and mobility were evaluated by oxygen temperature-programmed desorption (O<sub>2</sub>-TPD) using the same instrument. Prior to the analysis, 100 mg of the sample was pretreated in a He flow at 300 °C for 1 h (10 °C min<sup>-1</sup> ramp) and cooled to 50 °C. For NH<sub>3</sub>-TPD, the sample was saturated with ammonia by exposure to a 10% NH<sub>3</sub>/Ar stream (25 mL min<sup>-1</sup>) for 1 h, followed by Ar purging for 1 h to remove physisorbed ammonia, and then heated to 800 °C at a rate of 10 °C min<sup>-1</sup>, monitoring the amount of desorbed NH<sub>3</sub> using the TCD. In O<sub>2</sub>-TPD, oxygen saturation was achieved by exposing the pretreated sample to 10% O<sub>2</sub>/He (25 mL min<sup>-1</sup>) for 1 h, followed by Ar purging for 1 h and subsequent heating to 800 °C at 10 °C min<sup>-1</sup>.

#### 4.3 Reaction kinetics modeling

For the fixed bed reactor, the following assumptions were made: 1. negligible volumetric flow changes along the catalyst bed, maintaining consistency throughout the reaction section; 2. negligible pressure variations before and after the catalyst bed, *i.e.*, no pressure drop; 3. negligible radial and axial diffusion, maintaining uniform gas concentration at the interface. These assumptions simplified the model to a one-dimensional plug flow reaction process, establishing the conservation equation for gas component  $x$ :

$$\frac{\partial C_x}{\partial t} + u \frac{\partial C_x}{\partial z} = r_x \quad (14)$$

where  $u$  represents the main gas flow linear velocity (m s<sup>-1</sup>), and  $r_x$  represents the reaction rate of component  $x$  (mol m<sup>-3</sup> s<sup>-1</sup>). The corresponding boundary conditions are:

$$\begin{cases} z = 0, C_x = C_{x,\text{inlet}} \\ z = h, C_x = C_{x,\text{outlet}} \end{cases} \quad (15)$$

The catalyst bed thickness is  $h$ ,  $C_x$  represents the component concentration of reactants/products (mol m<sup>-3</sup>), primarily C<sub>NH<sub>3</sub></sub>, C<sub>NO</sub>, and C<sub>O<sub>2</sub></sub> in this study, and  $k_x$  (mol m<sup>-2</sup> s<sup>-1</sup>) represents the reaction rate constant for each component. Subsequently, the rate equation was established:

$$r_x = k_x f(C_x) \quad (16)$$

Specifically, for the  $\text{NH}_3 + \text{O}_2$  catalytic oxidation process on 0.1Fe@ZSM-5,  $\text{NH}_3$  adsorption based on the Langmuir model and  $\text{O}_2$  effects were primarily considered.<sup>58</sup> For the comprehensive  $\text{NH}_3 + \text{NO} + \text{O}_2$  reaction process, referring to standard SCR kinetic models, the reaction orders for  $\text{NH}_3$ ,  $\text{NO}$ , and  $\text{O}_2$  are 0, 1, and 0.5, respectively.<sup>59</sup> The  $\text{O}_2$  content in coal combustion flue gas is approximately 6 vol%, with concentrations being orders of magnitude higher than other reaction gases, allowing neglect of concentration changes due to reaction during calculations. Additionally, according to the Mear criterion, since the external diffusion rate of catalyst particles is much lower than the reaction rate, diffusion effects on the gas–solid reaction process in this study can be neglected.<sup>60</sup>

Considering the influence of reactant gas internal diffusion within catalyst particles, an effectiveness factor  $\eta$  was introduced:

$$\eta = \frac{2}{\phi_1} (\phi_1 \coth \phi_1 - 1) \quad (17)$$

The Thiele modulus expression is given as  $\phi_1 = R\sqrt{\frac{k_x}{D_{x,\text{eff}}}}$ , where  $R$  represents the catalyst particle diameter (m). For molecular sieve catalysts with porous structure characteristics, the comprehensive diffusion coefficient  $D_{x,\text{eff}}$  ( $\text{m}^2 \text{s}^{-1}$ ) of gas component  $x$  is not only influenced by molecular diffusion and Knudsen diffusion (assuming a zeolite pore diameter of 10 nm) but also requires porosity correction. For the catalytic  $\text{NO}_x$  reduction reaction, the effectiveness factor  $\phi_n$  approaches 1, indicating that the entire process is under surface reaction control. Other model-related parameter values are shown in Table S5.

$$D_{x,\text{eff}} = \varepsilon^2 D_x \quad (18)$$

Here,  $D_{x,\text{gas}}$  represents the diffusion coefficient of reaction gases in air. For  $\text{NH}_3$ , the Fuller equation yields a calculated value of  $0.198 \text{ cm}^2 \text{ s}^{-1}$  under standard conditions, while the diffusion coefficient of  $\text{NO}$  molecules in air is  $0.168 \text{ cm}^2 \text{ s}^{-1}$  (with temperature corrections applied as needed). In actual reaction processes, gas–solid reactions compete with intraparticle diffusion  $D_{x,\text{KA}} = \frac{d_{\text{pore}}}{3} \sqrt{\frac{8k_B NT}{\pi M}}$ . The combined effects of intraparticle diffusion and the chemical reaction on the overall reaction rate can be determined through the effectiveness factor and Thiele modulus.

#### 4.4 *In situ* DRIFT measurement

*In situ* DRIFT spectroscopic analysis was conducted using a NICOLET iS50 FTIR spectrometer. Diffuse reflectance infrared Fourier transform spectra (DRIFTS) were acquired with a Harrick Praying Mantis attachment (Model DRK-4, featuring a water-cooling circulation system). Ambient diffuse reflectance UV-vis spectroscopy was performed on a Cary 400 spectrometer

(Varian) outfitted with a diffuse reflectance unit. These UV-vis and DRIFTS examinations are pivotal for elucidating the nature of transient species in the *in situ* SCR process, thereby enhancing our comprehension of the reaction dynamics. To optimize detector performance, specifically the mercury cadmium telluride (MCT/A) detector, liquid nitrogen was utilized to regulate its operational temperature. The temperature within the experimental chamber was managed using a Harrick temperature control unit (Model ATC-024-2), complemented with a water-cooling system to mitigate potential overheating. Prior to initiating measurements, background spectra were obtained using the prepared samples. Subsequently, the catalyst was evenly distributed within the Harrick chamber. A mixture of reaction gases ( $\text{NH}_3/\text{NO}/\text{O}_2/\text{He}$ ) was precisely regulated using mass flow controllers (MFCs) and warmed before being introduced into the chamber, with an overall gas flow rate set at  $50 \text{ mL min}^{-1}$ .

The procedure for conducting *in situ* UV-vis and DRIFTS analyses comprised the following steps: (1)  $\text{NH}_3$  adsorption: the chamber was purged with He at  $500 \text{ }^\circ\text{C}$  for 1 h and then brought back to ambient temperature. Subsequently, a flow of 1000 ppm  $\text{NH}_3/\text{He}$  was introduced, gradually elevating the temperature from 100 to  $800 \text{ }^\circ\text{C}$  at  $10 \text{ }^\circ\text{C min}^{-1}$ . (2)  $\text{NH}_3$  oxidation: upon reaching adsorption equilibrium (typically within 1 h) at a set temperature, 6 vol%  $\text{O}_2$  was infused into the chamber for 30 min. (3)  $\text{NH}_3$ – $\text{NO}$ – $\text{O}_2$  co-presence and pulse: following equilibrium establishment (usually within 30 min) at the required temperature, a mixture of 1000 ppm  $\text{NO}$ , 6 vol%  $\text{O}_2$ , and 1000 ppm  $\text{NH}_3$  in He was simultaneously fed into the chamber at  $800 \text{ }^\circ\text{C}$ . For pulse tests, specific gas components were selectively discontinued. For the temperature programmed surface reaction (TPSR), the reaction chamber was heated from  $400 \text{ }^\circ\text{C}$  to  $850 \text{ }^\circ\text{C}$  in 1000 ppm  $\text{NO}$  and 6 vol%  $\text{O}_2$  after exposure to 1000 ppm  $\text{NH}_3/\text{He}$  for 1 h. *In situ* DRIFT spectra were recorded every 8 seconds, and the IR spectrum presented subsequently represents the average interference pattern across eight successive scans.

The acidity of the samples was determined by pyridine infrared spectroscopy (Py-IR) on a Bruker Vector 22 spectrophotometer. Prior to the tests, the samples were shaped into tablets and degassed under vacuum at  $400 \text{ }^\circ\text{C}$  for 1 h. After cooling to room temperature (RT), the samples were saturated with pyridine and then desorbed at RT, 200, and  $450 \text{ }^\circ\text{C}$  under vacuum for 30 min. The IR spectra were registered in the  $1400$ – $1700 \text{ cm}^{-1}$  range.
