Feasibility of switchable dual function materials as a flexible technology for CO_2 capture and utilisation and evidence of passive direct air capture†

Loukia-Pantzechroula Merkouri,[a] Tomas Ramirez Reina [ID] *[a,b] and Melis S. Duyar [ID] *[a]

The feasibility of a Dual Function Material (DFM) with a versatile catalyst offering switchable chemical synthesis from carbon dioxide (CO_2) was demonstrated for the first time, showing evidence of the ability of these DFMs to passively capture CO_2 directly from the air as well. These DFMs open up possibilities in flexible chemical production from dilute sources of CO_2, through a combination of CO_2 adsorption and subsequent chemical transformation (methanation, reverse water gas shift or dry reforming of methane). Combinations of Ni Ru bimetallic catalyst with Na_2O, K_2O or CaO adsorbent were supported on CeO_2–Al_2O_3 to develop flexible DFMs. The designed multicomponent materials were shown to reversibly adsorb CO_2 between the 350 and 650 °C temperature range and were easily regenerated by an inert gas purge stream. The components of the flexible DFMs showed a high degree of interaction with each other, which evidently enhanced their CO_2 capture performance ranging from 0.14 to 0.49 mol kg^{-1}. It was shown that captured CO_2 could be converted into useful products through either CO_2 methanation, reverse water–gas shift (RWGS) or dry reforming of methane (DRM), which provides flexibility in terms of co-reactant (hydrogen *vs.* methane) and end product (synthetic natural gas, syngas or CO) by adjusting reaction conditions. The best DFM was the one containing CaO, producing 104 μmol of CH_4 per kg_{DFM} in CO_2 methanation, 58 μmol of CO per kg_{DFM} in RWGS and 338 μmol of CO per kg_{DFM} in DRM.

1. Introduction

Global warming is increasing at an alarming rate, as carbon dioxide (CO_2) emissions reached 33 Gt in 2021.[1] Efforts, such as the Paris Agreement in 2015, are continuously made in attempt to control greenhouse gas concentrations and thus the extent of global warming,[2] while there is a need to achieve net zero CO_2 emissions by 2050 and have a substantial decrease in CO_2 emissions after 2030.[3] A solution to control CO_2 emissions is Carbon Capture, Utilisation and Storage (CCUS).[4] The current state-of-the-art technologies in terms of CO_2 capture include the widely commercialised amine absorption systems.[5–8] An alternative to amine absorption is solid adsorption, *e.g.* metal organic frameworks MOFs, zeolites, and alkali/alkaline oxides/carbonates. During adsorption, CO_2 is either chemisorbed or physisorbed onto the adsorbent's surface until

breakthrough, or saturation, is reached. The desorption of a concentrated CO_2 stream usually occurs *via* a pressure or temperature swing process.[5,9] The CO_2 utilisation step involves the use of CO_2 to produce added-value chemicals and fuels and is appealing because of the need for carbon in the chemical industry to produce chemicals. Currently CO_2 is used mainly in the production of urea (~160 Mt per year). However, CO_2 being a highly stable molecule thermodynamically, catalysts are needed for its conversion into various products.[8,10–12]

As far as the CO_2 catalytic upgrading routes are concerned, the dry reforming of methane (DRM),[13–15] the reverse water–gas shift (RWGS)[16–19] and the CO_2 methanation reactions[16,20,21] have attracted substantial attention in recent years. In DRM (eqn (1)), two of the most harmful greenhouse gases (CO_2 and CH_4) react to form syngas, which is a mixture of carbon monoxide (CO) and hydrogen (H_2). DRM can be used for biogas upgrading purposes because biogas is mainly a mixture of CO_2 and methane (CH_4). DRM requires high temperatures and catalysts developed for DRM are susceptible to deactivation *via* coke formation.[8,13] In RWGS (eqn (2)), hydrogen is used to reduce CO_2 to CO while producing water as byproduct. CO is an important chemical reagent for industrial chemicals synthesis such as through carbonylation reac-

tions. Careful catalyst design is necessary, to ensure selectivity towards CO and to overcome the competition with the CO_2 methanation reaction. H_2/CO ratio can be adjusted *via* the RWGS reaction to increase conversion while yielding a specific mixture of CO and H_2 (known as syngas) that can then be used for downstream chemicals production *via* methanol synthesis or Fischer–Tropsch synthesis.[8,10,16,22] CO_2 methanation (eqn (3)), which is another CO_2 hydrogenation reaction, can be used for the production of CH_4, or synthetic natural gas. This reaction attracted a lot of attention both in the 1970s, during the oil crisis, and nowadays, because of its possible use in power to gas schemes. As CO_2 methanation is favoured at lower temperatures, active catalysts are needed for overcoming significant kinetic limitations.[8,10,23] The aforementioned reactions are presented below.

DRM:

$$CO_2 + CH_4 \rightleftharpoons 2CO + 2H_2 \quad \Delta H_{298\ K} = +247\ kJ\ mol^{-1} \quad (1)$$

RWGS:

$$CO_2 + H_2 \rightleftharpoons CO + H_2O \quad \Delta H_{298\ K} = +41\ kJ\ mol^{-1} \quad (2)$$

CO_2 methanation:

$$CO_2 + 4H_2 \rightleftharpoons CH_4 + 2H_2O \quad \Delta H_{298\ K} = -165\ kJ\ mol^{-1} \quad (3)$$

The use of Dual Function Materials (DFMs) integrates CO_2 capture and utilisation to lower the energy demands, and thus the cost of CCU processes through a process intensification approach.[24] They are designed to work in cyclic operation, *i.e.* in successive CO_2 capture and reduction cycles based on a spill over mechanism.[25–27] DFMs are able to capture the CO_2 from a flue gas stream or air and then to catalyse it to produce various chemicals based on the co-reactant used. The most studied catalytic materials are the noble metals, like ruthenium (Ru) and rhodium (Rh) due to their increased catalytic activity in the DRM, RWGS and CO_2 methanation reactions. However, their high cost can be prohibitive and efforts are made to use cheaper, but highly active materials, such as nickel (Ni). The most studied reaction for the DFMs application to date is CO_2 methanation.[28–31] This reaction offers an isothermal solution to the DFMs system because the exothermicity of the CO_2 methanation can supply the required heat for the CO_2 desorption and its spill-over onto the catalytic sites.[24,27,32] The development of DFMs in the RWGS and DRM is still in its infancy, but several studies in RWGS[33–37] and DRM[38–41] have shown potential and are worthy of notice because the DFMs overcome their current limitations. A comprehensive summary of all DFMs studied can be found in some recent reviews.[28–31,42]

In our previous study, we examined the feasibility of using a switchable catalyst to catalyse the CO_2 methanation, RWGS, and DRM reactions that offers flexibility in terms of CO_2 utilisation in a changing energy landscape,[43] while other studies exist in literature.[44,45] It was shown that a combination of Ni and Ru onto a ceria oxide–alumina oxide support (CeO_2–Al_2O_3) was able to efficiently catalyse all three reactions

("switching" between them) by simply changing the reaction conditions, *i.e.* the co-reactant and the temperature. Herein, we present the flexible DFMs, which combine one of three adsorbents (Na_2O, K_2O or CaO) with the Ni–Ru switchable catalyst. This study is the proof of concept for switchable DFMs. CeO_2 was used as a support in combination with the widely used in DFMs Al_2O_3 due to its excellent redox properties and its important role in the CO_2 adsorption and conversion to various products.[43,44,46,47] The addition of Ru to Ni was chosen due to its ease of transformation between its oxides and metallic species which is carried out at low temperatures and is helpful when CO_2 capture is performed in a realistic oxidising environment. Their combination has also been effective to enable product versatility since their strong interaction leads to electronically rich surfaces which are active sites for reactants activation.[43,44]

The switchable DFMs system integrates the benefits of DFMs, as described earlier, with switchable catalysts. The flexibility in chemical synthesis offers a solution to the changing energy sector in the near-term future and resilience against the fluctuation in the supply and demand of chemicals. It is known that there is a seasonal and annual demand change; for example, methane is currently used for residential heating in the winter, but hydrogen is considered for use as residential fuel in the future.[48] Flexible DFMs allow versatile process designs that can work in different modes. For instance, synthetic natural gas may be produced when excess renewable electricity exists or when more heating is needed during winter, while by simply changing the reactor conditions, syngas or CO may be produced to act as a building block in the chemical industry for the production of dimethyl ether, urea, methanol and hydrocarbons. Herein we demonstrate the feasibility of switchable DFMs for the first time, while exploring the adsorption of CO_2 at different temperatures and evaluating the design principles needed to develop DFMs for switchable operation.

2. Experimental

2.1. Dual function materials synthesis

The three DFMs of this study were prepared by sequential impregnation. The adsorbents were impregnated onto the CeO_2–Al_2O_3 support and then, the two transition metals, Ni and Ru, were impregnated onto the supported adsorbents, as it was previously shown that impregnating metals on adsorbents resulted in better DFMs performance.[24] Table 1 shows the designed materials composition and the abbreviations used in this work.

Supported adsorbents were prepared by initially mixing the required amounts of the CeO_2–Al_2O_3 support (SCFa-160 Ce20 Puralox, Sasol) and $NaNO_3$ (Fluka), KNO_3 (Sigma Aldrich), and $Ca(NO_3)_2 \cdot 4H_2O$ (Sigma Aldrich) with deionised water. The suspensions were then mixed at room temperature with a magnetic stirrer and the excess water was removed in a rotary evaporator under reduced pressure. Afterwards, they were dried

Table 1 Materials composition and abbreviations

Material	Abbreviation	Catalyst loading (wt%)	Adsorbent loading (wt%)
$Na_2O/CeO_2-Al_2O_3$	Na	—	11.9 wt% Na_2O
$K_2O/CeO_2-Al_2O_3$	K	—	11.9 wt% K_2O
$CaO/CeO_2-Al_2O_3$	Ca	—	11.9 wt% CaO
$Ni-Ru/CeO_2-Al_2O_3$	NiRu	15 wt% Ni, 1 wt% Ru	—
$Ni-Ru, Na_2O/CeO_2-Al_2O_3$	NiRuNa	15 wt% Ni, 1 wt% Ru	10 wt% Na_2O
$Ni-Ru, K_2O/CeO_2-Al_2O_3$	NiRuK	15 wt% Ni, 1 wt% Ru	10 wt% K_2O
$Ni-Ru, CaO/CeO_2-Al_2O_3$	NiRuCa	15 wt% Ni, 1 wt% Ru	10 wt% CaO

overnight at 120 °C and calcined at 400 °C for 4 hours (5 °C min^{-1}). The resulting supported adsorbents were the $Na_2O/CeO_2-Al_2O_3$, $K_2O/CeO_2-Al_2O_3$, and $CaO/CeO_2-Al_2O_3$.

A similar impregnation procedure was performed when synthesising the three DFMs. The required amounts of $Ni(NO_3)_2 \cdot 6H_2O$ (Acros Organics) and $Ru(NO)(NO_3)_3$ solution (1.5 w/v Ru, Alfa Aesar) were mixed with the supported adsorbents in order to obtain 15 wt% Ni and 1 wt% Ru. These were mixed with excess deionised water, which was then removed in a rotary evaporator under reduced pressure, dried overnight at 120 °C, and calcined at 500 °C for 3 hours (5 °C min^{-1}). The amount of adsorbent precursor used for the supported adsorbents was adjusted to give a final DFMs loading of 10 wt% of the respective oxides and so the resulting supported adsorbents had 11.9 wt% Na_2O, K_2O, and CaO. Therefore, the prepared DFMs were the 15 wt% Ni, 1 wt% Ru–10 wt% $Na_2O/CeO_2-Al_2O_3$, the 15 wt% Ni, 1 wt% Ru–10 wt% $K_2O/CeO_2-Al_2O_3$, and the 15 wt% Ni, 1 wt% Ru–10 wt% $CaO/CeO_2-Al_2O_3$. In some experiments, the 15 wt% Ni, 1 wt% Ru/$CeO_2-Al_2O_3$ switchable catalyst, whose synthesis method was described in,[43] was used as a reference material so as to show the impact of the addition of the adsorbents. In order for the supported adsorbents to have the same heat treatment as DFMs, they were recalcined at 500 °C for 3 hours (5 °C min^{-1}). For the sake of simplicity, the supported adsorbents were called Na, K, and Ca, the DFMs, NiRuNa, NiRuK, and NiRuCa, and the switchable catalyst NiRu.

2.2. Characterisation

The Brunauer–Emmett–Teller (BET) equation and the Barett–Joyner–Halenda (BJH) methods were used to obtain the specific surface area and pore volume of the materials. Initially, degassing at 250 °C in vacuum for 4 hours took place and then, the textural properties of the materials were determined by nitrogen adsorption–desorption measurements at −195 °C in a Micrometrics 3Flex apparatus.

X-ray Diffraction (XRD) was performed on fresh supported adsorbents and on fresh, reduced, and spent DFMs in a X'Pert Powder from PANalytical apparatus. The diffraction patterns were obtained at 30 mA and 40 kV by using Cu Kα radiation (λ = 0.154 nm). The $2\theta°$ angle was increased every 450 seconds by 0.05° in the range of 10–90°.

Scanning Electron Microscopy (SEM) was carried out on the fresh supported adsorbents and DFMs by using a JEOL JSM-7100F instrument, which also had an Energy Dispersive

X-ray Spectroscope (EDS) analyser. Carbon paint was used to fix the samples to the holder and gold coating was conducted to eliminate the charging effects.

Transmission Electron Microscopy (TEM) was carried out on the reduced DFMs in a Talos F200I instrument from ThermoFisher with an electron source of 200 kV. The DFMs were reduced *ex situ* at 800 °C for 1 hour at a 50 ml min^{-1} total flow rate of a 10% H_2/N_2 mixture. To prepare the TEM samples, the materials were dispersed in ethanol in an ultrasonic bath, dropped onto copper grids coated with lacey carbon film and dried. Prior to sample insertion in the instrument, the specimen holder with the sample was dried in a UV furnace.

H_2-Temperature Programmed Reduction (H_2-TPR) was performed on the fresh (after calcination) DFMs in fixed bed quartz reactor. The data were logged by using the Quadera software package and the H_2 consumption was observed in an online mass spectrometer (Omni-Star GSD 320). A 10% H_2/Ar mixture with a total flow of 50 ml min^{-1} was passed through the reactor with 50 mg of sample while the temperature was raised from room temperature to 950 °C with 10 °C min^{-1} rate.

CH_4-Temperature Programmed Surface Reaction (CH_4-TSPR) was conducted on the fresh NiRuCa sample in a fixed bed reactor similar to H_2-TPR experiments. In this experiment, 30 mg of fresh (after calcination) NiRuCa was used and the temperature was increased from room temperature to 950 °C (10 °C min^{-1}) with a pure CH_4 feed of 30 ml min^{-1}. No N_2 was used in the feed in order the mass to charge ratio (m/z) of 28 to be solely attributed to CO.

CO_2-Temperature Programmed Desorption (CO_2-TPD) was carried out on fresh DFMs and adsorbents in a fixed bed quartz reactor. In the CO_2-TPD experiments, 50 mg of sample were initially reduced *in situ* at 800 °C for 1 hour with a 10% H_2/N_2 mixture and a total flow of 50 ml min^{-1} (10 °C min^{-1}). After cooling down to 40 °C with a N_2 purge, a 50 ml min^{-1} flow of a 10% CO_2/N_2 mixture was used for 45 minutes to saturate the samples. Subsequently, 50 ml min^{-1} of N_2 was introduced through the reactor to remove the weakly adsorbed CO_2 for 30 minutes and, finally, the temperature was raised to 800 °C at a 10 °C min^{-1} rate. The mass to charge ratio (m/z) of 44 corresponding to CO_2 was recorded using an online mass spectrometer (Omni-Star GSD 320) during the temperature ramp.

Thermogravimetric Analysis (TGA) was performed on the reduced and post-reaction DFMs in an SDT650 apparatus from

TA Instruments in order to measure the amount of carbon depositions. A flow of 100 mL min⁻¹ of air was employed while the temperature was raised from room temperature to 950 °C at a 10 °C min⁻¹ rate.

2.3. Performance testing

2.3.1. Adsorption and desorption study at different temperatures. An SDT650 apparatus from TA Instruments was used so as to understand the adsorption and desorption behaviour of the materials at different temperatures. 10–15 mg of a reduced sample was used in each run. Firstly, the temperature was increased from room temperature to 150 °C with 100 mL min⁻¹ of Ar at a 10 °C min⁻¹ rate and was held at that temperature for 30 minutes in order for all the weakly adsorbed gases to be desorbed. Next, it was raised to 350 °C, 450 °C, 550 °C, or 650 °C with the same Ar flow and temperature rate as before. Subsequently, the temperature was stabilised at the desired level for 200 minutes, allowing 5 cycles to be conducted, each of which consisted of 20 minutes of CO₂ adsorption and 20 minutes of CO₂ desorption. In each adsorption step, 20 ml min⁻¹ of CO₂ and 100 ml min⁻¹ of Ar were used and in each desorption step, 100 ml min⁻¹ of Ar. The test was carried out on the reduced supported adsorbents, switchable catalyst and DFMs. The reduction was performed *ex situ* at 800 °C for 1 hour at a 50 ml min⁻¹ total flow rate of a 10% H₂/N₂ mixture.

2.3.2. Feasibility study of flexible DFMs. The three DFMs were tested in a tubular fixed bed quartz reactor (0.5 in OD) at atmospheric pressure and were supported on a quartz wool bed. The volumetric percentages of CO₂, CH₄, CO, and H₂ in the outlet stream were monitored, using an ABB AO2020 online gas analyser, which was placed after the water was condensed and separated in a chiller. In the ABB AO2020 online gas analyser, infrared gas detectors were used for CO₂, CH₄ and CO and thermal conductivity for H₂. A bubble meter was used to allow the accurate measurement of the total volumetric flow rate. Two different modes of experimental set up were used in those feasibility experiments: the 'reactor' mode and the 'bypass' mode. In the former, the desired gases were passing through the reactor, whereas in the latter, they were bypassing it, going to the condenser and then to the ABB gas analyser or the bubble meter. A simplified process diagram is shown in Fig. 1 below.

Each DFM was tested for methanation, RWGS and DRM applications in that order. Initially, 250 mg of sample were reduced *in situ* at 800 °C for 1 hour at a 50 ml min⁻¹ total flow rate of a 10% H₂/N₂ mixture (10 °C min⁻¹). Then, the temperature was decreased to 350 °C with a N₂ purge stream in order to perform a cycle of CO₂ capture-N₂ purge-CO₂ methanation. The CO₂ capture step was performed in the 'reactor' mode with a 10% CO₂/N₂ mixture of 50 ml min⁻¹ total flow rate for 20 minutes. After the 20 minutes had elapsed, a 10 minute N₂ purge step was carried out, resulting in the removal of the weakly adsorbed CO₂ and ensuring no cross-mixing of CO₂ and H₂. This purge step was continued until a zero CO₂ reading in the gas analyser was obtained so as to demonstrate

Fig. 1 Simplified process flow diagram for experimental set up.

that the produced gases were formed from the captured CO₂. Subsequently, in the 'bypass' mode, a mixture containing 10% of H₂ in N₂ was introduced through the system until its reading in the analyser was stabilised and then the stream was switched to pass through the reactor. This constituted the reaction step which was performed for 20 minutes. Once the CO₂ capture-N₂ purge-CO₂ methanation cycle was carried out at 350 °C, the temperature was increased to 650 °C at a 10 °C min⁻¹ rate. A cycle of CO₂ capture-N₂ purge-RWGS and a cycle of CO₂ capture-N₂ purge-DRM followed as described above, but in the case of DRM, CH₄ instead of H₂ was used as co-reactant. A N₂ purge step was also used following the CO₂ methanation reaction and prior to the heating-up step for 10 minutes, as well as after the RWGS reaction and before the CO₂ capture step in order to obtain zero readings in the gas analyser.

It is worth noting that the N₂ flow remained the same throughout the experiment as in all the CO₂ capture and reaction steps, making up 90% of the feed mixture in every case. The exact flow rate of N₂ (*i.e.* 45 mL min⁻¹) was measured at the beginning of the experiment so that it could be used as internal standard. This meant that when the total flow rates in CO₂ capture and reaction steps were measured with the bubble meter, the exact flow rates of CO₂ and co-reactant, either H₂ or CH₄, were calculated by subtracting the known N₂ flow rate from the corresponding total flow rate. Moreover, all the total volumetric flow rate measurements and the stabilisation of the gases percentage were performed in the 'bypass' mode to make sure that the DFMs were exposed to the desired gases only during the CO₂ capture, N₂ purge, and reaction steps.

In addition, the percentages of CO₂, CH₄, CO, and H₂ in the outlet stream shown in the gas analyser were recorded every 5 seconds throughout the experiment and it was assumed that the remaining volume percentage in the mixture was N₂. Hence, the volumetric flow rates of all gases were calculated according to the following formula, where the brackets represent the volumetric percentage of each gas, *i.e.* CO₂, CH₄, CO, and H₂, the F the flow rate (mL min⁻¹), and the subscript 'i' the respective gas. The amount of products (in mL) was calculated based on the area under the curve at a flow rate (mL min⁻¹) *vs.* time (min) graph.

$$F_i = \frac{[i]}{[N_2]} \times F_{N_2}. \tag{4}$$

3. Results and discussion

3.1. Performance testing

3.1.1. Adsorption and desorption studies in TGA. Switchable DFMs need to be able to operate in the 350–650 °C temperature range to be able to perform all of the RWGS, methanation and DRM reactions, which makes it essential to promote adsorption of CO_2 in this temperature range. CO_2 adsorption is an exothermic process and it is favoured at lower temperatures, which can make a lot of different (low and intermediate temperature) adsorbents suitable for DFMs performing only CO_2 methanation, a reaction that is thermodynamically favoured at lower temperatures.[28] To evaluate cyclic CO_2 adsorption capacity of adsorbent and DFMs developed in this work, 5 cycles of CO_2 adsorption and desorption were performed at different temperatures. The results pertaining to the CO_2 adsorption and desorption performance of the DFMs are presented in Fig. 2 and S1,† those of the supported adsorbents in Fig. 3 and S2,† and the results from the reference NiRu catalyst are shown in Fig. S4.† Table 2 summarises the adsorption capacities of the DFMs at different temperatures based on their first cycle, while it includes CO_2 adsorption capacity information of similar DFM materials found in literature that show comparable results.

Fig. 1 shows that the DFMs designed in this study were able to reversibly adsorb CO_2 in the temperature range of 350–650 °C, making them suitable for the flexible DFMs scenario. They all displayed relatively high adsorption capacities without the requirement of high regeneration temperatures as the desorption was carried out by an inert gas purge. Concerning the NiRuNa sample, a drop in the adsorption

capacity was demonstrated with rising temperature, except when the temperature reached 650 °C. A similar trend was also observed in the NiRuCa sample. A pattern was not easily detected in the NiRuK sample, but it was noted that it had the best performance at intermediate temperatures, in accordance with the CO_2-TPD results presented later. As a general outcome of this study, NiRuNa seemed to perform best at low temperatures, NiRuK at intermediate temperatures, and NiRuCa at high temperatures, in agreement with other findings[49,50] and following the logics of Pearson's hard/soft acid–base interactions. Nevertheless, these results indicated that it would be possible to use all of these materials as flexible DFMs at this temperature range. Indeed, the fact that the working adsorption capacity at 650 °C was even better than that of the DFMs at 350 °C was unexpected. However, it can be explained by a change in mechanism of CO_2 capture or a kinetic limitation, which had been overcome at 650 °C, as steeper slopes at higher temperatures are observed in Fig. S1.†

As can be seen in Fig. 1, a substantial amount of CO_2 was adsorbed during the first cycle for all DFMs, which was not the case in the supported adsorbents or the switchable catalyst. Especially at 350 °C, the adsorption capacity of the DFMs was higher than the supported adsorbents and the catalyst together, indicative of a synergy between those materials took place, which enhanced the CO_2 adsorption capacity. In other words, CO_2 was not adsorbed only onto the adsorbents and the catalysts, a fact that has already been established in literature.[51,52] Consequently, these results indicate that when adsorbents and catalysts are in close proximity, they benefit from each other, especially at high temperatures that the mechanism is kinetically activated. In fact, previous

studies[25,52] demonstrated that both Ni and Ru were adsorbing CO_2 when combined in a DFM, which meant that spill over and methanation took place over onto both Ni and Ru sites. The findings showcase the importance of having one material performing both the CO_2 adsorption and reduction, rather than two different materials being mixed together. There can also be a role of CeO_2 in CO_2 adsorption because CeO_2 is known to promote CO_2 adsorption. After all, ceria is well known for its excellent redox properties[35,46,53,54] and further mechanistic studies need to be done in the future. Nevertheless, it was believed that a small quantity of CO_2 was used to oxidise the reduced ceria species and form CO.

Fig. S1–S3† show the amount of CO_2 adsorbed per mg of sample during those five cycles at different temperatures. All the materials demonstrated that the adsorption was performed in two steps. An initial fast adsorption of CO_2 took place,

accounting for the substantial weight gain at the beginning of each capture cycle. The second step was a slower one, evident from the change in slope. In addition, it was observed that the supported adsorbents were able to reach equilibrium and reversibly adsorb CO_2 onto the adsorbents' sites, meaning that they had managed to adsorb and desorb the same CO_2 amounts, which was not the case with the DFMs. An interesting observation was that there were different slopes for the "slow CO_2 adsorption step" in all DFMs when comparing the uptake behaviour at 650 °C to that at 350 °C, pointing to a kinetically limited capture mechanism that becomes favourable at higher temperatures. The different CO_2 adsorption mechanism at 350 °C and 650 °C could not be fully attributed to the former being weak chemisorption and the latter Ca, Na, K carbonate formation, because our TGA results shown in Fig. S2† demonstrated that the supported adsorbents reversibly adsorbed CO_2 at these temperatures. Hence, the formation of stable Ca, Na, K carbonates was not the main mechanism at this high temperature. Additionally, based on the CO_2-TPD results shown below, these DFMs had a negligible amount of strong basic sites that could have favoured the carbonate formation. Therefore, it was found that the change in slope was not attributed to the adsorbents, but to the Ni–Ru species, as can be seen by comparing Fig. S1–S3† at 650 °C. This result also showcased that the catalytic component of the DFMs contributed to the CO_2 adsorption too, since various carbonate species have been reported for Ni–Ce catalysts in literature,[55] and highlighted the importance of a synergy between these two components. Nevertheless, a DRIFTS study is under way to identify the species responsible for this behaviour and for clarifying the differences in adsorption mechanisms.

3.1.2. Feasibility study of flexible DFMs. All DFMs were tested to evaluate their feasibility for use in a switchable operation scenario, by performing CO_2 capture and methanation first, followed by CO_2 capture and RWGS, then CO_2 capture and DRM. While this is not necessarily how these materials would operate (they might be used for DRM until a larger supply of green hydrogen becomes available, for instance), this testing methodology was chosen to facilitate comparison to our previous studies on switchable catalysts.[43–45] It is worth mentioning that the high reduction temperature was chosen due to RWGS and DRM being performed at high temperatures

and due to our previous work on switchable catalysts.[43] However, a reduction optimisation study should be performed in the future by considering the structure–activity relationships in order to further improve the DFMs economics. The percentage of CO_2 in the mixture was 10% so as to simulate as far as possible the CO_2 content in post combustion or cement production effluent gas streams.[28] Fig. 4 shows the amount of CO_2 desorbed and the product formation (CH_4, CO or H_2) in each reaction for the three DFMs and Fig. S4, S5 and S6† show the volumetric flow rates of all gases *vs.* time plots of NiRuNa, NiRuK, and NiRuCa, respectively.

Fig. 4 reveals the feasibility of switchable DFMs, where 100% selectivity in conversion of captured CO_2 to either methane or CO is obtained for all 3 cases (methanation, RWGS and DRM) and for all DFMs investigated herein. In all cases, the CO_2 was captured at the desired temperature and was subsequently converted into CH_4, CO, and syngas, depending on the temperature and the co-reactant used. It was demonstrated that the formation of by-products *via* side reactions was prevented except for the DRM scenario where DFMs were shown to also catalyse methane cracking once captured CO_2 was consumed. In this case, a surplus of H_2 was obtained which could be useful depending on the envisaged application. A small amount of CO_2 was desorbed during all reactions. However, it appeared that this was not temperature dependent because it was found that approximately the same amount of CO_2 was desorbed in all three reactions. This is interpreted as an indication that some fraction of adsorption sites was not in sufficient proximity with the catalytic sites, and so the adsorbed CO_2 ended up being desorbed. Therefore, there is room for improvement both in material design by fine-tuning the DFMs nanostructure and in reaction engineering by adding another catalyst bed to convert the residual CO_2 or improving mass transfer by reactor design, for instance, by using microchannel reactors or micro-monoliths.[58,59] No CO_2 was detected during the heating ramp between methanation and RWGS, demonstrating that the entire amount of CO_2 adsorbed had either been converted into CH_4 or was desorbed.

It was observed that all DFMs were more active in the DRM reaction compared to RWGS. NiRuK was the best performing DFM in the CO_2 methanation followed by NiRuCa and NiRuNa. In both RWGS and DRM, NiRuCa was the best DFM and after that, it was NiRuK and NiRuNa. It was concluded that the performance of the DFMs strongly depended on the materials basicity and their CO_2 desorption ability at the selected temperature, as observed in the CO_2-TPD profiles later on. Additionally, it was shown that the proximity of the adsorption and catalytic sites was a more vital parameter compared to the adsorption capacity. This was evident in the case of NiRuNa, which had the highest CO_2 capacity at 350 °C, yet had the worst performance in the CO_2 methanation reaction, indicating an unsatisfactory interaction between the Na and Ni–Ru species. In terms of overall performance, DFMs can be ranked in the order NiRuCa > NiRuK > NiRuNa.

In terms of product signals, as observed in Fig. S4–S6,† an initial spike in the products was detected, demonstrating a fast reaction between the captured CO_2 and the excess co-reactant (H_2 or CH_4), followed by a slower decrease in their signals. Additionally, it was observed that the reactions took place in the first 10 minutes, allowing space for further optimisation of the process by minimising the reaction time. It is worth noting, however, that in order for two reactors to run in paral-

Fig. 4 Results of feasibility study of flexible DFMs, showing the amount of CO_2 desorbed and products formation in each reaction for NiRuNa, NiRuK and NiRuCa.

lel in the DFM technology, the CO_2 capture and reduction steps need to have the same duration and if this is not the case, alternative configurations are required. Typically, in adsorption systems, regeneration is the slow step that necessitates boosting *via* temperature or pressure swing. Therefore, the fast reaction (which is also regeneration) time observed in DFMs is a major advantage for designing industrially applicable systems.

An interesting finding was that of the CO formation during the capture steps, an indication that CO_2 may have been reduced by Ce^{3+}, or even by Ni and Ru species, leading to CO formation and Ce^{4+}. These species were re-reduced when H_2 was either flowing or being generated in the subsequent steps.[35,41] This would in turn mean that the materials were able to sequentially be oxidised and reduced throughout the duration of the experiment without any structure alteration, as shown by the post-characterisation of the spent materials. Another explanation for the CO formation during the capture step would have been the occurrence of the reverse Boudouard reaction between the CO_2 and some carbon species, resulting in CO production. The occurrence of RWGS between the available CO_2 and the chemisorbed H_2 could not be excluded too, as only a small amount of CO was formed during the CO_2 capture step at 350 °C, which was not the case at 650 °C. In addition to the CO formation, there was an amount of H_2 produced during the capture step. This might have happened because of H_2 being chemisorbed in a previous step, and thus being displaced by CO_2. Alternatively, H_2 might have been produced from the oxidation of Ce^{3+} species with some leftover H_2O species coming from previous reactions including the initial DFMs reduction, CO_2 methanation and RWGS. Due to the increased complexity of these materials, further mechanistic studies are required to verify exact mechanisms and based on their results, optimisation and redesign of such experiments can take place in the future. In particular, it is necessary to test DFMs also under real flue gas and active direct air capture conditions to assess their performance for a range of realistic applications. In this study, we show that the DFMs passively capture CO_2 from the ambient air and are able to convert it into CH_4 or syngas *via* CO_2 methanation and DRM respectively, which is a strong indication that they can tolerate oxygen and some moisture.

By observing the CO and H_2 profiles of the NiRuNa during RWGS, an unexpected result emerged. It appeared that even when no CO and H_2 were produced during that reaction, the H_2 signal decreased and no CH_4 was formed. However, during the subsequent CO_2 capture step, these gases were indeed detected. Therefore, it was assumed that there had not been enough heat produced during that step so as to release the products of the endothermic RWGS. Once a small amount of heat was produced during the next exothermic adsorption step, these gases were able to be released, and thus detected by the gas analyser. As a result, the DFM's sites were once again free to adsorb CO_2 during the capture step.

During DRM, the DFMs were able to initially convert the captured CO_2 into syngas, as illustrated by the CO and H_2

signals. However, methane cracking was observed for all DFMs as a significant amount of CH_4 was used and H_2 was produced. This was anticipated because the captured CO_2 had initially been converted into syngas and, as time went by and its availability was limiting, the CH_4 was decomposed into carbon and H_2. This phenomenon had already been reported during the post-breakthrough stage.[39] As a result, the H_2/CO ratio was higher than its stoichiometric value of 1 and a H_2 rich syngas was produced, which could be useful in CO_2 applications that require a higher H_2/CO ratio. A good strategy for limiting the carbon formation would have been to decrease the DRM duration, as it had taken place predominantly in the first 5 to 10 minutes, because allowing this step to occur for longer would serve no purpose. In a realistic scenario, the stoichiometric amount of CH_4 would have been added to the system based on the CO_2 uptake to control the ratio of CO_2 and CH_4. In general, as CH_4 cracking was observed after DRM reaction (Fig. S4–S6†), pulsing a controllable amount of CH_4 to minimise the extent of cracking and coke formation would have been the way forward from an engineering perspective. Nevertheless, previous reports[38–40] demonstrated that the carbon formed during the DRM reaction was able to be regenerated during the subsequent CO_2 capture step *via* the endothermic reverse Boudouard reaction. The occurrence of the reverse Boudouard reaction would have been expected for these materials too if a CO_2 capture step had occurred after the DRM step.

Table 3 shows a comparative analysis of these switchable DFMs with similar materials in literature.[28] It can be observed that the designed DFMs of this work have similar performance to the ones in literature who were prepared by the same synthesis method, impregnation. Hence, studies that directly compare the various DFMs synthesis methods should be carried out, with an emphasis on understanding the structure–activity relationships. It is worth mentioning that in this work, a longer N_2 purge step had been carried out in between the CO_2 capture and reaction steps compared to other studies, which definitely had decreased the product formation. However, this took place just to confirm the spill over mechanism of DFMs and their ability to convert the adsorbed CO_2 into various products. So, this is not how the DFM technology would necessarily work in industry, although a N_2 purge step would potentially be needed when O_2-containing CO_2 capture feed would be used to avoid the mixing of O_2 and H_2. Besides fine-tuning the synthesis method of DFMs, reaction engineering optimisation, design and technoeconomic assessment are also necessary to scale up DFMs.
3.2. Characterisation

3.2.1 Reducibility profiles H_2-TPR and evidence of passive direct air capture. The reduction properties and interaction between the species of the supported adsorbents and the DFMs were observed in the H_2-TPR studies. Fig. S7† shows the H_2 signals of the DFMs and Fig. 5 the CH_4, H_2O, CO and CO_2 signals (m/z = 15, 18, 28, 44) recorded during the

H_2-TPR experiments. In Fig. 5, NiRu switchable catalyst, which we developed previously,[43] was used as a reference material.

A striking finding was the detection of CO and CH_4 in the DFMs compared to the NiRu catalyst, as seen in Fig. 5B and D. By looking at the CO_2, H_2O, and H_2 signals, besides the CH_4, it

can be seen that after their synthesis, all DFMs synthesised in this work were able to adsorb CO_2 directly and passively from the atmospheric air and convert it into CH_4 *via* the CO_2 methanation reaction. CO formation was also observed on NiRuK and NiRuNa. Therefore, Ni and Ru, which were already reduced by these temperatures (*i.e.* 440 °C for NiRuNa, 455 °C for NiRuK, and 520 °C for NiRuCa) were used to produce CH_4 and H_2O from the atmospheric CO_2 captured on adsorbent sites using the H_2 feed during the H_2-TPR study. Desorption of CO_2 and generation of other products of CO_2 reduction were also detected mainly at low temperatures, in agreement with the CO_2-TPD results and the different types of basic sites, as presented later. Consequently, the main peak of the DFMs in the H_2O signal profiles corresponded to the H_2O from the methanation reaction, holding promise for using DFMs for flexible chemicals synthesis from CO_2 in the air.

As seen in Fig. S7,† which presented similar peaks to the H_2O signal, the NiRuNa and NiRuK samples had a similar pattern since three distinct peaks were observed. The NiRuCa sample showed a broader reduction pattern up to 350 °C, but two peaks were seen over that temperature. By observing the H_2O signals of the three DFMs in Fig. 5A, it can be seen that the first peak at 200 °C corresponded to the reduction of Ru^{4+} to metallic Ru. These were located at a higher temperature compared to the reference material, indicating a better interaction of the Ru species with the other species.[60] Moreover, a broad reduction zone located at 440 °C for the NiRuNa, another at 455 °C for the NiRuK, and another one at 520 °C for the NiRuCa were detected. In all those reduction events, a shoulder at the lower temperature range was displayed, attributed to the medium-sized NiO_x species interacting with the CeO_2 particles.[61,62] The slow decrease of the signal over 800 °C corresponded to the reduction of a small amount of bulk CeO_2 species,[63] confirming the reduced XRD profiles, which showed that surface CeO_2 species were the main CeO_2 species in the samples.

3.2.2. Basicity profiles CO_2-TPD. The CO_2-TPD was used to assess the basicity of the supported adsorbents and DFMs. In a CO_2-TPD profile (Fig. 6), different types of basic sites are observed, which can be categorised into weak, medium, and strong ones. Weak basic sites are characterised by CO_2 desorp-

tion up to 250 °C, while medium basic sites are characterised by CO_2 desorption between 250 °C and 700 °C. Finally, the strong basic sites result in stable adsorption of CO_2 and are characterised by desorption temperatures exceeding 700 °C.[50,64] The strength of basic sites is an important descriptor for designing switchable DFMs because it provides insight into available reactant species at different temperature ranges that can be used for CO_2 methanation, RWGS and DRM. In other words, weak basic sites can be beneficial for CO_2 methanation, while medium basic sites for RWGS and DRM.

Fig. 6 demonstrates the CO_2-TPD results of DFMs and supported adsorbents, while Fig. S8† shows the corresponding results of the reference Ni–Ru switchable catalyst. All the materials displayed mainly weak and medium basic sites. By comparing the DFMs with the NiRu catalyst, it was noted that the addition of the adsorbents contributed to the formation of medium basic sites. Therefore, it was shown that the adsorbents were in a dispersed form rather than bulk species, meaning that the DFMs would behave like intermediate-temperature adsorbents and reversibly adsorb CO_2 at intermediate temperatures in agreement with literature.[65] Although the CO_2-TPD profiles of the DFMs had been mainly influenced by the supported adsorbents, by comparing the DFMs and supported adsorbents profiles, it was observed that the addition of Ni and Ru to the supported adsorbents suppressed the medium basic sites. This meant that, to some extent, Ni and Ru covered a small amount of adsorption sites during impregnation.[50] Although NiRuK displayed a higher intensity signal for medium basic sites (300–700 °C) than NiRuNa, the CO_2-TPD profiles of these materials were similar to each other. As regards the NiRuCa sample, a different profile was observed with a smaller amount of weak basic sites and more medium-strong ones, in agreement with its CO_2 signal profile in the H_2-TPR study as well as the TGA study at high temperatures.

3.2.3. CH_4-TPSR and evidence of passive direct air capture. Furthermore, a CH_4-TPSR experiment was carried out on the best performing DFM, NiRuCa. Its aim was to observe the fresh DFM performance in a CH_4 environment, similar to the H_2-TPR experiment, and identify opportunities for a potential temperature reduction of the high-temperature reactions. This would ultimately be translated into lower energy requirement,

Fig. 6 CO_2-TPD profiles of the (A) DFMs and (B) supported adsorbents.

Fig. 7 CH_4-TPSR profile of NiRuCa: (A) H_2O, (B) CH_4, (C) CO_2, (D) CO and (E) H_2 signals.

minimising the operating costs in a potential scale-up of the switchable DFMs.

Fig. 7 shows the CH_4-TPSR results. Overall, it was demonstrated that the DFM's oxidation (since the sample used was after calcination) did not shut down its activity for DRM which was remarkable. In agreement with the H_2-TPR results, atmospheric CO_2 was adsorbed onto the DFM and was gradually released until a peak at 400 °C was observed. A peak at higher temperature analogous to the H_2-TPR and CO_2-TPD results was not identified, meaning that CO_2 was fully consumed during low temperature reaction. A CO peak was also seen at this temperature (400 °C). Additionally, CH_4 cracking took place starting at 350–400 °C and peaked at 635 °C, as observed from the H_2 and CH_4 signals. Therefore, it was shown that in a CH_4-rich environment and in the temperature range of 400–600 °C, CH_4 cracking supplied the H_2 needed for the reduction of Ni and Ru which was feasible at these temperatures. Thus, DRM was able to take place because of the available CH_4 and atmospheric CO_2. However, after the consumption of CO_2, excessive CH_4 cracking took place, which was expected based on our isothermal experiment results shown in section 3.1.2. It is worth mentioning that RWGS and reverse Boudouard reactions could also be responsible for some CO formation as well.

Based on these results, it was confirmed that a DRM temperature reduction to 400 °C could be feasible. It may also be possible to lower the temperature of DRM using other driving

forces for reaction.[66,67] It should be kept in mind that the DFMs operate under dynamic conditions, meaning that a deviation from the well-known steady state conditions is possible. A significant RWGS temperature reduction would require a catalyst that is not active for the methanation reaction, thus being beyond the aim of the present study which focuses on switchable performance with 100% selectivity depending on reaction conditions. As CO_2 methanation and RWGS have the same reactants, the reaction parameter changed to achieve a different product formation is temperature. So, if the RWGS temperature is significantly reduced, then 100% CO selectivity may not be achieved. The initial temperature of RWGS and DRM, i.e. 650 °C was considered useful for this validation study since higher temperatures are more representative of the current industrial reformers that operate close to equilibrium conversions at 900–1000 °C.[68] However, investigating the DFM behaviour at a temperature higher than 650 °C was considered to be unnecessary, because the DFMs had 100% selectivity in these reactions. In fact, it would have had a negative effect due to reduced CO_2 adsorption and sintering, let alone the increase of operating costs in a potential scale up.

3.2.4. Textural properties. The textural properties of the supported adsorbents and DFMs and the N_2 adsorption–desorption isotherms of these materials are presented in Fig. 8. There appear to be no substantial differences between the BET surface areas, pore volumes and pore diameters when comparing adsorbents and DFMs. As regards to the isotherms generated, they corresponded to the type IV isotherms with a characteristic H1 hysteresis loop, according to IUPAC classification. This type of isotherm is linked to well-developed cylindrical mesoporous materials and the high steepness was indicative of the mesopores being homogeneously distributed throughout the structure of the samples,[69,70] as observed in SEM and TEM as well.

3.2.5. Crystalline structure. Fig. 9 shows the crystalline phases of the fresh materials. All the supported adsorbents and DFMs had the characteristic peaks of γ-Al_2O_3 and CeO_2 phases (JCPDS 00-004-0880 and JCPDS 03-065-5923, respectively). CaO, K_2O and Na_2O peaks were not observed, indicating that these species were likely present as amorphous and/or highly dispersed phases.[71,72] In the fresh Na, K, and NiRuNa samples, some residual nitrates peaks were observed, which eventually disappeared upon reduction, as seen in Fig. 10. In the fresh DFM XRD patterns, the peaks located at $2\theta° = 37.2°$, 43.3°, 62.9°, and 75.4° (JCPDS 00-047-1049) were ascribed to NiO. The existence of nickel aluminate ($NiAl_2O_4$) spinels was discarded due to the low calcination temperature used.[56] Peaks of RuO_2 were also observed in the fresh samples (JCPDS 01-070-2662). No evidence of a Ni–Ru alloy was detected in the fresh DFMs.

Upon reduction at 800 °C, as observed in Fig. 10, the CeO_2 peaks either disappeared or were significantly lower in intensity. As a result, it was concluded that surface CeO_2 species were mainly present in the samples, which was in agreement with the H_2-TPR results presented previously for Ce–Al supported catalysts.[73] No ceria aluminate ($CeAlO_3$) species were

| Sample	S_{BET} (m²/g)	V_{PORE} (cm³/g)	D_{PORE} (nm)
Na	109	0.29	10.5
K	136	0.36	10.4
Ca	170	0.39	8.7
NiRuNa	173	0.41	9.4
NiRuK	170	0.40	8.9
NiRuCa	194	0.37	6.9

Fig. 8 Textural properties of the materials on the left-hand side and nitrogen adsorption–desorption isotherms of the (A) supported adsorbents and (B) DFMs on the right-had side.

Fig. 9 XRD patterns of the fresh (A) supported adsorbents and (B) DFMs.

seen, which is consistent with the use of a reduction temperature of 800 °C.[69] Metallic Ni peaks were also detected in the reduced DFM XRD patterns (JCPDS 01-070-1849). In contrast, metallic Ru peaks were not observed, which led us to believe that Ru was well dispersed and/or a Ni–Ru alloy was formed; however, due to the low Ru weight content (1 wt%) compared to Ni (15 wt%), no shift of Ni peaks could be discerned in the XRD patterns.[21,74]

3.2.6. Morphological structure. The morphological structure of the fresh supported adsorbents and the DFMs was observed in SEM. Fig. S9–S14† showed that after calcination,

the materials presented porous structure, which was in accordance with the BET results. The EDX mappings of the DFMs are shown in Fig. 11–13 and of the supported adsorbents in Fig. S15–S17.† The EDX mapping indicated that the materials were successfully impregnated as dispersed and homogenous materials were created. The high dispersion, porosity, and homogeneity of the DFMs were significant parameters that contributed to their impressive performance, as described earlier, due to the need to have a plethora of adsorption and catalytic sites in close proximity in order for them to work efficiently.[24,75]
Fig. 10 XRD patterns of reduced DFMs.

Additionally, TEM images of the three reduced DFMs are presented in Fig. 14. These images revealed the nanostructure of these materials with Ni and Ru having a particle diameter of less than 10 nm overall. In general, a good dispersion of their active catalytic phases was achieved in accordance with their EDX profiles.

3.3. Post reaction characterisation

As shown in Fig. S4–S6,† CH_4 cracking took place in the feasibility study of the switchable DFMs that resulted in the formation of coke, and hence XRD and TGA were carried out on the spent catalysts to characterise and quantify the carbon species.

Fig. 15 shows the XRD patterns of the post-reaction NiRuNa, NiRuK, and NiRuCa samples. The patterns were similar to their reduced ones presented in Fig. 10, displaying the characteristic peaks of Ni, CeO_2, and Al_2O_3. No carbon peak was observed in the spent NiRuNa and NiRuK XRD profiles, meaning that the type of carbon formed was soft with a poorer degree of crystallinity. However, this was not the case with the NiRuCa, as a carbon peak at $2\theta° = 26$ was observed, signifying the formation of a harder carbon potentially requiring higher regeneration temperatures. A slight shift of the Ni peak to lower angles appeared on the NiRuNa and NiRuCa samples indicating the formation of a NiRu alloy, which was not the case with their reduced materials.[21] Hence, it was concluded that a NiRu alloy was formed during reduction even though it was not evident from their XRD patterns. Such alloy plays a key role in the catalytic conversion process.

Thermogravimetric analysis during temperature programmed oxidation (TPO) was also used to quantify the carbon formed on post-reaction DFMs after the feasibility

testing, especially expected from the performance during the DRM step. In order to accurately measure the amount of carbon, *ex situ* reduced DFMs were also tested under the same conditions. Therefore, the weight loss due to the atmospheric CO_2 and moisture adsorption and material degradation, as well as the weight gain due to the oxidation of the materials, were also taken into account. The results are presented in

Fig. 16. In all the samples, an initial weight loss took place up to 200–300 °C because of the weakly adsorbed atmospheric CO_2 and moisture. A higher weight loss was seen in the reduced materials because they were able to absorb a higher amount of atmospheric impurities. Moreover, a weight gain was observed at the 300–400 °C temperature range, which was associated with the oxidation of the remaining Ni and Ru particles. At temperatures higher than 400 °C, a significant weight

loss was detected, showing the carbon oxidation. The coke oxidation was completed by 500 °C for the NiRuNa and NiRuK samples, while a higher temperature was needed for the NiRuCa sample, confirming the existence of softer carbon species in the former samples and of harder ones in the latter. The formation of soft carbon was an intriguing result as it will likely allow an easier regeneration process in the future. Overall, the amount of carbon formed during the DRM reaction was 0.083 g_C/g_{Sample} for NiRuNa, 0.072 g_C/g_{Sample} for NiRuK and 0.075 g_C/g_{Sample} for NiRuCa, showing a similar extent of CH_4 cracking for the three DFMs.

4. Conclusions

In this work, a series of advanced universal materials for the integrated CO_2 capture and conversion were designed. The combination of an adsorbent and a switchable catalyst led to the development of switchable DFMs that were shown for the first time to be able to capture CO_2 at various temperatures and, depending on the reaction conditions, to convert it into different added-value chemicals through the CO_2 methanation, RWGS, and DRM catalytic upgrading routes. This proof of concept is a milestone in the development of carbon negative technologies to combat the increased CO_2 emissions and the resulting global warming. Switchable DFMs can be adapted to the current infrastructure as a CCU unit, while offering a solution to the highly variable energy sector.

The designed DFMs of this work were highly dispersed and nanostructured porous materials and their species, located in close proximity, showed a high degree of interaction with each other. The H_2-TPR experiments demonstrated that these materials were able to passively adsorb atmospheric CO_2 through direct air capture and to convert it into synthetic natural gas. The CO_2 adsorption–desorption studies of the selected DFMs surprisingly proved that they were able to reversibly adsorb CO_2 at different temperatures, making them ideal for a flexible DFM scenario. A synergy between the species also took place, contributing to their increased adsorption capacities. Overall, the CO_2 adsorption capacities of the DFMs were in accordance with their basicity profiles, as revealed by the CO_2-TPD results. NiRuCa was the best DFM, producing 104 μmol of CH_4 per kg_{DFM} in CO_2 methanation, 58 μmol of CO per kg_{DFM} in RWGS and 338 μmol of CO per kg_{DFM} in DRM. It was also concluded that the DFMs displayed a complex CO_2 capture behaviour over different types of adsorption sites, which will necessitate mechanistic studies for understanding their behaviour during DFM operation. CO_2 capture under realistic flue gas conditions with O_2, steam and SO_2 was out of the scope of this manuscript, even if some degree of oxygen tolerance is expected given their behaviour during H_2-TPR. Future studies dealing with these impurities similar to literature[76] are highly recommended as a future direction.

The feasibility study of performing CO_2 capture and then either CO_2 methanation, RWGS or DRM reactions was demonstrated, providing a new tool for devising low emission chemical production schemes in the near term when availability of green hydrogen will be increasing and the demand for different products (such as synthetic natural gas vs. syngas or CO) will be variable. Our findings make it possible to adapt to uncertainty by designing flexible chemical production schemes from CO_2 emissions, whether they are captured from stationary sources or the ambient atmosphere.
