Lifshitz transition was proposed to explain a change of the topology structure in a Fermi surface induced by continuous lattice deformation without symmetry breaking since 1960. It is well known that the anomalies of the kinetic coefficients (the coefficient of heat conduction and electrical conductivity, viscosity, sound absorption, etc.) are usually closely connected with the Lifshitz transition behavior. 2H-TaS<sub>2</sub> is a typical representative to study its anomalies of temperature dependence of heat capacity, resistivity, Hall effect, and magnetic susceptibility. Its geometrical structure of the charge density wave (CDW) phase and layer number dependence of carrier-sign alternation upon cooling in the Hall measurements have not been well understood. The geometrical structure (T–Ts) of the CDW phase was predicted through first principles calculations for bulk and mono-layer 2H-TaS<sub>2</sub>. Driven by electron-lattice coupling, Ta atoms contract to form a partially gapped CDW phase. The CDW phase has a larger average interlayer separation of S–S atoms in the adjacent two layers compared with the metal phase, which results in a weaker chemical bonding among S–S atoms in the adjacent two layers and then a narrower bandwidth of the energy band. The narrower bandwidth of the energy band leads to a larger density of states (DOS) in the out-of-plane direction above the Fermi level for the CDW phase. As the Fermi level continually drops from the DOS region with a negative slope to that with a positive slope on cooling, the reversal of the p → n type carrier and the pocket-vanishing-type Lifshitz transition occur in the bulk 2H-TaS<sub>2</sub>. However, the Fermi level slightly drops by 6 meV and happens to be at the positions of pseudo band gaps, so the reduction of in-plane DOS and total DOS is responsible for the always p-type carrier in the mono-layer samples. Our CDW vector of the *k*-space separation between two saddle points is  $Q_{SP} \approx 0.62$  GK and can provide a theoretical support for the “saddle-point” CDW mechanism proposed by Rice and Scott. Our theoretical explanation gives a new understanding of both Lifshitz transition for symmetry breaking and reversal for the p–n carrier sign in the Hall measurements in various two-dimensional transition metal disulfides.

## 1. Introduction

Half a century ago, Lifshitz considered an electronic phase transition (PT) associated with a change in the Fermi surface topology induced by continuous lattice deformation for non-interacting fermions.<sup>1</sup> This electronic PT, now called the Lifshitz transition, is unique in the sense that it is not associated with structural symmetry breaking. Lifshitz gave two types of changes in the Fermi surface topology: one is associated with the collapse of a cylindrical Fermi surface and the

other is characterized by the emergence of an additional Fermi surface. It has been known for several decades that the Lifshitz transition always exists in non-stoichiometric materials<sup>2,3</sup> because it is easy for the Fermi surface to shift upwards or downwards as a result of a continuous change of the compound composition without involving symmetry breaking. In two-dimensional transition metal dichalcogenides (TMDs), there are widespread electronic and geometric PTs associated with symmetry breaking from a high-temperature metal phase to a low-temperature CDW phase on cooling. The Lifshitz transition was surprisingly observed in experimental measurements during the metal to CDW PT for two-dimensional TMDs under the existence of symmetry breaking.<sup>4,5</sup>

Amongst various TMDs, 2H-TaS<sub>2</sub> can be accepted as a typical representative to study its anomalies of temperature dependence of heat capacity, resistivity, Hall effect, and magnetic susceptibility. These anomalies should be closely related to the

† Electronic supplementary information (ESI) available. See DOI: <https://doi.org/10.1039/d4cp00977k>

existence of Lifshitz transition. There exists a geometrically structural PT at around 75 K from the room-temperature metal phase (space group  $P6_3/mmc$ , hereafter abbreviated as the metal phase) to the lower-temperature CDW metal phase (hereafter abbreviated as the CDW phase) in the bulk 2H-TaS<sub>2</sub> upon cooling.<sup>6–12</sup> This PT is usually accompanied by a sudden fall in resistivity and a reversal for carrier sign from the p-type to n-type in the Hall measurements.<sup>7,12,13</sup> However, the CDW phase occurs at around 55–140 K, while its switch of p–n carrier sign is absent when reducing the sample thickness toward the 2D limit.<sup>14–16</sup>

Early theoretical studies<sup>17,18</sup> proposed a two-band model for the normal state of some superconductors with a  $\beta$ -tungsten structure to explain the anomalous temperature dependence of a variety of properties. Their model requires two bands that slightly overlap or almost overlap. If the Fermi level ( $E_F$ ) lies close enough to the region of overlap (or near overlap) so that a change in temperature could shift  $E_F$  from one band to the other, then this could change the behavior of the charge carriers in the magnetic field from electron-like to hole-like. Bromley<sup>19</sup> predicted through tight-binding theory that the low-temperature reversal of the Hall effect may be due to a shift of the Fermi energy, which removes the holes if interlayer interactions are considered. Evtushinsky *et al.*<sup>20</sup> predicted that pseudo-gaps may drive the sign reversal of carriers in the Hall effects for bulk 2H-TaS<sub>2</sub>. Yang *et al.*<sup>14</sup> further explained that the pockets around  $K$  and  $\Gamma$  points in the Brillouin zone (BZ) are either partially or fully gapped in the CDW phase. This reconfiguration of electronic structures may account for the abnormal change of sign in the Hall measurement. Our group has predicted that the carrier sign of 2H-NbSe<sub>2</sub> bulk samples is dependent on the reversal of the slope of the DOS at the Fermi level.<sup>21</sup>

Despite the above mentioned previous studies having found out that the low-temperature reversal of the Hall effect is related to the shift of Fermi energy, the layer number dependence of carrier-sign alternation upon cooling, even the geometric structure of the CDW phase, has not been well understood up to now. This type of PT behaviors and their reversal of p–n type carrier dependence on sample thickness are widespread and unresolved in TMD materials for decades.<sup>15,22–26</sup>

In this work, the geometrical structures of the CDW phase were predicted through first principles calculations for bulk and mono-layer 2H-TaS<sub>2</sub>. Their pseudo band gaps of CDW phases are partially open around the  $G$ – $A$  and  $K$ – $H$  points. During Ta atoms contracting to form the CDW phase (T–Ts configuration) with symmetry breaking in the in-plane direction, the average interlayer separation of S–S atoms in the adjacent two layers rises. This leads to a weakening of the chemical bonds among S–S atoms and then a decrease of the bandwidth, which will inevitably lead to an increase in the projected DOS in the out-of-plane direction. As the Fermi level continually drops and then more energy bands in the out-of-plane direction emerge from the Fermi surface, Lifshitz transition occurs in the out-of-plane direction without symmetry breaking even though its minimum repeating unit in periodic crystal cells has been changed during the geometrically structural PT.

## 2. Calculation details

All calculations were performed using Vienna *ab initio* simulation package (VASP) software<sup>27</sup> based on the density functional theory. The Perdew–Burke–Ernzerhof parametrization with generalized gradient approximation (GGA-PBE) was chosen to describe exchange and correlation effects. Projected augmented wave (PAW) pseudopotential was applied to describe the interaction between atomic core and valence electrons.<sup>28</sup> Different long-range van der Waals (vdW) interactions were tested for geometrically structural parameters of 2H-TaS<sub>2</sub> as shown in Supplementary-I, Table S1-1 (ESI<sup>†</sup>), and then the OPT-B86b method<sup>29</sup> was finally chosen to perform vdW correction in the following calculation. All geometric structures including the metal and CDW phase of 2H-TaS<sub>2</sub> were fully relaxed until the remnant force on each atom becomes less than  $0.01 \text{ eV } \text{\AA}^{-1}$ , and our energy-convergence criterion is  $1 \times 10^{-6} \text{ eV}$ . An energy cutoff of 400 eV was chosen for the real-space integration and Methfessel–Paxton smearing of 0.05 eV.  $12 \times 12 \times 2$  Monkhorst-Pack grids were used to calculate the geometrical and electronic structures. To demonstrate the stability of the CDW phase, we used the finite-displacement Parlinski–Li–Kawazoe method, which was implemented in the PHONOPY package.<sup>30,31</sup> The energy and force convergence thresholds for each atom of the CDW phase reached  $1 \times 10^{-6} \text{ eV}$  and  $1 \times 10^{-8} \text{ eV } \text{\AA}^{-1}$ , respectively. Phonon calculations were performed using a  $3 \times 3 \times 3$  supercell. Real-space force constants of supercells were calculated in the VASP code, and phonon frequencies were calculated from the force constants using the PHONOPY code. Using the Boltzmann transport equation<sup>32</sup> in the VASPKIT package,<sup>33</sup> the temperature dependence of conductivity was obtained by post-processing the output of VASP calculations. In particular, the conductivity was calculated using a relaxation time approximation ( $\tau = 10$ )<sup>33</sup> (as shown in Supplementary-II, ESI<sup>†</sup>).

The basic idea behind DFT+ $U$  is to treat the strong on-site Coulomb interaction of localized electrons occupying d and f orbitals, which is not corrected as described by LDA or GGA, with an additional Hubbard-like term in the strongly correlated systems.<sup>34</sup> The strength of the on-site interactions is usually described by parameters  $U$  (on-site Coulomb) and  $J$  (on-site exchange). These parameters  $U$  and  $J$  can be extracted using *ab initio* calculations, but usually are obtained semi-empirically. In practical computations to determine the  $U$  and  $J$  values, it is necessary to consider whether the magnetic moment matches the experimental values, whether the magnetic ground state matches the experimental observations, whether the theoretical energy gap matches the experimental data, and so on. Since the bulk 2H-TaS<sub>2</sub> sample is found to be a non-magnetic metal,<sup>35</sup> we only need to determine the  $U$  value based on whether the theoretical band gap matches the experimental values.

The Fermi level and theoretical lattice parameters increase with the increase of  $U$  value as shown in Fig. S1-1 and Table S1-2 (ESI<sup>†</sup>). The theoretical lattice parameters ( $a = 3.316 \text{ \AA}$ ,  $c = 12.025 \text{ \AA}$  at  $U = 0 \text{ eV}$ ) of the metal phase are well consistent with the experimental measurements ( $a = 3.316 \text{ \AA}$ ,  $c = 12.070 \text{ \AA}$ )<sup>36</sup>. Our theoretical CDW energy gap monotonically rises with the increase of  $U$  value and quickly exceeds the 324 meV at  $U = 3$ .

The theoretical CDW energy gap (*i.e.* 209 meV at  $U = 0$  eV) is nearly equal to the previous theoretical calculations (200 meV<sup>14</sup>). Previous theoretical studies also support the use of  $U = 0$  eV for the CDW in the 2H-MX<sub>2</sub> (M = Ta and Nb).<sup>37–39</sup> So,  $U = 0$  was finally chosen and used in our following calculations.

### 3. Results and discussion

#### 3.1. Geometrical structure of the bulk CDW phase

The stable structure is a metal phase for bulk 2H-TaS<sub>2</sub> at room temperature. It is composed of two layers with S-Ta-S sandwich-type configuration stacked together as shown in Fig. S1-2(a) (ESI<sup>†</sup>). There is a weak van der Waals interaction between its two sandwich-type configurations. No perceptible effect with spin-orbit coupling (SOC) in its energy band exists as shown in Fig. S1-2(b) (ESI<sup>†</sup>), so SOC was not taken further into account in our subsequent calculations. The positions of imaginary frequency in the phonon spectra of metal phases are directly related to the structural distortion of the lower-temperature CDW phase. Its typical position in TMDs is located at  $Q_{\text{CDW}} \approx 0.652\text{--}0.679$  *GM*. The  $Q_{\text{CDW}}$  vector, called CDW vector, is oriented along the *GM* directions of the hexagonal BZ and depends on the material properties.<sup>40</sup> For bulk 2H-TaS<sub>2</sub>, two longitudinal acoustic phonon branches exhibit strong instability at the  $Q_{\text{CDW}} = 0.675$  *GM* point as shown in Fig. S1-2(c) (ESI<sup>†</sup>), which is close to  $2/3$  *GM*, indicating that its CDW phase should be a  $3 \times 3$  periodic superstructure.

The CDW phase of mono-layer 1H-NbSe<sub>2</sub> exhibits four types of images that may exist predicted by a recent theoretical study,<sup>37</sup> so the CDW phase of mono-layer 1H-TaS<sub>2</sub> should also have similar structures owing to them being an isoelectronic group of materials. Four types of possible images of mono-layer 1H-TaS<sub>2</sub>, called H, S, T, and Ts, were obtained by distorting Ta atomic positions in a  $3 \times 3$  supercell and then fully optimizing the  $3 \times 3$  supercell as shown in Fig. 1(a). The formation energy of three additional images from all  $3 \times 3$  CDW structures reported at present, called C, R, and T', was also calculated and listed in Table S1-5 (ESI<sup>†</sup>). The formation energy of the CDW image is defined as  $\Delta E_{\text{CDW}} = (E_{\text{CDW}} - E_{\text{metal}})/N_{\text{Ta}}$ , where  $E_{\text{CDW}}$  and  $E_{\text{metal}}$  are the total energies of the CDW image and the metal phase with the same number of atoms, respectively.  $N_{\text{Ta}}$  is the number of Ta atoms in the CDW image, namely, 9. After full structural optimization, the C and R images lose their stability and finally transform into the Ts structure, while the T' image becomes the T structure. Interestingly, the total energy differences between these four types of mono-layer 1H-TaS<sub>2</sub> are approximately within 24 meV per CDW. This indicates that they can coexist and mutually transform under certain conditions. The T configuration is found to be the most stable state in our calculations after geometric structural optimization for these four types of images at low temperature, even though the Gibbs free energy is considered as shown in Fig. S1-3(a) (ESI<sup>†</sup>).

CDW images (Ta<sub>18</sub>S<sub>36</sub>) of bulk 2H-TaS<sub>2</sub> were randomly stacked with these four-type images of mono-layer 1H-TaS<sub>2</sub>. H-T, T-Ts, T-T and Ts-Ts images are actually the same and the

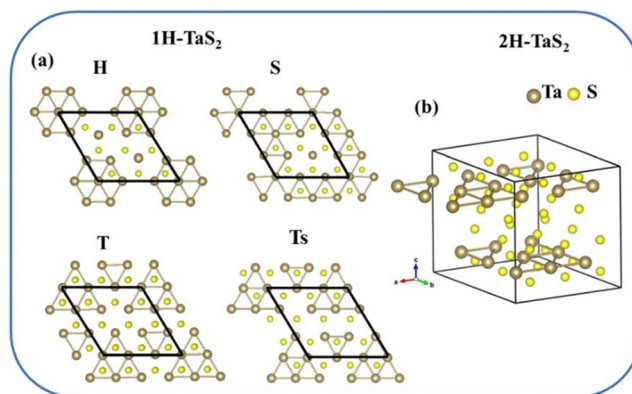

Fig. 1 (a) Four types of possible stable images of CDW phase for mono-layer 1H-TaS<sub>2</sub>. (b) T-Ts configuration of CDW phase for bulk 2H-TaS<sub>2</sub>. Brown spheres represent tantalum atoms while other spheres represent oxygen atoms.

most stable structure is shown in Table 1 and Fig. 1(b). This image is very close to the un-distorted T-Ts geometrical structure, therefore the T-Ts image is chosen to represent the geometrical structure of CDW phase for bulk 2H-TaS<sub>2</sub>. After further calculating the zero vibrational energies of various configurations, we found that these zero vibrational energies have little effect on the formation energies of various isomers at the level of optB86-vdW corrections. Owing to space limitations, the zero vibrational energy correction will no longer be discussed in the subsequent paragraphs.

The T-Ts configuration has the same symmetry in the out-of-plane direction as its metal phase, but each of its two layers has a different geometrical structure from the metal phase. Its symmetry in the in-plane direction breaks during in-plane contracting of Ta atoms. The in-plane area of T-Ts unit cell (Ta<sub>18</sub>S<sub>36</sub>) unexpectedly increases by 0.08% and its interlayer spacing of Ta-Ta atoms decreases by 0.08%, finally it has a 0.05% reduction in total volume as shown in Table S1-3 (ESI<sup>†</sup>). Its thicknesses of both T and Ts sandwich-type structures decrease by 0.004–0.012 Å and the average interlayer separation of S-S atoms in the T-Ts configuration increases by 0.004 Å after shrinkage of Ta atoms. This decrease of thickness of S-Ta-S sandwich-type structure is completely opposite to its increase of thickness in the CDW phase of bulk 1T-TaS<sub>2</sub> upon cooling.<sup>41</sup> The total energy of CDW configuration can drop by  $-38$  meV/Ta<sub>18</sub>S<sub>36</sub> ( $-62$  meV fall for total energy without vdW and  $+24$  meV enhancement for vdW energy =  $-38$  meV) for only intralayer shrinkage and then its total energy can further drop by  $-26$  meV/Ta<sub>18</sub>S<sub>36</sub> (0 meV change for total energy without vdW and  $-26$  meV fall for vdW energy =  $-26$  meV) for only reduction by 0.08% of interlayer spacing between Ta-Ta atoms if such a hypothetical PT path exists. Higher vdW energy always corresponds to farther average separation of S-S atoms for an OPT-B86v vdW correction, therefore the enhancement for vdW energy ( $+24$  meV) also reveals a larger average interlayer separation of S-S atoms. The stability of the T-Ts configuration is verified through its phonon spectrum and there is no imaginary frequency in the whole BZ as shown in Fig. S1-4 (ESI<sup>†</sup>), which reveals its dynamical stability.

**Table 1** Formation energy  $\Delta E_{\text{CDW}}$  (meV/TaS<sub>2</sub>) of various possible CDW images for bulk 2H-TaS<sub>2</sub>

Structure	H-S	H-Ts	H-T	S-T	S-Ts	T-Ts	H-H	S-S	T-T	Ts-Ts
$\Delta E_{\text{CDW}}$ (meV)	84.82	-0.633	-3.49	82.05	6.75	-3.45	-2.65	-1.3	-3.47	-3.45

### 3.2. Electronic structure of bulk CDW phase

The Fermi surface of the metal phase includes two separate hole-like sheets as shown in Fig. 2(a). In the first BZ as shown in Fig. S1-5 (ESI<sup>†</sup>), these include two open hole-type cylindrical surfaces along the *G-A* and *K-H* lines. The CDW distortion results in six pseudo band gaps (209/130/63 meV at  $g_1/g_2/g_3$  points in the BZ and 112/119/98 meV at  $g_4/g_5/g_6$  points in the BZ) around the saddle points along the *G-A* and *K-H* lines. Our theoretical pseudo-gaps at the “ $g_3$ ” and “ $g_6$ ” *k*-points in the BZ have not been predicted by previous theoretical calculations.<sup>14</sup> Since these partially opened pseudo-gaps of CDW phase always appear even in the mono-layer 1H-TaS<sub>2</sub> samples as shown in Fig. S1-6 (ESI<sup>†</sup>), and then the positions of  $g_1$ – $g_6$  pseudo band gaps are all located at the high symmetry points of the BZ boundary of the CDW phase as shown in Fig. S1-5 (ESI<sup>†</sup>), the origin of pseudo band gaps for the CDW phase mainly derives from Ta atoms contracting and then electron-lattice coupling plays a key role in driving the formation of CDW for bulk 2H-TaS<sub>2</sub>. Previous frequency-dependent optical reflectivity measurements<sup>42</sup> indicated that the Fermi surface of 2H-TaS<sub>2</sub> is only partially gapped in the CDW state. The spectral evolution of two different Na<sub>x</sub>TaS<sub>2</sub> crystals further confirms that the partial-gapped structure observed in 2H-TaS<sub>2</sub> clearly corresponds to its CDW transition. The resistivity of 2H-TaS<sub>2</sub> remains metallic below  $T_{\text{CDW}}$  and shows only a small anomaly at the PT, indicating that the CDW does not involve a large modification of the Fermi surface.<sup>42,43</sup> Our nesting vector is  $Q_{\text{FS}} \approx 0.86 \text{ GM}$ , so it does not satisfy the required nesting condition ( $Q_{\text{CDW}} \approx 0.68 \text{ GM}$ ) to induce CDW PT. Rice and Scott<sup>44</sup> suggested that the two-dimensional conduction band with saddle points close to the Fermi level was unstable against CDW formation. Our CDW vector of the *k*-space separation between two saddle points is  $Q_{\text{SP}} \approx 0.62 \text{ GK}$ , where the Fermi vectors along *GK(AH)* are in good correspondence with previous band theory<sup>44</sup> and experimental observations.<sup>45</sup> Our theoretical calculations provided a theoretical support for the “saddle-point” CDW mechanism proposed by Rice and Scott.<sup>44</sup>

**Fig. 2** (a) Energy band of metal phase and unfolding energy band of CDW phase for bulk sample. The gray and blue lines represent the CDW and metal phases. The  $g_1$ – $g_6$  symbols indicate that the pseudo band gaps are located at the  $g_1$ – $g_6$  points in the BZ, respectively. (b) Total DOS for bulk 2H-TaS<sub>2</sub>.

Ta atoms in the adjacent two layers do not form chemical bonds owing to being too far away, and can interact only through bridges composed of sulfur atoms. The average distance between sulfur atoms in the adjacent two layers rises from 2.872 Å to 2.876 Å during the PT, which will lead to a weakening of the chemical bonds from their  $p_z$  orbitals between sulfur atoms in the adjacent two layers. The energy band at the high-symmetry points *M-L* segment in the out-of-plane direction is mainly composed of a hybrid of the d orbital of Ta atoms and the p orbital of S atoms as shown in Fig. S1-7 (ESI<sup>†</sup>). The bandwidth is proportional to the overlap integral  $\gamma$ , which decreases exponentially with these S-S atomic separations based on the tight binding theory in solid state physics for energy bands.<sup>46</sup> The bandwidth for the energy band at the Fermi level of the CDW phase increases approximately by 20 meV in the in-plane direction owing to contracting of Ta atoms, while it decreases approximately 10 meV in the out-of-plane direction relative to the metal phase owing to farther apart average distance of S-S atoms in the adjacent two layers as shown in Fig. 2(a). Such a decrease of bandwidth in the out-of-plane direction will inevitably lead to an increase in the density of states (DOS) around the Fermi level as shown in Fig. 2(b).

Its total energy of T-Ts configuration drops by 64 meV relative to the supercell of the metal phase with the same number of atoms and then the Fermi surface subsequently drops by 170 meV. The in-plane and out-of-plane whole energy bands upshift by approximately 195 and 243 meV relative to the new Fermi level, respectively. The energy band of the high-symmetry out-of-plane *M-L* segment finally crosses the Fermi level.

The slope of the total DOS has a reversal at the Fermi level from the metal phase to the CDW phase as shown in Fig. 2(b). This means an emergence of an additional Fermi surface and the pocket vanishing without the change of out-of-plane symmetry, which is called the pocket-vanishing-type Lifshitz transition.

### 3.3. Electronic structure of mono-layer CDW phase

Binding energy and formation energy are important indicators for describing structural stability. The binding energies of CDW configuration (Ta<sub>9</sub>S<sub>18</sub>) of bulk and multi-layer 2H-TaS<sub>2</sub> are defined as  $E_b = (E_{\text{CDW}} - 9E_{\text{Ta}} - 18E_{\text{S}})$ , where  $E_{\text{CDW}}$  and  $E_{\text{Ta}}$  (or  $E_{\text{S}}$ ) are total energies without vdW correction of the CDW configuration and the cubic unit cell with a 20 Å crystal constant including only one Ta (or S) atom, respectively.

Both binding energy and formation energy as shown in Table 2 reveal that the stability of the CDW phase for a mono-layer sample is the poorest in the 2H configurations. Our theoretical PT temperature  $T_{\text{CDW}}$  from CDW to metal phase is roughly estimated as approximately 59 K for mono-layer 2H-TaS<sub>2</sub>, which is strongly supported by recent temperature-dependent resistance measurements ( $T_{\text{CDW}} \approx 50$ –60 K).<sup>14,15</sup>

**Table 2** Binding energy  $E_b$  (eV) without vdW correction, formation energy  $\Delta E_{\text{CDW}}$  (eV), vdW interaction  $E_{\text{vdw}}$  (eV), average separation  $D_{\text{S-S}}$  (Å) between sulfur atoms in the adjacent two layers, and average thickness  $D_{\text{S-Ta-S}}$  (Å) of S-Ta-S sandwich-type structure of metal and CDW phase for multi-layer 2H-TaS<sub>2</sub> (Ta<sub>9</sub>S<sub>18</sub>) samples

	$E_b$ (CDW)	$\Delta E_{\text{CDW}}$	$E_{\text{vdw}}$ (metal)	$E_{\text{vdw}}$ (CDW)	$D_{\text{S-S}}$ (metal)	$D_{\text{S-S}}$ (CDW)	$D_{\text{S-Ta-S}}$ (metal)	$D_{\text{S-Ta-S}}$ (CDW)
T	-138.900	-0.040	30.973	30.967			3.136	3.116
Mono-layer	-140.161	-0.049	28.981	28.991	2.877	2.882	3.135	3.127
Bilayer	-140.736	-0.053	27.963	27.965	2.876	2.881	3.137	3.128
Trilayer	-140.944	-0.058	27.602	27.621	2.874	2.880	3.137	3.128
Bulk	-141.399	-0.062	26.919	26.919	2.872	2.876	3.138	3.130

The pseudo band gaps of mono-layer T-Ts configuration are also partially open around the *G-A* and *K-H* segments during Ta atoms contracting for mono-layer 2H-TaS<sub>2</sub> as shown in Fig. 3(a). The mono-layer CDW phase also has six pseudo band gaps (127/115/56 meV at  $g_1/g_2/g_3$  points in the BZ and 108/118/47 meV at  $g_4/g_5/g_6$  points in the BZ) around the saddle points along the *G-A* and *K-H* line in the BZ. The positions of  $g_1-g_6$  pseudo band gaps are also all located at the high symmetry points of the BZ boundary of the CDW phase. Overall the pseudo band gaps of mono-layer 2H-TaS<sub>2</sub> are smaller than corresponding values at all *k*-points in the bulk samples, which also reveals its poorer stability relative to the bulk samples. Surprisingly, the positions of pseudo band gaps happen to be at the Fermi level for mono-layer Ts configurations in Fig. S1-6 (ESI<sup>†</sup>) and for mono-layer T-Ts configuration. The projected in-plane DOS will have a significant drop at around the Fermi level when the Fermi surface locates inside the region of pseudo-gaps.

The absolute value of formation energy of a mono-layer sample is smaller than that of a bulk sample, which means that the whole energy band of a mono-layer sample has less enhancement than that of bulk when we put their Fermi surface at the same level. This is why the positions of pseudo band gaps happen to be at the Fermi level for mono-layer Ts configurations and mono-layer T-Ts configuration. Its total energy of T-Ts configuration drops by 49 meV compared with the supercell of the metal phase with the same number of atoms as shown in Fig. 3(a). The Fermi surface also subsequently drops only by 6 meV, while its energy band is shifted upwards only by only 24 meV relative to the new Fermi level. The high-symmetry point *M-L* segment along the out-of-plane direction does not emerge over the Fermi level, while an additional out-of-plane energy band emerges over the Fermi

level and leads to a bulge above the Fermi level as shown in Fig. 3(a and b).

Larger average distance between sulfur atoms in the adjacent two layers and in-plane area of S-Ta-S sandwich-type configurations always corresponds to larger vdW energy for mono-layer samples as shown in Table 2 and Table S1-3 (ESI<sup>†</sup>). The decrease in binding energy  $\Delta E_b = (E_{b,\text{bulk}} - E_{b,\text{mono-layer}}) + (E_{\text{vdw,bulk}} - E_{\text{vdw,mono-layer}}) = -1.238 - 2.072 = -3.310$  (eV) as shown in Table 2. During the stacking from mono-layer to bulk, vdW interaction can contribute more to reducing binding energy, by approximately twice the chemical energy. Moreover, the smaller average distance between sulfur atoms in the adjacent two layers and in-plane area of S-Ta-S sandwich-type configurations in the bulk samples means that its spatial structure is relatively tight or dense. Its structural distortion will release significant formation energy or latent heat during its geometrically structural PT as shown in Table 2. Therefore the Fermi surface has a larger drop in the bulk samples, while it has a smaller drop in the mono-layer samples.

#### 3.4. Temperature dependence of resistivity for 2H-TaS<sub>2</sub>

The entry of the CDW state below the lock-in temperature 75 K is experimentally detected by a sudden change of the resistivity slope with temperature for bulk 2H-TaS<sub>2</sub>.<sup>11</sup> Its metal phase exhibits a p-type carrier conductivity at room temperature, while the CDW phase exhibits an n-type carrier conductivity below 50 K in the experimental measurements.<sup>13</sup> Our theoretical resistivity (description of computational details as shown in Supplementary-II, ESI<sup>†</sup>) also has a sudden decrease at approximately 75 K from the metal to the CDW phase on cooling as shown in Fig. 5(a). A negative or positive slope of the total DOS at the Fermi level means that n-type or p-type carriers are dominant in the bulk materials. So the dominant p-type carrier conductivity in the metal phase and the n-type carrier conductivity in the bulk CDW phase can be easily found out from their total DOS as shown in Fig. 2(b). Comparing the DOS of the CDW phase with that of the metal phase for bulk samples, it was found that the larger total DOS at the Fermi surface in the CDW phase was mainly attributed to the upshift of in-plane and out-of-plane bands as shown in Fig. S1-8 (ESI<sup>†</sup>). The opening of the pseudogap reduces the effective number of charge carriers in the pseudogap region, the effective number of charge carriers at several bottoms of electronic pockets *i.e.* around the middle point of *GK(AH)* segments significantly rises. This upshift of electronic pockets near the Fermi level is responsible for the larger DOS above the Fermi surface in the

**Fig. 3** (a) Energy band of metal phase and unfolding energy band of CDW phase for mono-layer sample. The gray and blue lines represent the CDW and metal phases. The  $g_1-g_6$  symbols indicate that the pseudo band gaps are located at the  $g_1-g_6$  points in the BZ, respectively. (b) Total DOS for mono-layer 2H-TaS<sub>2</sub>.

in-plane direction as shown in Fig. S1-8(a) and (c) (ESI<sup>†</sup>). The opening of the pseudogap actually reduces significantly the value of the DOS at the B point as shown in Fig. S1-8(c) and (d) (ESI<sup>†</sup>), however, it has little influence on the reversal in carrier sign and the slope of the DOS owing to it being far away from the Fermi level for bulk samples.

The theoretical resistivity has a sudden decrease at approximately 60 K from the metal to the CDW phase on cooling and tends to flatten out below around 50 K for the CDW phase of mono-layer 2H-TaS<sub>2</sub> as shown in Fig. 4(b), which is consistent with recent temperature-dependent-resistivity measurements.<sup>14</sup> The out-of-plane DOS still takes a key role in raising the total DOS around the Fermi level as shown in Fig. 3(b) and Fig. S1-9(d) (ESI<sup>†</sup>). The Fermi surface drops only by 6 meV during PT, and then the B–C segment in Fig. S1-9(c and d) (ESI<sup>†</sup>) actually locates inside the region of one or two pseudo-gaps as shown in Fig. S1-9(a) (ESI<sup>†</sup>), which leads to a significant reduction of the in-plane DOS around the Fermi level in Fig. S1-9(c) (ESI<sup>†</sup>). This causes a reversal of slope for the total DOS in Fig. 3(b) and alternation for p–n type carriers to fail in the mono-layer samples. In this case, only the slope of the projected DOS in the out-of-plane direction has a reversal at the Fermi level during PT, which means that the pocket-vanishing-type Lifshitz transition occurs only in the out-of-plane direction.

### 3.5. Doping-induced PT

The formation energies of the bulk 2H-TaS<sub>2</sub> (Ta<sub>18</sub>S<sub>36</sub>) and mono-layer 2H-TaS<sub>2</sub> (Ta<sub>18</sub>S<sub>36</sub>) were calculated for the situations of electron and hole doping as shown in Fig. 5. In our calculations of carrier-doping effects, electron (or hole) doping was simulated by increasing (or decreasing) the total number of electrons in the system, together with a compensating uniform positive (or negative) background to maintain charge neutrality. As expected, electron doping always increases the lattice parameters, while hole doping shrinks the lattice. The unit volume of the CDW phase without doping is smaller than that of the metal phase as shown in Table S1-3 (ESI<sup>†</sup>), so the hole doping will promote the appearance of the CDW phase, while the electron doping suppresses it in the bulk phase as shown in Fig. 5. The smaller magnitude of the change of formation energies for mono-layer samples resulted from its open structure *i.e.* larger average distance between sulfur atoms in the adjacent two layers as shown in Table 2. Our theoretical PT temperature  $T_{\text{CDW}}$  from the CDW to the metal phase is roughly estimated as approximately 68 K for mono-layer 2H-TaS<sub>2</sub> after hole doping. Recent

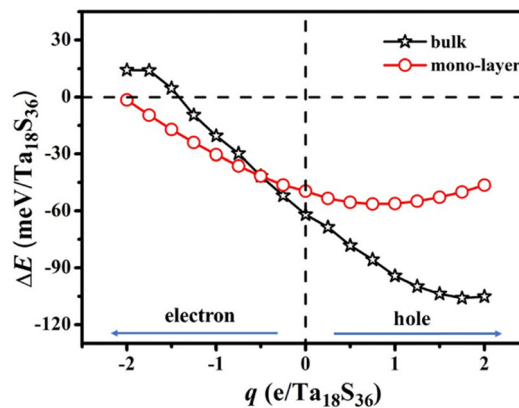

Fig. 5 Excess charge dependence of formation energy for bulk and mono-layer materials.

temperature-dependent resistance experiments<sup>16</sup> indicate that mono-layer 2H-TaS<sub>2</sub> on SiO<sub>2</sub>/Si substrates undergoes a PT at 140 K upon heating which is far above that (75 K) of bulk samples. Its higher  $T_{\text{CDW}}$  was attributed to the reduced dimensionality and enhancement of electron–phonon coupling. However, its larger thermal hysteresis effect (PT temperature at 93 K upon cooling) reveals that its PT is a strong first-order structural PT rather than weak structural T–Ts → metal PT. In fact, after injecting holes, the total energy of some CDW images (called the X image) in Table 1 is significantly reduced. Large geometric structural difference and small energy difference between T–Ts and X configurations can reasonably explain the wider-temperature thermal hysteresis effect<sup>16</sup> at low temperature for mono-layer TaS<sub>2</sub>.

Interestingly, the CDW phase was found to be absent in epitaxial mono-layered 2H-TaS<sub>2</sub> on a Au(111) substrate<sup>47</sup> but persisted in MBE grown mono-layered TaS<sub>2</sub> on graphene/Ir(111).<sup>48,49</sup> These findings provided further evidence that the CDW formation in such atomically thin TMDs is, in general, highly susceptible to the surrounding environment that could be a neighboring layer or even a substrate. One important difference between these two substrates is that Au(111) as a metal is a better electron dopant than graphene that is a semimetal. We calculated the 2H-TaS<sub>2</sub> mono-layer/Au(111) and 2H-TaS<sub>2</sub> mono-layer/graphene systems and then performed Bader charge analysis to study the electron transfer from the substrate to 2H-TaS<sub>2</sub>. It is found that TaS<sub>2</sub> (Ta<sub>18</sub>S<sub>36</sub>) obtains 0.71e from Au(111), which is sufficient to suppress the 3 × 3 CDW phase according to electron doping to induce the CDW phase. Recent theoretical calculations<sup>50</sup> indicated that there is a charge transfer of about 1.44e from Au(111) to each 2H-TaS<sub>2</sub> mono-layer. Such a quantity of charge injection can more effectively suppress the occurrence of the CDW phase. Since the CDW phase of the mono-layer model is more reasonable as mentioned above, our theoretical results are more reliable owing to the mono-layer 2H-TaS<sub>2</sub> model used in their calculations. The electron doping level from mono-layered and bilayered graphene to 2H-TaS<sub>2</sub> significantly reduces to 0.39e and 0.37e, respectively, which is low enough to keep the 3 × 3

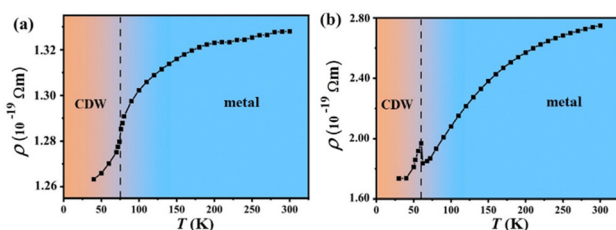

Fig. 4 Temperature dependence of theoretical resistivity for 2H-TaS<sub>2</sub>. (a) Bulk samples, (b) mono-layer samples.

CDW phase. Although the substrate effects are complex and usually cannot be ascribed to one single factor, the difference of the electron doping contributed by Au(111) and graphene is already large enough to affect the CDW phase in 2H-TaS<sub>2</sub>, leading to different experimental observations.<sup>47–49</sup>

### 3. Conclusions

The geometrical structure (T–Ts) of the CDW phase with several pseudo-gaps (50–200 meV order of magnitude) was predicted through first principles calculations for bulk and mono-layer 2H-TaS<sub>2</sub>. Driven by electron-lattice coupling, Ta atoms contract to form the CDW phase and the Fermi level continually drops on cooling. Its whole energy bands upshift and then the positions of the pseudo band gap finally become much higher (around 200 meV) relative to the Fermi level for the bulk sample, while they happen to be at the Fermi level for mono-layer samples. The vdW interaction makes bulk samples have larger density and latent heat, which result in a larger upshift for the whole energy bands in the bulk samples.

The average interlayer separation of S–S atoms in the adjacent two layers increases after the shrinkage of Ta atoms for bulk samples during PT, which leads to a weaker chemical bonding among S–S atoms in the adjacent two layers. Its bandwidth in the out-of-plane direction of the CDW phase decreases relative to the metal phase owing to the weaker chemical bonding, which results in a substantial bulge of the projected out-of-plane DOS and total DOS around the Fermi level. However, the existence of the pseudo band gap will reduce the projected in-plane DOS and then total DOS around the Fermi level for mono-layer samples. The bulge for the total DOS of the CDW phase located at the Fermi level is responsible for the n-type carrier in the bulk 2H-TaS<sub>2</sub>, while the reduction of the total DOS owing to the existence of the pseudo-gap at the Fermi level is responsible for the p-type carrier in the mono-layer 2H-TaS<sub>2</sub>.

The T–Ts configuration has the same symmetry in the out-of-plane direction as its metal phase, but each of its two layers has a different geometrical structure from the metal phase. Its symmetry in the in-plane direction breaks during in-plane contracting of Ta atoms. Lifshitz transition with an emergence of additional Fermi surface occurs in the out-of-plane direction without symmetry breaking during the structural PT. Our CDW vector of the *k*-space separation between two saddle points is  $Q_{SP} \approx 0.62 \text{ GK}$  and can provide a theoretical support for the “saddle-point” CDW mechanism proposed by Rice and Scott.
