## Hybrid superlattice cathodes unlocking diffusion-barrier-free proton storage for high-rate Zn–MnO<sub>2</sub> batteries†

 Yumin Chen,<sup>a</sup> Da Zhang,<sup>a</sup> Chengmin Hu,<sup>c</sup> Pingxuan Liu,<sup>a</sup> Xiaozhe Yang,<sup>a</sup> Hui Duan,<sup>a</sup> Ling Miao,<sup>a</sup> Yaokang Lv,<sup>id</sup> Ziyang Song,<sup>\*a</sup> Lihua Gan<sup>id</sup> <sup>\*a,b</sup> and Mingxian Liu<sup>id</sup> <sup>\*a,b</sup>

Diffusion-controlled Zn<sup>2+</sup> intercalation often suffers from strong lattice repulsion when using a MnO<sub>2</sub> cathode in Zn-ion batteries, leading to slow reaction kinetics and irreversible phase transitions. Boosting intercalation-barrier-free Grotthuss proton storage in competition with Zn<sup>2+</sup> in the MnO<sub>2</sub> host provides a highly promising path to develop high-kinetics and stable Zn-ion batteries, but this remains challenging. Here we incorporate tetraamino-benzoquinone (TABQ) into a nickel-doped δ-MnO<sub>2</sub> host to design a two-dimensional hybrid superlattice cathode (Ni–TABQ@δ-MnO<sub>2</sub>), which triggers ultrafast proton transfer *via* Grotthuss topochemistry. Conductive Ni–TABQ effectively modulates the electronic properties of δ-MnO<sub>2</sub> through π–d electron coupling, enabling a transition from semiconducting to metallic behavior and markedly increasing the current response from 205 to 305 pA. Furthermore, the intermolecular H-bonding network between the coordination water of Ni–TABQ and lattice oxygen of δ-MnO<sub>2</sub> allows H<sub>3</sub>O<sup>+</sup> to transfer protons through the continuous breaking and reformation of O–H bonds. Accordingly, dynamic proton hopping within the Ni–TABQ@δ-MnO<sub>2</sub> cathode shows an ultralow energy barrier (0.124 eV) compared to Zn<sup>2+</sup> intercalation (0.741 eV), leading to superior rate capacities (453 mA h g<sup>−1</sup> at 0.2 A g<sup>−1</sup>; 151 mA h g<sup>−1</sup> at 10 A g<sup>−1</sup>) and a long lifespan (8000 cycles). This study gives new insights into the design of diffusion-barrier-free proton-conductive hybrid superlattice cathodes for advanced energy storage.

### Broader context

Aqueous rechargeable Zn–MnO<sub>2</sub> batteries have gained significant attention due to their inherent safety, low cost and favorable operating voltages, making them promising candidates for large-scale energy storage. However, the large size and high desolvation energy of [Zn(H<sub>2</sub>O)<sub>6</sub>]<sup>2+</sup> ions result in sluggish intercalation kinetics and diminished (dis)charge rates in Zn–MnO<sub>2</sub> batteries. Additionally, the strong lattice repulsion between Zn<sup>2+</sup> ions and the MnO<sub>2</sub> host often leads to irreversible phase transitions and structural collapse, severely compromising the rate capacity and cycling stability. In this work, we design a hybrid superlattice cathode (Ni–TABQ@δ-MnO<sub>2</sub>), which triggers ultrafast proton transfer *via* Grotthuss topochemistry. Conductive Ni–TABQ effectively modulates the electronic properties of δ-MnO<sub>2</sub> through π–d electron coupling, and the intermolecular H-bonds between coordination water (Ni–TABQ) and lattice oxygen (δ-MnO<sub>2</sub>) facilitate dynamic proton transfer through the continuous breaking and reformation of the H-bonding network. The unique proton hopping processes empower Zn–MnO<sub>2</sub> to deliver a high-rate and ultrastable charge storage process. This study may shed new light on the design of diffusion-barrier-free proton-conductive hybrid superlattice cathodes for advanced energy storage.

## Introduction

Aqueous rechargeable zinc-ion batteries (ZIBs) have gained significant attention due to their inherent safety, low cost, and the high theoretical capacity of zinc anodes (820 mA h g<sup>−1</sup>) coupled with a favorable redox potential (−0.76 V *vs.* standard hydrogen electrode), making ZIBs promising candidates to act as large-scale energy storage solutions.<sup>1–5</sup> Among the various Zn<sup>2+</sup>-hosting inorganic cathode materials, manganese-based oxides show significant properties, such as a high theoretical capacity, favorable operating voltage and natural abundance.<sup>6–10</sup> In particular, layered δ-MnO<sub>2</sub> has a two-dimensional open crystal structure and large interlayer

spacing enabling efficient charge-carrier (de)intercalation, distinguishing it among manganese-based oxides and making it an ideal candidate for high-performance energy storage.<sup>11–15</sup>

However, the large hydrated structure and high desolvation energy of  $[\text{Zn}(\text{H}_2\text{O})_6]^{2+}$  ions pose significant challenges, triggering sluggish intercalation kinetics and (dis)charge rates in ZIBs.<sup>16–18</sup> Additionally, strong lattice repulsion between  $\text{Zn}^{2+}$  ions and the  $\delta\text{-MnO}_2$  host lattice often triggers irreversible phase transitions and structural collapse, further limiting the capacity performance and cycling stability.<sup>19–22</sup> Addressing these issues requires innovative approaches to optimize the charge storage behavior of manganese-based cathodes and stabilize their structures during cycling.

Compared with sluggish  $\text{Zn}^{2+}$  storage, protons ( $\text{H}^+$ ), having the smallest size and lightest weight, can enable fast (de)intercalation kinetics and reduce structural degradation in Mn-based hosts during cycling, significantly improving the rate performance and high-power energy storage of ZIBs.<sup>23–26</sup> Therefore, activating superior  $\text{H}^+$  storage offers a compelling solution to overcome the electrochemical limitations of  $\text{Zn}^{2+}$ , with significant potential to improve the rate performance and lifespan of Zn–MnO<sub>2</sub> batteries.<sup>27–30</sup> For instance, Pan *et al.* introduced the Grotthuss proton transport mechanism in  $\alpha\text{-MnO}_2$ , highlighting the rapid proton migration within the  $[2 \times 2]$ -tunnel structure.<sup>31</sup> He *et al.* showed that the lattice water in  $\text{NiMn}_3\text{O}_7 \cdot 3\text{H}_2\text{O}$  facilitates hydrated proton migration to interlayer spaces, where protons bind with  $\text{O}^{2-}$  ions in the Mn–O layer, thereby enabling efficient charge transport and structural stability during cycling.<sup>32</sup> These findings highlight the critical role of the crystal structure in facilitating proton migration and enhancing electrochemical performance. However, during prolonged cycling, competition with  $\text{Zn}^{2+}$  insertion and the structural instability of reported Mn-based host materials frequently undermine the efficiency of Zn–MnO<sub>2</sub> energy storage systems, leading to decreased proton storage, especially at high current densities. Therefore, it is of great significance to precisely design Mn-based cathodes with more favorable crystal lattice structures for better selective proton intercalation for the purpose of propelling high-performance Zn–MnO<sub>2</sub> batteries.

In this work, a hybrid superlattice Ni–TABQ@ $\delta\text{-MnO}_2$  cathode is designed to enhance proton transfer by taking advantage of the Grotthuss topochemistry mechanism. Incorporated conductive Ni–TABQ can modulate the electronic properties of  $\delta\text{-MnO}_2$  *via*  $\pi$ –d electron coupling, establishing efficient conductive pathways. Moreover, rich intermolecular H-bonds between coordination water (Ni–TABQ) and lattice oxygen ( $\delta\text{-MnO}_2$ ) facilitate proton conduction for rapid redox reactions, and the formed intermolecular H-bonding network allows  $\text{H}_3\text{O}^+$  to transfer protons through the continuous breaking and reformation of O–H bonds. This dynamic hopping of protons significantly reduces the charge-transfer energy barrier compared to the (de)intercalation of  $\text{Zn}^{2+}$  (0.082 eV *vs.* 0.741 eV), enabling fast and stable energy storage. As a result, the Ni–TABQ@ $\delta\text{-MnO}_2$  cathode demonstrates excellent performance, including high capacity, large-current tolerance,

and an ultralong lifespan. This study paves the way for the development of Grotthuss proton-conductive hybrid superlattice cathodes towards advanced energy storage.

## Results and discussion

During the cyclic charging and discharging of a layered  $\delta\text{-MnO}_2$  cathode, zinc-ion insertion induces strong lattice repulsion and irreversible phase transitions, resulting in rapid structural degradation and performance decline. A widely adopted approach to mitigate these effects is cation pillar engineering.<sup>24,33</sup> While cation pre-intercalation modestly enhances the (de)intercalation kinetics of Ni– $\delta\text{-MnO}_2$ , it leads to limited improvement of its intrinsic electronic properties. Additionally, cation pillar dissolution during ion exchange over periods of extended cycling compromises structural integrity, leading to a sharp decline in capacity retention (Fig. S1†). To address these challenges, TABQ was selected due to its conjugated planar structure and easy combination with  $\text{Ni}^{2+}$  ions to form a  $\pi$ –d electronic coupling configuration; these are beneficial for boosting electronic conductivity and triggering ultrafast proton transfer *via* Grotthuss topochemistry, thereby optimizing the electrochemical properties. We innovatively incorporate TABQ into Ni– $\delta\text{-MnO}_2$  to form a two-dimensional conductive metal–organic framework (Ni–TABQ). This framework further integrates with the  $\delta\text{-MnO}_2$  host to construct an organic–inorganic hybrid superlattice structure (Ni–TABQ@ $\delta\text{-MnO}_2$ ). The hybrid superlattice cathode combines the superior electronic conductivity of the organic components with the high-energy storage capabilities of the  $\delta\text{-MnO}_2$  lattice, offering a promising solution for zinc-ion energy storage. Furthermore, the superlattice architecture enables precise control over the lattice arrangement and interfaces of the organic and inorganic components, significantly enhancing the proton transfer efficiency. This synergistic integration optimizes the electronic properties and rate performance of the Ni–TABQ@ $\delta\text{-MnO}_2$  cathode, making it a robust candidate for use in high-rate and stable energy storage systems (Fig. 1a).

Rietveld refinement of the crystal diffraction profiles (Fig. 1b) shows that the hybrid superlattice Ni–TABQ@ $\delta\text{-MnO}_2$  cathode retains the same monoclinic phase ( $C2/m$  space group) as  $\delta\text{-MnO}_2$ , with refined lattice parameters of  $\alpha = \gamma = 90^\circ$ ,  $\beta = 116.99^\circ$ ,  $a = 10.38$ ,  $b = 5.84$ , and  $c = 8.09$  Å, achieving a satisfactory agreement factor ( $R_{\text{wp}} = 6.47\%$ ). Morphological characterization shows that  $\delta\text{-MnO}_2$ , Ni– $\delta\text{-MnO}_2$  and Ni–TABQ all feature nanoflower structures composed of nanosheets (Fig. S2a–f and S3†). Notably, Ni–TABQ@ $\delta\text{-MnO}_2$  retains its morphology after incorporating the TABQ component into the Ni– $\delta\text{-MnO}_2$  framework (Fig. 1c and Fig. S2g–i†), which is helpful for the exposure of active sites and fast ion (de)intercalation. Fourier transform infrared (FT-IR) spectra (Fig. 1d) and thermogravimetric analysis results (Fig. S4†) further confirm that TABQ has been successfully incorporated into the Ni– $\delta\text{-MnO}_2$  host.<sup>34</sup> High-resolution transmission electron

microscopy (HRTEM) images provide detailed insights into the crystal structure and diffraction planes of manganese-based materials. For  $\delta$ -MnO<sub>2</sub>, a monoclinic crystal structure with an interlayer spacing of 0.672 nm along the (100) plane is observed, which expands to 0.695 nm upon pre-intercalation with Ni<sup>2+</sup> cation pillars (Fig. 1e and f). Further characterization of Ni-TABQ@ $\delta$ -MnO<sub>2</sub> based on HRTEM and fast Fourier transformation (FFT) patterns (Fig. 1g) confirms the successful incorporation of TABQ into the (001) plane of Ni- $\delta$ -MnO<sub>2</sub>. The integration of Ni-TABQ induces the formation of a hybrid superlattice structure, further expanding the interlayer spacing

to 0.705 nm. XRD patterns substantiate these changes, showing broadened (001) peaks and their shift to lower  $2\theta$  angles (Fig. S5<sup>†</sup>), indicative of improved crystallinity and interlayer expansion.<sup>35</sup> HRTEM maps reveal the distinct elemental signals of Ni and N, originating from Ni-TABQ, further confirming the uniform integration of TABQ into the Ni- $\delta$ -MnO<sub>2</sub> crystal framework to form the hybrid superlattice Ni-TABQ@ $\delta$ -MnO<sub>2</sub> cathode (Fig. S6<sup>†</sup>).

Density functional theory (DFT) simulations were conducted to investigate the intermolecular forces and electronic properties of Ni-TABQ@ $\delta$ -MnO<sub>2</sub>. The independent gradient

b).<sup>41,42</sup> After introducing Ni-TABQ MOFs as interlayer electron carriers, metallic properties emerge, markedly enhancing the conductivity (Fig. 2c and d). Through the hybridization of Ni-3d and N-2p orbitals, Ni-TABQ MOFs enable  $\pi$ -d electron coupling to establish an electronic conductive network that facilitates both ion and electron transfer (Fig. 2e).<sup>43,44</sup> Conductive atomic force microscopy (CAFM) was employed to evaluate the local current distribution on the surface of manganese-based materials, providing precise insights into their conductivity behavior (Fig. S9†). As depicted in Fig. 2f,  $\delta$ -MnO<sub>2</sub> demonstrates a peak current of 205 pA, accompanied by an uneven current distribution, indicating its limited intrinsic conductivity. Upon doping with Ni<sup>2+</sup> cation pillars, the peak current slightly increases to 229 pA, reflecting a moderate improvement in conductivity (Fig. 2g). In contrast, the most significant enhancement of peak current (307 pA) is observed in Ni-TABQ@ $\delta$ -MnO<sub>2</sub> (Fig. 2h). This improvement is accompanied by a notably uniform current distribution across the surface, highlighting the superior electronic transport pathways established by the conductive Ni-TABQ. The enhanced conductivity can be attributed to the  $\pi$ -d electron coupling induced electron transfer in the hybrid superlattice structure, which collectively facilitated faster ion and electron mobility.

To evaluate the electrochemical conductivity properties of  $\delta$ -MnO<sub>2</sub>-based cathodes, electrochemical impedance spectroscopy (EIS) analysis was carried out (Fig. 2i and Fig. S10a†). It reveals that the hybrid superlattice Ni-TABQ@ $\delta$ -MnO<sub>2</sub> cathode achieves a significantly lower charge transfer resistance ( $R_{ct}$ ) of 48.8  $\Omega$ , outperforming both Ni- $\delta$ -MnO<sub>2</sub> (88.2  $\Omega$ ) and  $\delta$ -MnO<sub>2</sub> (118.5  $\Omega$ ). The real impedance component  $Z'$  and angular frequency  $\omega$  further verify the superior charge transfer kinetics of the hybrid superlattice structure (Fig. 2j).<sup>45,46</sup> The activation energy ( $E_a$ ) for charge transfer was obtained using the Arrhenius equation (eqn (S5) and (S6)†). The Ni-TABQ@ $\delta$ -MnO<sub>2</sub> cathode demonstrates an exceptionally small  $E_a$  value of 11.88 kJ mol<sup>-1</sup> (Fig. 2k and Fig. S10b†), which is significantly lower than those of Ni- $\delta$ -MnO<sub>2</sub> (19.10 kJ mol<sup>-1</sup>) and  $\delta$ -MnO<sub>2</sub> (21.87 kJ mol<sup>-1</sup>). These results underscore the high ionic conductivity, efficient ion diffusion pathways, and reduced reaction barrier of the hybrid superlattice structure of Ni-TABQ@ $\delta$ -MnO<sub>2</sub>. The incorporation of Ni-TABQ enhances the charge transfer efficiency and ion transport, highlighting its role in enabling high-kinetics charge storage, and positioning the hybrid superlattice Ni-TABQ@ $\delta$ -MnO<sub>2</sub> as a promising cathode material for advanced energy storage.

Zn-MnO<sub>2</sub> batteries were constructed, which involve a Zn metal anode,  $\delta$ -MnO<sub>2</sub>-based cathodic materials, and 2 M ZnSO<sub>4</sub> + 0.2 M MnSO<sub>4</sub> aqueous electrolyte (Fig. S11†). Cyclic voltammetry (CV) curves of Ni-TABQ@ $\delta$ -MnO<sub>2</sub> (Fig. 3a) exhibit pronounced redox peaks and reduced polarization, indicating its superior redox activity compared to  $\delta$ -MnO<sub>2</sub> and Ni- $\delta$ -MnO<sub>2</sub>. The Ni-TABQ@ $\delta$ -MnO<sub>2</sub> cathode achieves an impressive specific capacity of 453 mA h g<sup>-1</sup> at 0.2 A g<sup>-1</sup>, outperforming  $\delta$ -MnO<sub>2</sub> (236 mA h g<sup>-1</sup>), Ni- $\delta$ -MnO<sub>2</sub> (346 mA h g<sup>-1</sup>) and Ni-TABQ (12 mA h g<sup>-1</sup>) (Fig. 3b and Fig. S12†). The Ni-

TABQ@ $\delta$ -MnO<sub>2</sub> cathode also demonstrates excellent rate capacities of 370, 331, 274, 218, 183, and 152 mA h g<sup>-1</sup> at current densities of 0.5, 0.8, 1, 3, 5, and 10 A g<sup>-1</sup>, respectively (Fig. 3b and c). Significantly, the Zn||Ni-TABQ@ $\delta$ -MnO<sub>2</sub> battery achieves a record energy density of 586 W h kg<sup>-1</sup> (calculated based on the mass of active cathode material; Fig. 3d and Table S1†), which is superior to reported Mn/V-based and organic cathode materials.<sup>47-54</sup> At mass loadings of 2.9 and 5.0 mg cm<sup>-2</sup>, the TABQ@ $\delta$ -MnO<sub>2</sub> cathode delivers capacities of 423 and 362 mA h g<sup>-1</sup>, respectively. Even at a high mass loading of 10.2 mg cm<sup>-2</sup>, it retains a remarkable capacity of 289 mA h g<sup>-1</sup>, highlighting its exceptional large-scale energy storage potential (Fig. S13†). Furthermore, the TABQ@ $\delta$ -MnO<sub>2</sub> cathode maintains 88.76% of its initial capacity (328 mA h g<sup>-1</sup>) after 200 cycles at 0.5 A g<sup>-1</sup>, with high coulombic efficiency (Fig. 3e). Conversely, Ni- $\delta$ -MnO<sub>2</sub> and  $\delta$ -MnO<sub>2</sub> exhibit inferior cycling stability, with low-capacity retention of 45.16% and 34.08% in the absence of the TABQ component, due to the dissolution of pre-intercalated Ni<sup>2+</sup> cations and structural degradation. Remarkably, even at a high current density of 5 A g<sup>-1</sup> for 8000 cycles, the capacity retention remains at 93.82%, underscoring the robust structural and electrochemical stability of the hybrid superlattice cathode (Fig. 3e, Fig. S14 and S15†). Three integrated Zn||Ni-TABQ@ $\delta$ -MnO<sub>2</sub> batteries can power an LED toy (Fig. S16†), demonstrating the application promise of Zn-MnO<sub>2</sub> batteries.

In addition, the redox kinetics of the Zn||Ni-TABQ@ $\delta$ -MnO<sub>2</sub> cell were analyzed by using CV curves and Dunn's method.<sup>55,56</sup> Across scan rates in the range of 0.2–1.0 mV s<sup>-1</sup>, CV profiles maintain consistent shapes with minor shifts in redox peaks (Fig. S17†), indicating the excellent electrochemical reversibility of the Zn||Ni-TABQ@ $\delta$ -MnO<sub>2</sub> battery. Three distinct redox signals (denoted as P<sub>R1</sub>, P<sub>R2</sub>, and P<sub>O1</sub>) are observed, corresponding to the Zn<sup>2+</sup>/H<sup>+</sup> co-intercalation redox reaction. The power-law relationship between the peak current ( $i$ ) and scan rate ( $\nu$ ) yields  $b$ -values of 0.56, 0.77, and 0.53 for the three peaks (Fig. 3g), demonstrating a rapid surface-dominated proton charge storage process coupled with Zn<sup>2+</sup> intercalation during discharging. Further analysis reveals that the rapid surface capacitive contribution dominates charge storage, accounting for 75.66–94.47% of the total capacity across all scan rates (Fig. 3h and i). However, the  $b$ -values and rapid surface capacitive contributions of  $\delta$ -MnO<sub>2</sub> and Ni- $\delta$ -MnO<sub>2</sub> cathodes indicate their slow reaction kinetics processes (Fig. S18 and S19†). These findings underscore the critical role of the conductive Ni-TABQ component in modulating the electronic properties of the hybrid superlattice cathode, facilitating high-power energy storage.

To further identify the charge-storage mechanism of the Ni-TABQ@ $\delta$ -MnO<sub>2</sub> cathode, spectroscopic characterization was performed to delve into the proton storage behavior in specific potential states (Fig. 4a). Based on *ex situ* XRD patterns (Fig. 4b and Fig. S20†), the peak intensities of HMnO<sub>2</sub> at 20.8° and 32.7° increase during discharging (state A → D) and disappear during subsequent charging (state D → G),<sup>32,57</sup> verifying the highly reversible phase transition process. HRTEM

images in state D further confirm the evolution of HMnO<sub>2</sub>, accompanied by the appearance of the (1, 1, −1) crystal plane with a width of 0.342 nm (Fig. 4c). Operando pH measurements were conducted to accurately monitor the H<sup>+</sup> redox behavior in the Ni–TABQ@δ-MnO<sub>2</sub> cathode during the discharge/charge process (Fig. S21†). The pH value is significantly boosted from 2.47 to 3.01 during discharging from 1.80–1.25 V. Subsequently, it slightly increases in the voltage range of 1.25–0.80 V, with pH values of 3.01 to 3.09 (Fig. 4d). Such results imply a strong proton-coupled charge storage process in the Ni–TABQ@δ-MnO<sub>2</sub> cathode over the voltage range of 1.80–1.25 V (state A → C). In the subsequent recharging procedure, the pH value returns back to its initial level. In addition, the reversible formation of Zn<sub>4</sub>(OH)<sub>6</sub>(SO<sub>4</sub>)·5H<sub>2</sub>O (ZHS) functions (Fig. S22†) as a pH buffer and holds the solution pH value constant within a certain range.

An electrochemical quartz crystal microbalance (EQCM) was employed for the operando monitoring of the mass change of Ni–TABQ@δ-MnO<sub>2</sub> with continuous ion intercalation. Consistent with the GITT results, the mass change of the Ni–TABQ@δ-MnO<sub>2</sub> electrode during ion intercalation involves

two stages. In the first stage (state A → C), the average weight increase calculated based on the curve slope (Fig. 4e) is 19.72 g per mol charge, close to the weight of H<sub>3</sub>O<sup>+</sup> (19 g per mol charge), suggesting hydrated proton (H<sub>3</sub>O<sup>+</sup>) intercalation in Ni–TABQ@δ-MnO<sub>2</sub>. Meanwhile, the average weight increase in the second stage (state C → D) is 32.94 g per mol charge, which suggests the intercalation of Zn<sup>2+</sup> in Ni–TABQ@δ-MnO<sub>2</sub>. The galvanostatic intermittent titration technique (GITT) is applied to measure the ion diffusion coefficient (*D*; Fig. 4f and Fig. S23†). The higher *D* values of ~10<sup>−9</sup> cm<sup>2</sup> s<sup>−1</sup> during discharging (state A → C) are ascribed to the fast-kinetics incorporation of H<sup>+</sup>, while the lower *D* values of ~10<sup>−11</sup> cm<sup>2</sup> s<sup>−1</sup> (state C → D) belong to the slow intercalation of Zn<sup>2+</sup> in the Ni–TABQ@δ-MnO<sub>2</sub> cathode. These results verify the two-step H<sup>+</sup>/Zn<sup>2+</sup> co-intercalation redox process. Thanks to the mixed superlattice structure of Ni–TABQ@δ-MnO<sub>2</sub>, protons can be transferred *via* H<sub>2</sub>O media through Grotthuss topochemistry, which is beneficial for rapid charge storage and high-power energy storage.

High-resolution X-ray photoelectron spectroscopy (XPS) analysis of the O 1s signal was carried out to elucidate the

redox behavior of the Ni-TABQ@ $\delta$ -MnO<sub>2</sub> cathode during cell operation. In the pristine state, two peaks at 530.1 and 531.7 eV are observed, corresponding to lattice oxygen (O1) and oxygen from adsorbed H<sub>2</sub>O (O2), respectively.<sup>58</sup> Notably, an additional peak at 533.8 eV (O3) emerges during the charge/discharge process. This peak is attributed to the terminal oxygens of [MnO<sub>6</sub>] bilayers, and it splits from the O2 peak due to H-bond formation with intercalated H<sub>2</sub>O/H<sub>3</sub>O<sup>+</sup> (as illustrated in Fig. 4g). Compared with Ni- $\delta$ -MnO<sub>2</sub> and  $\delta$ -MnO<sub>2</sub> cathodes, the Mn 2p XPS spectra of Ni-TABQ@ $\delta$ -MnO<sub>2</sub> reveal the largest fluctuations of Mn valence due to enhanced redox activity from proton involvement (Fig. S24a and b<sup>†</sup>). This confirms that the extra capacity contribution originates from the multielectron redox activity of Mn sites and is enabled by a strong proton-electron coupling process. The Ni-TABQ@ $\delta$ -MnO<sub>2</sub> cathode in HOTF-H<sub>2</sub>O electrolyte exhibits the highest proton storage capacity of 233.2 mA h g<sup>-1</sup> (Fig. S24c<sup>†</sup>), which outperforms Ni- $\delta$ -MnO<sub>2</sub> (95.6 mA h g<sup>-1</sup>) and  $\delta$ -MnO<sub>2</sub>

(52.3 mA h g<sup>-1</sup>), highlighting the key role of Ni-TABQ incorporation in improving the electrochemical capacity. Operando FT-IR spectra exhibit the generation/disappearance of O-H signals, which derive from reactions between the lattice oxygen of Ni-TABQ@ $\delta$ -MnO<sub>2</sub> and protons (Fig. S24d<sup>†</sup>). Such a result confirms the participation of protons through distinct shifts in the O-H stretching bands during the (dis)charge process. Simultaneously, the Zn 2p signal intensity increases during the discharge process (state A  $\rightarrow$  D) due to Zn<sup>2+</sup> intercalation into the Ni-TABQ@ $\delta$ -MnO<sub>2</sub> host and weakens during the recharge process (state D  $\rightarrow$  G) as Zn<sup>2+</sup> ions are extracted (Fig. 4h). Compared to pristine  $\delta$ -MnO<sub>2</sub>, the hybrid superlattice Ni-TABQ@ $\delta$ -MnO<sub>2</sub> cathode exhibits a reduced Zn<sup>2+</sup> intercalation capacity due to steric hindrance imposed by Ni-TABQ. Elemental distribution maps of Mn, O, and Zn, along with their relative proportions, further validate the selective ionic storage behavior (Fig. 4i and Fig. S25a and b<sup>†</sup>). Moreover, coupled plasma optical emission spectroscopy (ICP-OES) ana-

lyses of the Ni-TABQ@ $\delta$ -MnO<sub>2</sub> cathode at various rates confirmed that proton storage becomes more dominant with increasing current density, reaching 93.91% at 10 A g<sup>-1</sup> (Fig. S25c and Table S2†). Accordingly, the structural design of hybrid superlattice Ni-TABQ@ $\delta$ -MnO<sub>2</sub> can not only suppress excessive Zn<sup>2+</sup> intercalation but also promote efficient proton storage through Grotthuss topochemistry, enabling fast and stable charge storage performance.

To investigate the mechanisms of proton transport and charge storage, DFT calculations were performed to simulate the structural evolution of the Ni-TABQ@ $\delta$ -MnO<sub>2</sub> cathode during electrochemical reactions. As shown in Fig. 5a, the hybrid superlattice Ni-TABQ@ $\delta$ -MnO<sub>2</sub> exhibits highly protophilic reactivity (H<sub>3</sub>O<sup>+</sup>, -1.65 eV) and weaker zincophilic behavior (Zn<sup>2+</sup>, -0.26 eV), while  $\delta$ -MnO<sub>2</sub> demonstrates stronger Zn<sup>2+</sup> adsorption (-1.17 eV) but relatively limited interaction with H<sub>3</sub>O<sup>+</sup> (-0.85 eV). The pronounced protophilic activity of Ni-TABQ@ $\delta$ -MnO<sub>2</sub> facilitates efficient Grotthuss proton conduction. The interaction bonding types were further explored using IGMH and ELF maps. Hydrated protons exhibit strong

hydrogen bonding within the hybrid superlattice framework of Ni-TABQ@ $\delta$ -MnO<sub>2</sub> (Fig. 5b), whereas Zn<sup>2+</sup> predominantly forms Zn-O ionic bonds (Fig. 5c). In contrast with the rigid Zn-O ionic bonds, the dynamic and flexible nature of H-bonds enhances the proton transport kinetics and charge storage. Differential electron density isosurfaces and Bader charge analysis reveal the charge transfer behavior between charge carriers and the Ni-TABQ@ $\delta$ -MnO<sub>2</sub> host (Fig. 5d). Notably, H<sub>3</sub>O<sup>+</sup> enables better charge transfer to the Ni-TABQ@ $\delta$ -MnO<sub>2</sub> host (0.824 e) in comparison to Zn<sup>2+</sup> (0.413 e), further confirming its superior protonophilic reactivity. To evaluate ion diffusion pathways and energy barriers, the climbing-image nudged elastic band (CI-NEB) method was employed. Fig. 5e and Fig. S26† illustrate the migration trajectories of Zn<sup>2+</sup> and H<sup>+</sup> ions. The calculated activation energy barriers for Zn<sup>2+</sup> and H<sup>+</sup> migration are 0.741 and 0.124 eV, respectively. The main barrier to Zn<sup>2+</sup> ion transport in the aqueous electrolyte originates from the spatial steric hindrance imposed by Ni-TABQ layers within the hybrid Ni-TABQ@ $\delta$ -MnO<sub>2</sub> superlattice structure. In contrast, the hydro-

gen-bonding network primarily facilitates proton transport through the Grotthuss mechanism, which affords fast redox kinetics at Mn sites but does not directly influence  $\text{Zn}^{2+}$  migration. This ultra-low energy barrier for  $\text{H}^+$  diffusion underscores the superior proton storage performance of the Ni-TABQ@ $\delta$ - $\text{MnO}_2$  cathode.

Here, the Grotthuss proton transfer mechanism, also known as proton hopping, is demonstrated, representing an efficient and dynamic pathway for proton conduction in H-bonding systems (Fig. 5f). Unlike conventional  $\text{Zn}^{2+}$  ionic diffusion, where ions physically migrate across the host material, the Grotthuss mechanism relies on the rapid relay of protons through hydrogen-bonding networks. This process involves the transient breaking and reformation of H-bonds, allowing protons to “hop” between adjacent water molecules, contributing to diffusion-free  $\text{H}^+$  transport (Fig. 5g). As a result, the net transport of protons occurs without the significant mass movement of ionic carriers, leading to faster proton mobility and reduced energy barriers. The strong protophilic nature of the hybrid superlattice TABQ@ $\delta$ - $\text{MnO}_2$  framework plays a critical role in enabling Grotthuss topochemistry. The hydrated protons ( $\text{H}_3\text{O}^+$ ) form dynamic and flexible H-bonds within Ni-TABQ@ $\delta$ - $\text{MnO}_2$ , creating an ideal environment for Grotthuss proton transfer. This well-connected H-bonding network facilitates the rapid and continuous hopping of protons, significantly enhancing the proton transport kinetics. Compared to rigid and slow  $\text{Zn}^{2+}$  transport through Zn-O ionic bonds, proton transfer *via* Grotthuss topochemistry ensures higher charge storage efficiency and faster response times during electrochemical reactions. Consequently, the Grotthuss mechanism contributes directly to the superior proton storage capabilities, high ionic conductivity, and enhanced energy storage performance of the Ni-TABQ@ $\delta$ - $\text{MnO}_2$  cathode, making this a promising strategy for advanced energy storage systems.

## Conclusions

We designed a hybrid superlattice Ni-TABQ@ $\delta$ - $\text{MnO}_2$  cathode to enhance proton transfer through Grotthuss topochemistry, offering a promising solution for ultrahigh-rate Zn-ion batteries. By incorporating two-dimensional Ni-TABQ, the electronic properties of  $\delta$ - $\text{MnO}_2$  are effectively modulated *via*  $\pi$ -d electron coupling, forming a highly efficient conductive network. The abundant intermolecular H-bonds between coordination water (Ni-TABQ) and lattice oxygen ( $\delta$ - $\text{MnO}_2$ ) facilitate proton conduction with rapid redox reactions. Through the dynamic hopping of  $\text{H}_3\text{O}^+$  ions, driven by the continuous breaking and reformation of O-H bonds within the intermolecular H-bonding network, Ni-TABQ@ $\delta$ - $\text{MnO}_2$  achieves a significantly reduced charge transfer energy barrier (0.082 eV) compared to the sluggish  $\text{Zn}^{2+}$  diffusion process (0.741 eV). This fast-kinetics proton transport mechanism mitigates the lattice repulsion and phase instability associated with  $\text{Zn}^{2+}$  intercalation, ensuring a Ni-TABQ@ $\delta$ - $\text{MnO}_2$  cathode

with exceptional electrochemical metrics, including high capacity, excellent rate performance, and an ultralong lifespan. These findings underscore the importance of hybrid superlattice cathode structures with efficient proton transfer for advanced energy storage systems.
