## Understanding the reaction energetics of oxygen-evolving electrocatalysts†

Ziqing Lin,<sup>a</sup> Payal Chaudhary,<sup>b</sup> S. Avery Vigil,<sup>a</sup> Matteo Fratarcangeli,<sup>a</sup> Conner J. Soderstedt,<sup>a</sup> Vitaly Alexandrov<sup>b</sup> and Ivan A. Moreno-Hernandez<sup>a</sup>

Electrocatalysts are crucial for efficient electrochemical devices that enable sustainable chemical transformations. Electrocatalyst activity has been correlated to the thermodynamics of reaction intermediates that balance intermediate formation and desorption. However, a lack of detailed experimental thermodynamic information about reaction energetics limits the design of next-generation electrocatalysts. Here we show kinetic and electroadsorption studies of precisely terminated first-row transition metal ruthenium oxide nanocrystals that elucidate how material chemistry influences the oxygen evolution reaction activity and reaction energetics. We established the energy scaling relations between the \*OH, \*O, and \*OOH intermediates involved in the oxygen evolution reaction. These energy scaling relations were leveraged to design an FeMn–RuO<sub>x</sub> electrocatalyst with an 876% increase in mass activity compared to RuO<sub>2</sub>. Our study highlights the potential for precise nanocrystal synthesis and electroadsorption analysis to rationally guide the design of next-generation electrocatalysts with improved activity and further elucidate mechanisms of catalyst activation.

### Broader context

The development of highly active electrocatalysts is vital for advancing renewable energy technologies that enable net-zero carbon emission energy and chemical infrastructures. The activity of electrocatalysts for multi-electron transfer reactions has been hypothesized to be dictated by the energetics of intermediate formation based on theoretical investigations. However, general methods to experimentally probe reaction energetics have remained elusive, preventing close integration of experimental and theoretical methods for rational catalyst design. Herein, we report electroadsorption and kinetic studies that elucidate the reaction energetics of oxygen-evolving electrocatalysts consisting of well-defined ternary first-row transition metal ruthenium oxide nanocrystals (M–RuO<sub>x</sub>, M = V, Cr, Mn, Fe, Co, Ni, Cu, and Zn). Analysis of the electroadsorption profiles for M–RuO<sub>x</sub> enabled the experimental measurement of intermediate binding energies that revealed energy scaling relations that exhibited linearity consistent with theoretical predictions. Electroadsorption analysis was utilized to aid the design of a quaternary transition metal ruthenium oxide electrocatalyst, FeMn–RuO<sub>x</sub>, that exhibited higher activity towards the acidic oxygen evolution reaction compared to the most active M–RuO<sub>x</sub> and RuO<sub>2</sub>. Our study highlights the potential for electroadsorption analysis to elucidate the reaction energetics of complex multi-electron transfer reactions, which can accelerate the rational design of next-generation electrocatalysts with superior activity.

## Introduction

Electrochemical devices powered by renewable energy enable the decarbonization of human activities to address ongoing energy and environmental challenges.<sup>1–4</sup> In electrolyzers,

cathodic reactions that can generate fuels, commodity chemicals, and fertilizers are paired with the oxygen evolution reaction (OER), which oxidizes water molecules to form molecular oxygen *via* four electron-transfer steps.<sup>4–9</sup> Ruthenium dioxide (RuO<sub>2</sub>) has been identified as one of the most promising binary oxides for the OER in acidic environments due to improved catalytic activity, but decreased stability, compared to iridium dioxide (IrO<sub>2</sub>) and greater elemental abundance.<sup>10–15</sup> Efforts to further enhance the activity and stability of RuO<sub>2</sub> have focused on chemical, defect, and structural modulations, with a substantial body of work indicating several promising approaches to activate oxygen electrocatalysis.<sup>13,15–23</sup> However, to date, state-of-the-art OER electrocatalysts still exhibit lower activity than cathodic electrocatalysts for fuel formation, necessitating high OER catalyst loading in

devices and decreasing the scalability of electrolyzer technologies for chemical transformations.<sup>24–29</sup>

The slow kinetics of oxygen-evolving electrocatalysts have been attributed to non-ideal energy scaling relations of the OER intermediates (\*OH, \*O, and \*OOH).<sup>30–34</sup> Seminal computational studies have explored energy scaling relations between the OER intermediates with quantum mechanical (QM) methods.<sup>35–41</sup> Additionally, electrochemical studies of single-crystalline RuO<sub>2</sub> and IrO<sub>2</sub> surfaces have revealed the energy scaling relations of elementary reaction steps involved in the OER *via* the analysis of electroadsorption features.<sup>34,42–44</sup> These approaches have provided important insights about electrocatalysts. However, understanding the OER intermediate energy scaling relations of next-generation electrocatalysts with nanoscale morphologies and complex chemical compositions remains a challenge. Recent studies have established synthetic pathways to obtain nanocrystals with precise crystallographic terminations, which have indicated that particle-to-particle heterogeneity and facet-dependent properties influence the macroscopic properties of particle ensembles.<sup>45,46</sup> Thus, there is a need to develop approaches to quantitatively study the energetic pathways of complex reactions such as the OER to rationally design electrocatalysts with high activity.

In this study, we report the synthesis of rutile oxide nanocrystals consisting of a first-row transition metal, ruthenium, and oxygen (M–RuO<sub>x</sub>, M = V, Cr, Mn, Fe, Co, Ni, Cu, and Zn) and the experimental determination of energy scaling relations between the \*OH, \*O, and \*OOH intermediates for the OER. The synthesis of M–RuO<sub>x</sub> nanocrystals with well-defined (110) and (111)/(112) crystallographic facets and minimal structural defects enabled the determination of chemical effects on electrocatalysis. Our experiments for binary systems revealed that only Mn–RuO<sub>x</sub> exhibits substantially improved activity compared to RuO<sub>2</sub> on an electrochemically-active surface-area basis. Electroadsorption analysis enabled the determination of absolute reaction energetics for the \*OH, \*O, and \*OOH intermediates and quantification of intermediate surface coverage for all M–RuO<sub>x</sub> nanocrystals. The energetics of the OER on (110) and (111)/(112) surfaces could be deconvoluted and revealed distinct facet-dependent energy scaling relations. The observed variation in catalytic activity for all M–RuO<sub>x</sub> samples could be accurately described by a kinetic model that incorporates OER energetics and intermediate surface coverage determined from electroadsorption analysis. Importantly, these insights enabled the design of a ternary FeMn–RuO<sub>x</sub> electrocatalyst that was predicted to exhibit improved activity and was experimentally validated to yield an 876% and 309% improvement in mass activity compared to RuO<sub>2</sub> and Mn–RuO<sub>x</sub>, respectively. The observed enhancement in activity for FeMn–RuO<sub>x</sub> was further validated by density functional theory (DFT) models of the OER on the (110) M–RuO<sub>x</sub> surfaces. Overall, our study highlights the potential for electroadsorption analysis and precise nanocrystal synthesis to provide key insights that elucidate electrocatalytic reaction pathways and enable the design of next-generation electrocatalysts.

## Experimental

### Synthesis method of nanocrystals

All samples were prepared using a previously reported molten salt synthetic method.<sup>46</sup> To synthesize ruthenium dioxide (RuO<sub>2</sub>) nanocrystals, 4.55 g of NaCl, 600  $\mu$ L of 80 mM RuCl<sub>3</sub>, and 500  $\mu$ L of 400 mM Na<sub>2</sub>SO<sub>4</sub> were added to a 10 mL ceramic crucible (470149-028, VWR International). To synthesize each ternary first-row transition metal ruthenium oxide nanocrystal sample (M–RuO<sub>x</sub>, M = V, Cr, Mn, Fe, Co, Ni, Cu and Zn), 4.55 g of NaCl, 250  $\mu$ L of 80 mM RuCl<sub>3</sub>, 500  $\mu$ L of 400 mM Na<sub>2</sub>SO<sub>4</sub>, 500  $\mu$ L of deionized water, and 50  $\mu$ L of 400 mM transition metal salt precursor dissolved in 2 M HCl were added to a ceramic crucible. To synthesize iron manganese ruthenium oxide (FeMn–RuO<sub>x</sub>) nanocrystals with different atomic percentage of Fe, 4.55 g of NaCl, 250  $\mu$ L of 80 mM RuCl<sub>3</sub>, 500  $\mu$ L of 400 mM Na<sub>2</sub>SO<sub>4</sub>, 500  $\mu$ L of deionized water, between 15 and 50  $\mu$ L of 400 mM MnCl<sub>2</sub> dissolved in 2 M HCl and between 0 and 50  $\mu$ L of 400 mM of FeCl<sub>3</sub> dissolved in 2 M HCl were added to a ceramic crucible.

For RuO<sub>2</sub> and M–RuO<sub>x</sub>, all the contents in the crucible were well-mixed *via* stirring and then heated at 700 °C for one hour in a box furnace with a heating rate of 20 °C min<sup>-1</sup> and with natural cooling. For FeMn–RuO<sub>x</sub>, all the contents in the crucible were well-mixed *via* stirring and then heated at 500 °C for one hour in a box furnace with a heating rate of 20 °C min<sup>-1</sup> and natural cooling. After cooling down to room temperature, all samples were purified with a series of washing steps. All the washing steps were conducted by centrifuging the samples at 6000 rpm and removing the supernatant. Approximately 35 mL of water was used to transfer the contents in each crucible to a 50 mL centrifuge tube. Each sample was washed for 10 minutes to ensure total dissolution of the salt matrix. Subsequently, each sample was re-dispersed in 1 mL of 2 M HCl and transferred into a 1.5 mL microcentrifuge tube. The microcentrifuge tubes were immersed in a 90 °C hot water bath for one hour unless otherwise specified to remove any excess oxides that were unstable in acid.<sup>17,47,48</sup> After cooling down from the water bath, the acid supernatant was removed *via* centrifugation. Each sample was washed twice with 1 mL of water and once with 1 mL IPA, centrifuging for 5 minutes and removing the supernatant after each washing step. After all the washing steps, samples were stored in a vacuum desiccator until completely dry.

### Electrochemical characterization

All electrochemical measurements were conducted using a rotating disk electrode (MSR Rotator, Pine Research) operated at 2000 rpm and a three-electrode system at room temperature (25 °C) using a digital potentiostat (Bio-logic VSP-300). The counter electrode was a platinum electrode (Pine Research), the reference electrode was an Ag/AgCl electrode (Pine Research), the working electrode was a glassy carbon rotating disk electrode (Pine Research, diameter of 5 mm), and the electrolyte was 1.0 M HClO<sub>4</sub>. Ultrahigh purity oxygen was bubbled during the experiments to saturate the electrolyte. The Ag/AgCl

reference electrode was calibrated to 0.1899 V *versus* the reversible hydrogen electrode (RHE). Electrocatalyst inks were prepared for each sample as follows. For every 1 mg of nanopowder, 83.5  $\mu$ L of  $\text{H}_2\text{O}$ , 35.5  $\mu$ L of IPA and 6  $\mu$ L of Nafion were added. The mixtures were sonicated for 40 minutes to fully suspend the particles. The catalyst inks were then drop-cast on top of a glassy carbon electrode polished to a mirror finish with 3.07  $\mu$ L of synthesized catalyst ink for a loading of 125  $\mu\text{g cm}^{-2}$ . The loading was repeated once for all samples, resulting in a final catalyst loading of 250  $\mu\text{g cm}^{-2}$ . To characterize the electrochemical performance of the catalysts, a series of experiments were conducted. Electrochemical impedance spectroscopy (EIS) was conducted to determine the series resistance with frequency ranging from 1 MHz to 1 Hz. Next, a cyclic voltammetry (CV) protocol with potential ranges from 0 to 1.45 V *versus* Ag/AgCl was performed at scan rate ( $\nu$ ) descending from 1000 mV s $^{-1}$  to 100 mV s $^{-1}$ . A 10 mV s $^{-1}$  scan-rate CV was performed with potential ranges from 0.95 to 1.45 V *versus* Ag/AgCl to measure the OER kinetics at steady-state.

## Results and discussion

### Nanocrystal synthesis and characterization

Rutile-type nanocrystals ( $\text{M}-\text{RuO}_x$ ) consisting of a first-row transition metal ( $\text{M} = \text{V, Cr, Mn, Fe, Co, Ni, Cu, Zn}$ ), ruthenium,

and oxygen were synthesized *via* a molten salt method to elucidate chemical effects on  $\text{RuO}_2$  electrochemical activity (Fig. 1a). While nanocrystals were synthesized with a loaded 1:1 M:Ru ratio, transition metal incorporation into the  $\text{RuO}_2$  is expected to be highly element dependent.<sup>49</sup> A 1:1 ratio was chosen to maximize the amount of transition metal incorporated in the  $\text{RuO}_2$  lattice to elucidate the maximal effects of transition metal incorporation on reaction energetics. Acid-stable electrocatalysts were obtained by treating the as-synthesized  $\text{M}-\text{RuO}_x$  nanocrystals in 2 M HCl at 90 °C for 1 hour as described in the Experimental section. Additional discussion on the influence of acid treatment on material and electrochemical properties, as well as repeated electrochemical cycling, are available in the ESI.<sup>†</sup> The  $\text{RuO}_2$  nanocrystal exhibited preferential growth along the [001] direction and surface termination by (110) facets on the nanocrystal sides, and (111) facets at the nanocrystal tips as determined by the projected angle and the spacing of the high-resolution transmission electron microscopy (HR-TEM) pattern (Fig. 1b). Selected-area electron diffraction (SAED) indicated the formation of a rutile-type crystal structure for all  $\text{M}-\text{RuO}_x$  and  $\text{RuO}_2$  samples (Fig. 1c and Fig. S2, ESI<sup>†</sup>). Scanning electron microscopy-based energy dispersive spectroscopy (SEM-EDS) confirmed the incorporation of all first-row transition metals in the  $\text{RuO}_2$  lattice (Table S1, ESI<sup>†</sup>). HR-TEM images of  $\text{M}-\text{RuO}_x$  nanocrystals with first-row transition metal incorporation showed that they exhibited anisotropic structures and surface

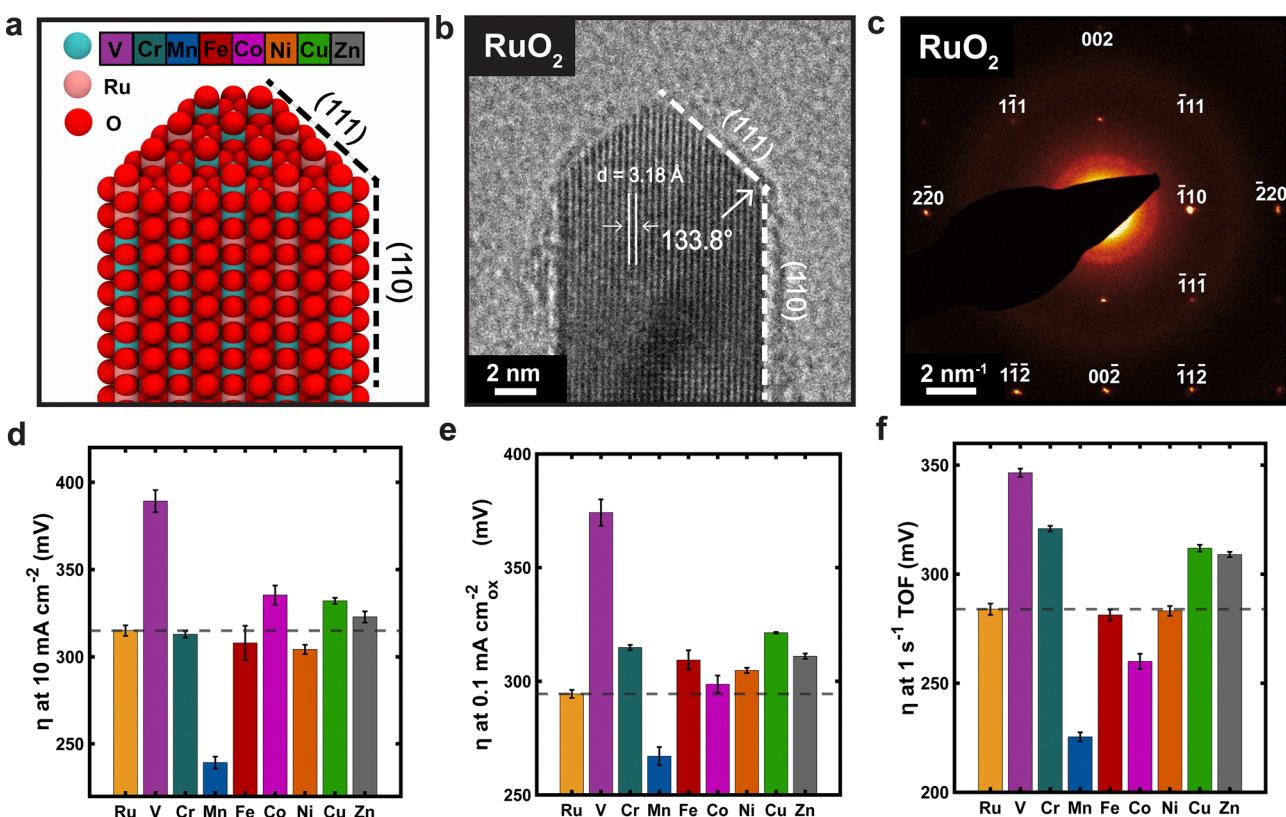

Fig. 1 Characterization of  $\text{RuO}_2$  and  $\text{M}-\text{RuO}_x$  electrocatalysts synthesized at 700 °C. (a) Model of  $\text{M}-\text{RuO}_x$  nanocrystals. (b) HR-TEM image of  $\text{RuO}_2$  nanocrystal with crystallographic facets and  $d$ -spacing labeled. (c) SAED of  $\text{RuO}_2$  single nanocrystal shown in (b) with diffraction spots labeled. Overpotentials of all  $\text{M}-\text{RuO}_x$  compared to  $\text{RuO}_2$  (dash line) at (d) 10 mA cm $^{-2}$ , (e) 0.1 mA cm $^{-2}$ , and (f) 1 s $^{-1}$  TOF.

faceting similar to  $\text{RuO}_2$  with minimal structural defects (Fig. S1, ESI<sup>†</sup>). The (110) crystallographic facet was present on all  $\text{M}-\text{RuO}_x$  nanocrystal samples. The intersection angle between the nanocrystal tip and (110) facet was between 113.9 and 143.6 degrees for  $\text{M}-\text{RuO}_x$  nanocrystals, corresponding to tip terminations due to (111) and (112) crystallographic facets. X-ray diffraction (XRD) of  $\text{M}-\text{RuO}_x$  and  $\text{RuO}_2$  confirmed the rutile-type structure and indicated that first-row transition metal incorporation resulted in changes to the rutile unit cell parameters (Fig. S3 and Table S2, ESI<sup>†</sup>). In particular, the  $c$  unit cell parameter decreased from 3.11 Å for  $\text{RuO}_2$  to 3.08, 3.07, 3.09, and 3.09 Å for  $\text{Cr}-\text{RuO}_x$ ,  $\text{Mn}-\text{RuO}_x$ ,  $\text{Fe}-\text{RuO}_x$ , and  $\text{Co}-\text{RuO}_x$ , respectively. Raman spectroscopy indicated the presence of  $\text{E}_g$ ,  $\text{A}_{1g}$ , and  $\text{B}_{2g}$  vibrational modes consistent with a rutile-type structure for  $\text{RuO}_2$  nanocrystals, and similar modes with different mode positions for all  $\text{M}-\text{RuO}_x$  except  $\text{Fe}-\text{RuO}_x$ , consistent with previous observations of transition-metal incorporated  $\text{RuO}_2$  materials (Fig. S4, ESI<sup>†</sup>).<sup>50,51</sup> Scanning transmission electron microscopy energy dispersive spectroscopy (STEM-EDS) confirmed the homogenous inclusion of all transition metals in the  $\text{M}-\text{RuO}_x$  lattice (Fig. S5, ESI<sup>†</sup>).

### Oxygen evolution reaction activity

Fig. 1d-f summarizes the electrochemical activity towards the OER in 1.0 M perchloric acid of  $\text{M}-\text{RuO}_x$  and  $\text{RuO}_2$  synthesized at 700 °C. The resistance corrected overpotential at 10 mA cm<sup>-2</sup> of geometric area for a catalyst loading of 250 µg cm<sup>-2</sup> was 315 ± 3 mV for  $\text{RuO}_2$  (Fig. 1d, Fig. S6 and Tables S3, S4, ESI<sup>†</sup>). The overpotential for  $\text{Mn}-\text{RuO}_x$  was 239 ± 3 mV, which was the lowest among all  $\text{M}-\text{RuO}_x$  samples.  $\text{Cr}-\text{RuO}_x$ ,  $\text{Fe}-\text{RuO}_x$ , and  $\text{Ni}-\text{RuO}_x$  exhibited overpotentials between 304 ± 3 and 313 ± 2 mV, indicating an improvement in activity compared to  $\text{RuO}_2$ .  $\text{V}-\text{RuO}_x$ ,  $\text{Co}-\text{RuO}_x$ ,  $\text{Cu}-\text{RuO}_x$ , and  $\text{Zn}-\text{RuO}_x$  exhibited a decrease in activity compared to  $\text{RuO}_2$ . In particular,  $\text{V}-\text{RuO}_x$  exhibited the highest overpotential of 389 ± 6 mV. The geometric area-normalized activity of the studied electrocatalysts could be influenced by two key factors: the surface area of the nanocrystals, and the density of active sites on a given surface. The electrochemically-active surface-area (ECSA) normalized activity is shown in Fig. 1e, Fig. S7 and Table S3 (ESI<sup>†</sup>). The overpotential at 0.1 mA per cm<sub>ox</sub><sup>2</sup> is 294 ± 2 mV for  $\text{RuO}_2$ . After ECSA normalization, only  $\text{Mn}-\text{RuO}_x$  exhibited higher activity than  $\text{RuO}_2$ , with an ECSA-normalized overpotential of 267 ± 4 mV. These results indicate that the enhanced activity of  $\text{Cr}-\text{RuO}_x$ ,  $\text{Fe}-\text{RuO}_x$ , and  $\text{Ni}-\text{RuO}_x$  could be attributed to surface area enhancements or differences in active site density, which was determined *via* electroadSORption analysis as described in the Supplementary Methods (ESI<sup>†</sup>). The active site density of  $\text{RuO}_2$  was 1.68 ± 0.06 sites nm<sup>-2</sup>, corresponding to 33% of the available Ru coordinately unsaturated sites (CUS) on a  $\text{RuO}_2$  (110) surface (5.1 sites nm<sup>-2</sup>) (Table S5, ESI<sup>†</sup>).<sup>52</sup>  $\text{Cr}-\text{RuO}_x$ ,  $\text{Cu}-\text{RuO}_x$ , and  $\text{Zn}-\text{RuO}_x$  exhibited site densities of between 1.61 ± 0.07 and 2.361 ± 0.003 sites nm<sup>-2</sup> (Table S5, ESI<sup>†</sup>).  $\text{Mn}-\text{RuO}_x$  exhibited a site density of 0.318 ± 0.002 sites nm<sup>-2</sup>, corresponding to 6.2% of the CUS sites on a  $\text{RuO}_2$  (110) surface (Table S5, ESI<sup>†</sup>). The results indicate that site density must be

accounted to determine the intrinsic activity of active sites for different electrocatalysts. The overpotential at a turnover frequency (TOF) of 1 oxygen molecule per active site accounts for both surface area and site density effects on catalysis. The overpotential at 1 s<sup>-1</sup> TOF was 284 ± 3 mV for  $\text{RuO}_2$  (Fig. 1f and Table S5, ESI<sup>†</sup>).  $\text{Mn}-\text{RuO}_x$ ,  $\text{Fe}-\text{RuO}_x$ ,  $\text{Co}-\text{RuO}_x$ , and  $\text{Ni}-\text{RuO}_x$  exhibited overpotentials at 1 s<sup>-1</sup> TOF of 225 ± 2, 281 ± 2, 260 ± 3, and 283 ± 2 mV, indicating that their active sites exhibited higher intrinsic activity than  $\text{RuO}_2$ .  $\text{V}-\text{RuO}_x$ ,  $\text{Cr}-\text{RuO}_x$ ,  $\text{Cu}-\text{RuO}_x$ , and  $\text{Zn}-\text{RuO}_x$  exhibited decreased activity at 1 s<sup>-1</sup> TOF compared to  $\text{RuO}_2$ . In particular,  $\text{V}-\text{RuO}_x$  exhibited the highest overpotential at 346 ± 2 mV for 1 s<sup>-1</sup> TOF. Tafel slope analysis from a limited current range of 0.1 to 10 mA cm<sup>-2</sup> indicated that  $\text{RuO}_2$ ,  $\text{Mn}-\text{RuO}_x$ , and  $\text{V}-\text{RuO}_x$  exhibited a Tafel slope of 32.5, 19.1, and 41.7 mV dec<sup>-1</sup>, and others exhibited Tafel slopes between 23.4 and 29.8 mV dec<sup>-1</sup> (Fig. S8, ESI<sup>†</sup>).

### ElectroadSORption and kinetic analysis

Unless otherwise stated, three cyclic voltammograms were collected at 1000 mV s<sup>-1</sup> and the third cyclic voltammogram was utilized for electroadSORption analysis. Fig. 2a-d summarizes electroadSORption analysis results of  $\text{RuO}_2$  nanocrystals. Microkinetic models of the OER for all permutations of unique reaction energies verified that electroadSORption features would be observed during fast cyclic voltammetry scans (Fig. S9-S12, ESI<sup>†</sup>). In most cases, the number of features observed would be one less than the rate-determining step. Many energy combinations could be adequately described by an electroadSORption model of surface-bound electrochemical reactions (Fig. S13 and S14, ESI<sup>†</sup>). Fig. S15 (ESI<sup>†</sup>) and Fig. 2a shows cyclic voltammograms collected for  $\text{M}-\text{RuO}_x$  and  $\text{RuO}_2$  nanocrystals at a scan rate of 1000 mV s<sup>-1</sup>. The capacitive current of the cyclic voltammograms was determined as described in the Supplementary Methods (ESI<sup>†</sup>). The electroadSORption features exhibited peak broadening that could not be explained by an idealized Nernstian surface-limited process (Fig. S16a, ESI<sup>†</sup>). Recent studies have indicated that the properties of individual  $\text{RuO}_2$  nanocrystals are highly heterogeneous and that intermediates could exhibit adsorbate-adsorbate interactions.<sup>34,45</sup> We developed an analytical model that could account for electroadSORption peak broadening that could be used to quantitatively describe the observed capacitive current of the electrocatalysts as discussed in the Supplementary Methods (ESI<sup>†</sup>). Fig. 2b shows the capacitive current obtained for  $\text{RuO}_2$  nanocrystals. ElectroadSORption features are observed between 0 V vs. RHE and ~1.45 V vs. RHE. The features could be separated into low-integrated-charge features below 1 V vs. RHE, and high-integrated-charge features above 1 V vs. RHE. Prior work on single crystals of  $\text{RuO}_2$  (110) observed electroadSORption features above 1 V vs. RHE, and the absence of electroadSORption features below 1 V vs. RHE.<sup>34</sup> The anisotropic structure of  $\text{M}-\text{RuO}_x$  and  $\text{RuO}_2$  results in the predominant areal exposure of (110) facets with minor contributions from (111) or other facets. Thus, we ascribe the observed features above 1 V vs. RHE to (110) facets and features below 1 V vs. RHE to (111)/(112) facets. The electroadSORption features were fit to an electroadSORption model of \*OH, \*O, and \*OOH intermediate formation.

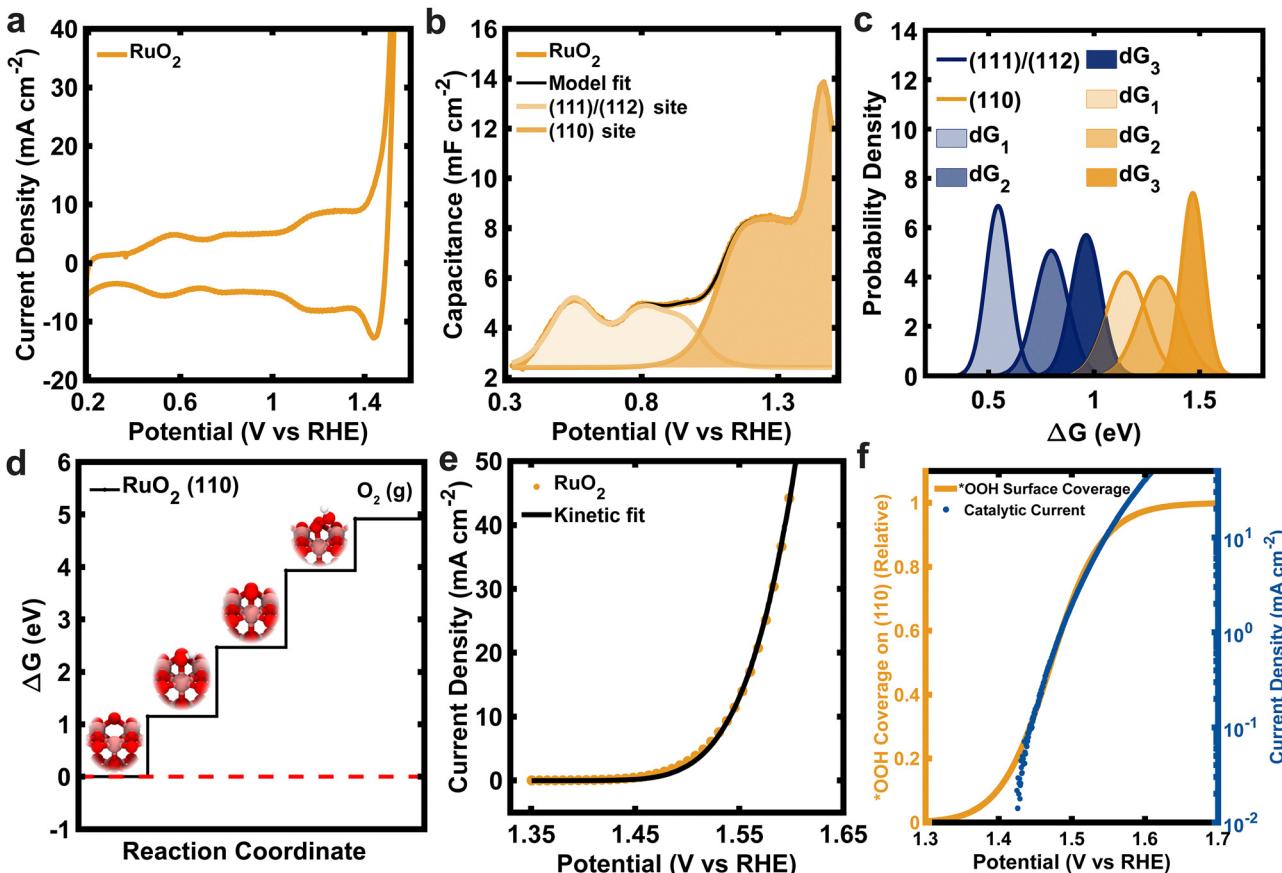

Fig. 2 Electroadsorption and kinetic analysis of  $\text{RuO}_2$  electrocatalyst synthesized at  $700\text{ }^\circ\text{C}$ . (a) Cyclic voltammogram scanned at  $1\text{ V s}^{-1}$ . (b) Comparison of electroadsorption model fits of (111)/(112) and (110) sites to electroadsorption profile derived from (a). (c) Distributions of reaction energies for the first three electron-transfer steps involved in the OER. (d) Free energy diagram constructed from electroadsorption analysis. (e) Comparison between steady-state current density and kinetic model fit. (f) Surface coverage of  $^*\text{OOH}$  species on (110) site and catalytic current density versus potential.

Analysis of the  $\text{RuO}_2$  capacitive current profile indicates the formation of  $^*\text{OH}$ ,  $^*\text{O}$ , and  $^*\text{OOH}$  intermediates at  $1.151 \pm 0.007$ ,  $1.313 \pm 0.004$ , and  $1.468 \pm 0.005\text{ V}$  vs. RHE on  $\text{RuO}_2$  (110) surfaces, and  $0.545 \pm 0.003$ ,  $0.797 \pm 0.003$ , and  $0.962 \pm 0.003\text{ V}$  vs. RHE on  $\text{RuO}_2$  (111)/(112) surfaces, respectively (Fig. 2b and Tables S6, S7, ESI<sup>†</sup>). Broadening of electroadsorption features could be described by collections of idealized Nernstian reactions exhibiting normal distributions with standard deviations in Gibbs free energy between 19 and 117 meV (Fig. 2c, Fig. S16b and Tables S8, S9, ESI<sup>†</sup>). The  $^*\text{OH}$  surface coverage was  $0.9 \pm 0.1\text{ mC cm}^{-2}$  and  $0.52 \pm 0.07\text{ mC cm}^{-2}$  on (110) and (111)/(112) surfaces, respectively (Tables S10 and S11, ESI<sup>†</sup>). The energetics obtained from electroadsorption analysis enabled the construction of a reaction coordinate diagram for the OER from the experimental dataset (Fig. 2d). The determined binding energies for the OER intermediates on  $\text{RuO}_2$  suggest that (110) and (111)/(112) surfaces exhibit a thermodynamic barrier of at least  $239 \pm 5\text{ meV}$  and  $1380 \pm 10\text{ meV}$ , respectively (Tables S6 and S7, ESI<sup>†</sup>). Fig. 2e and f summarizes kinetic analysis for the OER on  $\text{RuO}_2$  nanocrystals. Substantial overlap between the formation of  $^*\text{OOH}$  on the (110) surface and activity onset was observed (Fig. 2f). The overall activity could be adequately described by an electrochemical reaction with first-order

electrochemical reaction kinetics with respect to  $^*\text{OOH}$  on (110) crystallographic facets, which exhibit more optimal energetics for the OER compared to (111)/(112) active sites (Fig. 2e).

Fig. 3a and b shows the model analysis of  $\text{M}-\text{RuO}_x$ . Capacitive current measurements indicate that  $\text{M}-\text{RuO}_x$  electrocatalysts exhibit differences in electroadsorption compared to  $\text{RuO}_2$  (Fig. 3a). The resulting binding energies from electroadsorption analysis enabled the construction of experimental energy scaling relations between  $^*\text{OH}$ ,  $^*\text{O}$ , and  $^*\text{OOH}$  for (110) crystallographic facets (Fig. 3c and d). The  $^*\text{OH}$  binding energy ranged from  $1.076 \pm 0.002$  to  $1.209 \pm 0.007\text{ eV}$  for (110) facets (Fig. 3c and d). A linear fit of the  $^*\text{O}$  binding energy *versus* the  $^*\text{OH}$  resulted in a slope of 1.66, and an offset of 0.56 eV (Fig. 3c). A linear fit of the  $^*\text{OOH}$  binding energy *versus* the  $^*\text{OH}$  resulted in a slope of 1.98, and an offset of 1.64 eV (Fig. 3d). Similar analysis was conducted for active sites modeled by (111)/(112) crystallographic facets (Fig. S17a and b, ESI<sup>†</sup>). Electroadsorption analysis of the resulting scaling laws indicates that (111)/(112) facets for  $\text{M}-\text{RuO}_x$  and  $\text{RuO}_2$  exhibit thermodynamics barriers that are non-ideal for the OER (Table S6, ESI<sup>†</sup>). The thermodynamic barrier for  $\text{Mn}-\text{RuO}_x$  (110),  $185 \pm 1\text{ meV}$ , is close to the predicted optimum for the OER, 166 meV, based on the determined scaling law for  $^*\text{O}$  and  $^*\text{OOH}$  (Fig. S17c, ESI<sup>†</sup>).

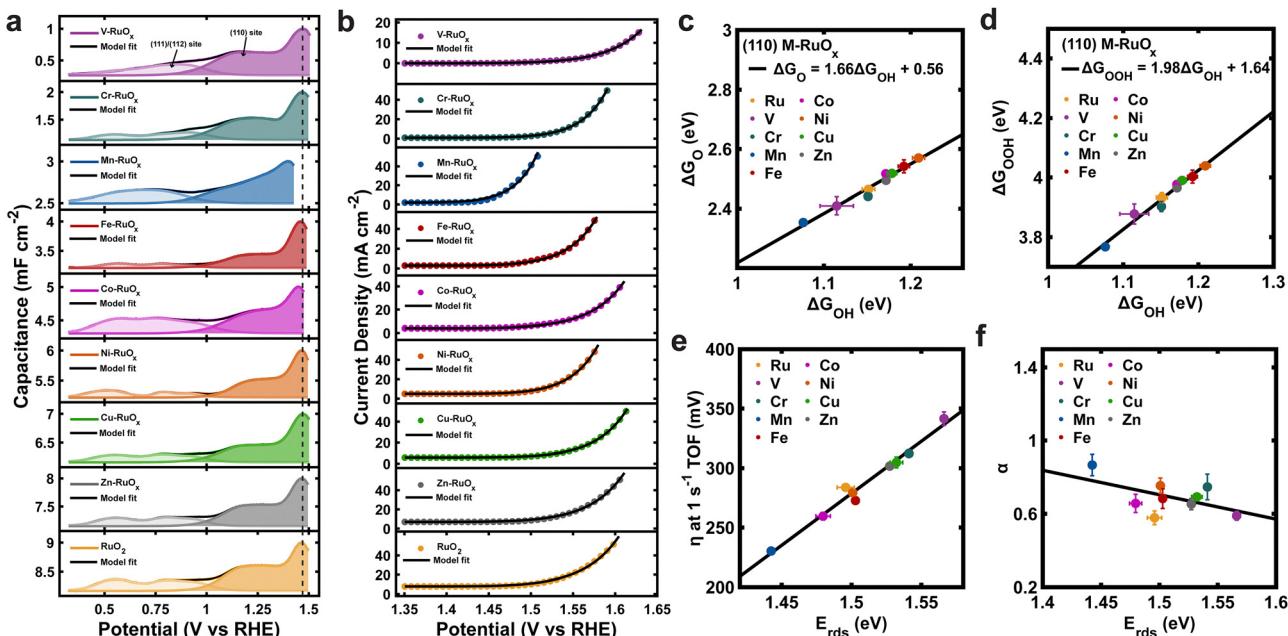

Fig. 3 Electroadsorption and kinetic analysis of  $M\text{-RuO}_x$  electrocatalysts synthesized at 700 °C. (a) Comparison of electroadsorption model fits of (111)/(112) and (110) sites to electroadsorption profiles for  $M\text{-RuO}_x$ . (b) Comparison between steady-state current density and kinetic model fits for  $M\text{-RuO}_x$ . Experimentally derived scaling relations of (c)  $\Delta G_O$  versus  $\Delta G_{OH}$  and (d)  $\Delta G_{OOH}$  versus  $\Delta G_{OH}$  on (110) site. (e) Overpotential at  $1\text{ s}^{-1}$  TOF versus  $E_{rds}$ . (f) Charge-transfer coefficient  $\alpha$  versus  $E_{rds}$ .

Electroadsorption analysis indicated that  $\text{Fe-RuO}_x$ ,  $\text{Co-RuO}_x$ ,  $\text{Ni-RuO}_x$ ,  $\text{Cu-RuO}_x$ ,  $\text{Zn-RuO}_x$  destabilized the  $^*\text{OH}$ ,  $^*\text{O}$ , and  $^*\text{OOH}$  intermediates, and  $\text{Mn-RuO}_x$ ,  $\text{V-RuO}_x$ ,  $\text{Cr-RuO}_x$  stabilized the intermediates (Fig. S17d and e, ESI<sup>†</sup>). Prior DFT results indicate that for  $^*\text{OH}$  binding energies between 1.0 eV and 1.2 eV, corresponding to the binding energies measured herein for  $M\text{-RuO}_x$ , the binding energies for  $^*\text{O}$  can vary between 2.4 eV and 4.4 eV.<sup>53</sup> In these prior studies, the  $^*\text{OOH}$  binding energy was found to vary between 3.6 eV and 4.7 eV in the 1.0 eV to 1.2 eV  $^*\text{OH}$  binding energy range.<sup>53</sup> Our electroadsorption studies indicate that experimental  $^*\text{O}$  and  $^*\text{OOH}$  binding energies fall within this range (Fig. 3c and d). The kinetic profiles of  $M\text{-RuO}_x$  were found to be adequately described by first-order kinetic rate laws with a rate-determining step of  $^*\text{OOH}$  oxidation to  $\text{O}_2$  (Fig. 3b). Analysis of the resulting kinetic parameters indicates that the activation barrier of the rate-determining step is correlated to the overpotential at  $1\text{ s}^{-1}$  TOF and the charge transfer coefficient ( $\alpha$ ) (Fig. 3e and f).

#### Design of quaternary oxide electrocatalyst

Fig. 4 demonstrates the design of a quaternary oxide OER electrocatalyst based on electroadsorption analysis.  $\text{Mn-RuO}_x$  was found to exhibit the highest intrinsic activity towards the oxygen evolution reaction, but also the lowest density of active sites. The interaction between first-row transition metals in a  $\text{RuO}_2$  lattice is highly complex, and electroadsorption analysis was used to understanding potential synergistic effects in the  $\text{Fe-Mn-Ru-O}$  chemical space. Our motivation for exploring this combination came from the observed decrease in Gibbs free

energy for the  $^*\text{O}$  to  $^*\text{OOH}$  transition (Table S7, ESI<sup>†</sup>) for both  $\text{Mn-RuO}_x$  and  $\text{Fe-RuO}_x$ , and the increase in active site density for  $\text{Fe-RuO}_x$  compared to  $\text{Mn-RuO}_x$  (Table S5, ESI<sup>†</sup>). Nanocrystals consisting of solid solutions between  $\text{Fe-RuO}_x$  and  $\text{Mn-RuO}_x$ , and  $\text{RuO}_2$ , were synthesized at 500 °C. XPS and SEM-EDS analysis confirms the inclusion of Mn, Fe, and Ru in the Mn(II), Fe(II), and Ru(IV) oxidation states, respectively, in the  $\text{FeMn-RuO}_x$  nanocrystals (Fig. S20 and Table S1, ESI<sup>†</sup>). XPS studies indicate the Ru, Mn, and Fe remain in the (IV), (II) and (II) oxidation states after electrochemical operation for 3 cyclic voltammograms between 0.00 V and 1.45 V vs. Ag/AgCl at  $1000\text{ mV s}^{-1}$  (Fig. S20, ESI<sup>†</sup>). Fig. S21a (ESI<sup>†</sup>) shows the HR-TEM image of the  $\text{FeMn-RuO}_x$  nanocrystal. The  $\text{FeMn-RuO}_x$  nanocrystal exhibited anisotropic structures and surface faceting similar to  $\text{RuO}_2$ , indicated by the (110) crystallographic facet. SAED and XRD of  $\text{FeMn-RuO}_x$  indicated a rutile-type crystal structure (Fig. S21b and c, ESI<sup>†</sup>).

Three cyclic voltammograms were collected at  $1000\text{ mV s}^{-1}$  and three cyclic voltammograms were collected at  $500\text{ mV s}^{-1}$ . The third cyclic voltammogram collected at  $500\text{ mV s}^{-1}$  was utilized for electroadsorption analysis. Electroadsorption analysis indicated that nanocrystals with both Fe and Mn exhibited cooperative intermediate stabilization as indicated by a decrease in  $^*\text{OH}$ ,  $^*\text{O}$ , and  $^*\text{OOH}$  binding energies that could not be described as a linear combination of  $\text{Fe-RuO}_x$  and  $\text{Mn-RuO}_x$  binding energies (Fig. 4a, d and Fig. S22, ESI<sup>†</sup>). This cooperative stabilization resulted in a different scaling relation for OER intermediates on (110)  $\text{Fe-Mn-Ru}$  rutile surfaces with a slope of 1.90 and an intercept of 0.28 eV for  $^*\text{O}$  vs.  $^*\text{OH}$ , and a slope of 2.22 and intercept of 1.32 eV for

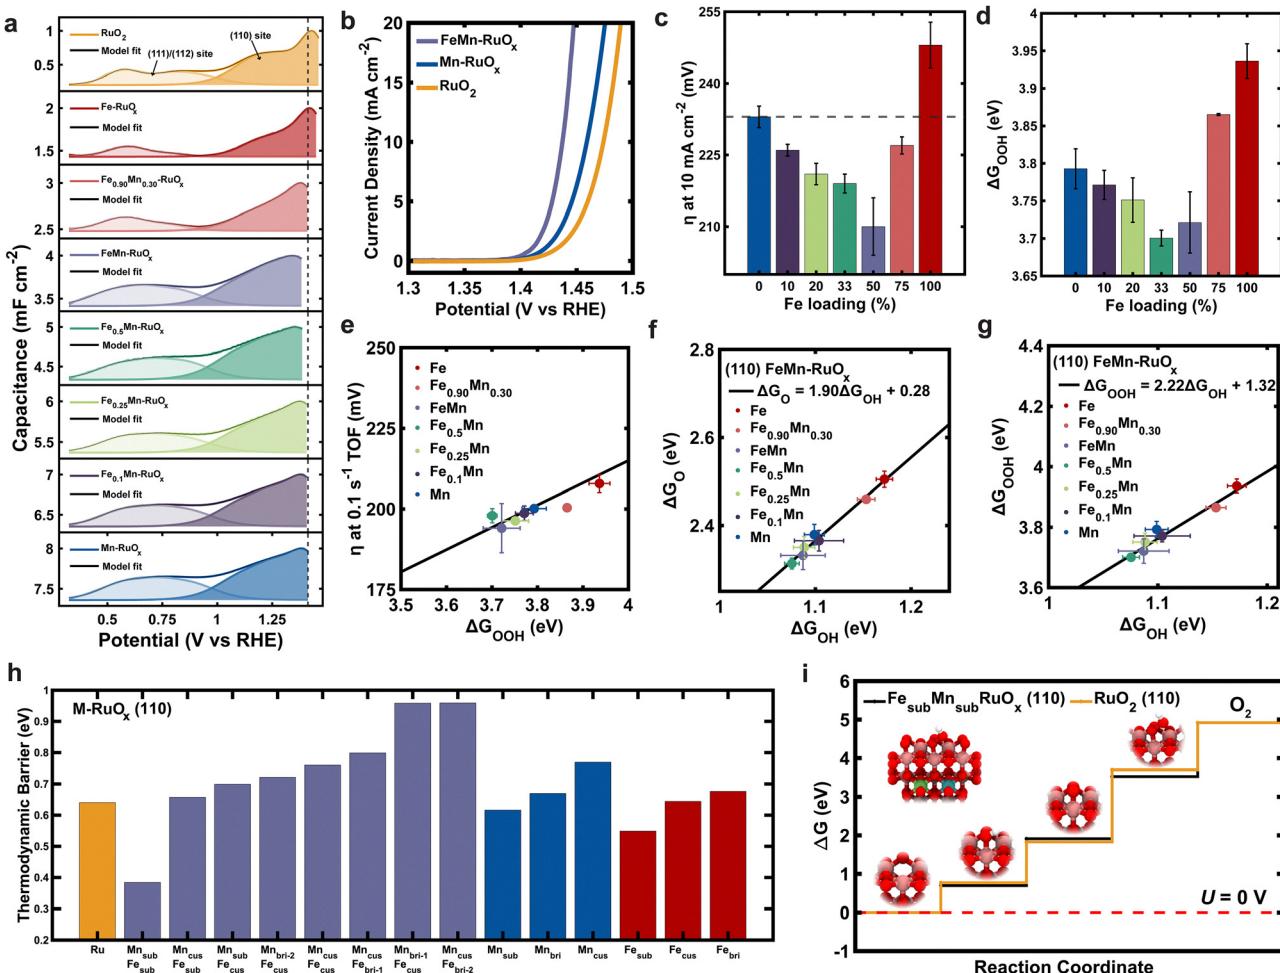

Fig. 4 Summary of electroadsorption and DFT analysis of  $\text{FeMn}-\text{RuO}_x$  electrocatalysts with different Fe loading [ $\text{Fe}/(\text{Fe} + \text{Mn})$ ] synthesized at  $500^\circ\text{C}$ . (a) Comparison of electroadsorption model fits of (111)/(112) and (110) sites to electroadsorption profiles for  $\text{FeMn}-\text{RuO}_x$  electrocatalysts. (b) Steady-state current density of  $\text{FeMn}-\text{RuO}_x$ ,  $\text{Mn}-\text{RuO}_x$ , and  $\text{RuO}_2$  synthesized at  $500^\circ\text{C}$ . (c) Overpotentials at  $10 \text{ mA cm}^{-2}$  for different Fe loading of  $\text{FeMn}-\text{RuO}_x$  [ $\text{Fe}/(\text{Fe} + \text{Mn})$ ]. (d)  $\Delta G_{\text{OOH}}$  on (110) site for different Fe loading of  $\text{FeMn}-\text{RuO}_x$ . (e) Overpotentials at  $0.1 \text{ s}^{-1}$  TOF versus  $\Delta G_{\text{OOH}}$  on (110) site for different Fe loading of  $\text{FeMn}-\text{RuO}_x$ . Scaling relations for (110) site of (f)  $\Delta G_{\text{O}}$  versus  $\Delta G_{\text{OH}}$  and (g)  $\Delta G_{\text{OOH}}$  versus  $\Delta G_{\text{OH}}$ . (h) DFT calculated thermodynamic overpotentials for  $\text{M}-\text{RuO}_x$  ( $\text{M} = \text{Ru, Fe, Mn}$ ) on (110) surface. See the corresponding atomic configurations in Fig. S24 (ESI†). (i) Free energy diagram of  $\text{Fe}_{\text{sub}}\text{Mn}_{\text{sub}}\text{RuO}_x$  and  $\text{RuO}_2$  on (110) site constructed from DFT calculations.

\*OOH vs. \*OH (Fig. 4f and g). Our studies indicate that  $\text{M}-\text{RuO}_x$  nanocrystals exhibit a linear correlation of \*O versus \*OH with a slope of 1.66, and that  $\text{FeMn}-\text{RuO}_x$  nanocrystals exhibit a corresponding slope of 1.9 (Fig. 3c and 4f). Prior DFT results, summarizing a decade of atomic scale simulations, indicate \*O versus \*OH slopes of 1.6 for all considered samples, closely matching our observed scaling relation.<sup>53</sup> Additionally, heavily doped samples with more than 1 dopant exhibit a slope of 1.75, and 2-dopant  $\text{TiO}_2$  exhibits a slope of 1.9.<sup>53</sup> Prior studies comparing measured electroadsorption energies for single-crystalline  $\text{RuO}_2(110)$  surfaces with DFT results have highlighted challenges in reproducing exact energies with DFT due to approximations in the theoretical technique.<sup>34</sup> In general, our electroadsorption studies on  $\text{M}-\text{RuO}_x$  and  $\text{FeMn}-\text{RuO}_x$  agree well with the observed trends from prior DFT results and provide key experimental findings for the development of more accurate atomic scale simulations.

Kinetic analysis indicated that activity could be attributed to (110)  $\text{Fe}-\text{Mn}-\text{Ru}$  rutile surfaces (Fig. S23 and Tables S6, S7, S12, ESI†). This new scaling relation resulted in more ideal thermodynamics for the OER, and  $\text{FeMn}-\text{RuO}_x$  exhibited a thermodynamic barrier of  $160 \pm 9 \text{ meV}$ , which is 25 meV lower than the most active  $\text{Mn}-\text{RuO}_x$  binary oxide (Table S7, ESI†). Fig. 4b shows the electrocatalytic activity of  $\text{FeMn}-\text{RuO}_x$  (1:1 Fe:Mn) compared to  $\text{Mn}-\text{RuO}_x$  and  $\text{RuO}_2$  synthesized under the same conditions. A synthesis ratio of 1:1 Fe:Mn was found to optimize the activity of  $\text{FeMn}-\text{RuO}_x$ -based electrocatalysts, consistent with the measured intermediate binding energies (Fig. 4c and Table S7, ESI†). The overpotential at  $10 \text{ mA cm}^{-2}$  for  $\text{RuO}_2$ ,  $\text{Mn}-\text{RuO}_x$ , and the optimized  $\text{FeMn}-\text{RuO}_x$  synthesized at  $500^\circ\text{C}$  was  $250 \pm 2$ ,  $233 \pm 2$  and  $210 \pm 6 \text{ mV}$ , respectively (Table S3 and Fig. S19, ESI†). Fig. 4h demonstrates DFT analysis of rutile (110) surfaces for the  $\text{Fe}-\text{Mn}-\text{Ru}-\text{O}$  chemical space. Mn and Fe inclusion in  $\text{RuO}_2$  (110) surfaces

could occur at CUS, bridge, and subsurface sites as indicated in Fig. S24 (ESI<sup>†</sup>). Analysis of the OER reaction energetics with DFT indicates that the thermodynamic OER overpotentials are highly sensitive to doping location, and that doping also influences the relative stability of the (110) surface (Fig. 4h and Table S14, ESI<sup>†</sup>). Overall, our DFT results support the experimental finding of improved OER activity of the FeMn–RuO<sub>x</sub> system in the case of subsurface Fe and Mn dopants (Fe<sub>sub</sub>–Mn<sub>sub</sub>) (Fig. 4h and i).

The electrochemical degradation of Ru-based electrocatalysts impedes widespread implementation in electrolyzer technologies.<sup>22,54</sup> Proton exchange membrane water electrolysis (PEMWE) devices constructed with FeMn–RuO<sub>x</sub> and RuO<sub>2</sub> to determine electrocatalyst activity and stability under realistic operation conditions are shown in Fig. S21 (ESI<sup>†</sup>). Catalyst-coated membranes were prepared on Nafion N115 to determine FeMn–RuO<sub>x</sub> and RuO<sub>2</sub> electrocatalyst stability. FeMn–RuO<sub>x</sub> exhibited stable operation with a potential below 1.65 V for over 200 hours of operation at 100 mA cm<sup>-2</sup>. A RuO<sub>2</sub>-based electrolyzer exhibited a potential above 1.8 V after 180 hours of operation, indicating operational instability after long-term electrolysis. Catalytic activity towards water electrolysis was further verified with electrolyzers optimized for activity by utilizing a thinner Nafion N212 membrane and 80 °C water feed. Thin membranes can result in membrane-induced device degradation but can be utilized to evaluate next generation electrolyzer performance.<sup>55</sup> Our results indicate that the FeMn–RuO<sub>x</sub> electrocatalyst can achieve 1 A cm<sup>-2</sup> at 1.58 V, and a current density of 6.54 A cm<sup>-2</sup> at 2.0 V, surpassing the activity of commercial RuO<sub>2</sub> (Fig. S21, ESI<sup>†</sup>). The device-scale Ru mass activity of the FeMn–RuO<sub>x</sub> electrolyzer was found to be 143.2% higher than the mass activity of the RuO<sub>2</sub> electrolyzer at 2 V, consistent with the high mass activity observed in three-electrode experiments.

## Conclusion

The energy scaling relations of intermediates involved in electrochemical reactions with multiple reaction steps limit catalyst activity and complicate material design. In this work, we demonstrated that the electroadsorption profile of electrocatalyst materials could be quantitatively analyzed to obtain reaction energetics. Systematic changes in RuO<sub>2</sub> nanocrystal chemistry enabled the study of chemical effects on the OER energetics and the experimental determination of energy scaling relations between \*OH, \*O, and \*OOH intermediates. We expect that the precise determination of reaction energetics from experiments will accelerate the discovery of electrocatalysts and help bridge the gap between experiment and theoretical predictions. In particular, our study revealed that Mn inclusion resulted in a substantial enhancement in catalyst activity for Ru-based oxygen-evolving electrocatalysts, and that this enhancement was associated with the stabilization of the \*OOH intermediate to a more favorable energy. The activity could be further improved *via* the incorporation of Fe to form an FeMn–RuO<sub>x</sub> electrocatalyst, which exhibited cooperative

stabilization of \*OOH and an 876% increase in mass activity compared to RuO<sub>2</sub>. The principles applied in this study are universal, and we expect that electroadsorption analysis will be useful for other multi-electron reactions and to understand other mechanisms of catalyst activation.

## Author contributions

I. A. M.-H. and Z. L. conceived and designed the project. Z. L., S. A. V., M. F., C. J. S. conducted the experiments and collected the data. I. A. M.-H. and Z. L. analyzed and discussed the data. Z. L. and I. A. M.-H. wrote the manuscript. P. C. and V. A. contributed density functional theory results and discussion. The project was supervised by I. A. M.-H. All authors provided feedback on the manuscript.
