Organometallic Ru^{II}, Os^{II} and Rh^{III} complexes of lapachol induce apoptosis in human tumour cell lines in the low μM range by a mode of action involving oxidative stress, especially in the case of the ruthenium compound.

Multi-targeted drugs are molecules whose different components impact multiple separate biotargets.¹ In cancer chemotherapy this approach provides a means of overcoming major disadvantages of currently applied drugs by influencing pharmacological properties, metabolism and resistance development, enabling tuneable anti-tumour activity, “intramolecular combination therapy”, and introduction of more selective targeted properties.¹ One approach to multi-targeted compounds is the combination of anticancer metal complexes with bioactive ligands, as reported for ethacrynic acid, flavonol derivatives and other compound classes.^{2–4} Lapachol (2-hydroxy-3-(3-methylbut-2-en-1-yl)naphthalene-1,4-dione) and flavonols share with hydroxypyridones used in medicinal chemistry the same 5-membered ring coordination motif of *O,O*-bidentate anionic ligands.⁵ Furthermore, lapachol has antibiotic and anticancer properties and was investigated in clinical trials as an anticancer agent.^{6,7} Its mode of action is supposed to be related to the generation of reactive oxygen species (ROS), which harm DNA and subsequently induce apoptosis, and biologically active Bi and Sb complexes were reported recently.^{8,9} Active organometallic

Ru^{II}(arene) complexes have clearly emerged as highly promising candidates to overcome the disadvantages of clinically-used platinum drugs.¹⁰ The RAPTA family and ethylenediamine complexes are the most prominent representatives of this compound class and are at an advanced preclinical development stage.¹¹ Therefore, the combination of bioactive lapachol with an organometallic moiety is a promising strategy, with the metal centre altering the chemical and biological properties of the ligand.

The organometallic complexes **1a–c** were synthesised by deprotonating commercially available lapachol **L** with NaOMe followed by conversion with the respective dimer $[\text{MCl}_2(\text{arene})]_2$ ($\text{M} = \text{Ru}^{\text{II}}$ **1a**, Os^{II} **1b**, Rh^{III} **1c**; arene = η^6 -*p*-cymene for Ru^{II} , Os^{II} and η^5 -pentamethylcyclopentadiene for Rh^{III}) to the corresponding organometallics **1a–c** in good to excellent yields (75–96%). The complexes were characterised by NMR, ESI-MS and elemental analysis, confirming the proposed structure of the compounds. In addition, single crystals of **1a** and **1b** suitable for X-ray diffraction analysis (Table S1, ESI†) were obtained from dichloromethane/*n*-hexane by using the slow diffusion method. Complexes **1a** and **1b** crystallise in the monoclinic space group $P2_1/n$ and adopt the pseudo-octahedral “piano-stool” configuration (Fig. 1,†), which is typical for this class of organometallic compounds. Lapachol acts as an anionic bidentate *O,O*-chelating ligand leading to the formation of a five-membered, non-planar ring with envelope conformation. The M–O2 distances were slightly shorter (2.0764(10) Å for **1a**, 2.077(2) Å for **1b**) than the corresponding M–O1 bond lengths (2.1072(11) Å for **1a**, 2.128(2) Å for **1b**), which is in good agreement with data obtained for related organometallic complexes.

The coordination of the keto group to the metal centre induces an elongation of the C–O bond length of the coordinated carbonyl group (1.259(4) Å for **1b**) as compared to the uncoordinated carbonyl in *para*-position (1.240(4) Å for **1b**), which confirms the [1,4]-dioxo form of the attached ligand.

The aqueous chemistry of the lapachol-containing organometallics **1a–c** was studied by ESI-IT-MS (Scheme 1). In all cases, aquation gave the respective aqua complexes (**2a–c**; Scheme 1), accompanied by ligand release and resulting in the formation of chlorido-bridged (**2c**) or hydroxido-bridged (**2a**, **2b**) dimers.

Fig. 1 Molecular structure of the $M^{II}(\eta^6\text{-}p\text{-cymene})$ complexes **1a** ($M = \text{Ru}$) and **1b** ($M = \text{Os}$) drawn at 50% probability level. The hydrogen atoms were omitted for clarity.

Scheme 1 Synthesis of the organometallic lapachol (L) complexes **1a-c** and their subsequent aquation to the aqua complexes **2a-c**: (i) NaOMe, $[\text{MCl}_2(\text{arene})]_2$ (**a** $M = \text{Ru}^{II}$, **b** $M = \text{Os}^{II}$, arene = $\eta^6\text{-}p\text{-cymene}$; **c** $M = \text{Rh}^{III}$; arene = $\eta^5\text{-pentamethylcyclopentadiene}$).

The extent of ligand release followed the order $2\text{c} < 2\text{a} < 2\text{b}$, *i.e.* compound **2c** is largely stable for at least 24 h, while ligand release was most pronounced for **2b** as determined by analysis of relative abundances of ions in mass spectra (see Fig. S1, ESI[†]).

The reactivity of metal complexes towards biomolecules is a crucial parameter for their biological activity. Therefore, **1a-c** were exposed to a mixture containing the DNA model 9-ethylguanine (EtG) and the amino acids glycine (Gly), L-cysteine (Cys), L-histidine (His) and L-methionine (Met). EtG adducts were only transiently formed during the first hour and were only observed for **1a** and **1b**, while Gly adducts were not detected. Compounds **1a-c** formed structurally similar products, *i.e.*, His and mainly Met adducts detected as $[\text{M}(\text{aa}) - \text{H}]^+$ ions ($M = (\text{Cp}^*)\text{Rh}$, (cym)Ru or (cym)Os; aa = His or Met). Interestingly, different reaction pathways were observed for **1a-c**. **1c** transiently formed Cys adducts, which disappeared again after 24 h. A two-step binding process of amino acids was detected involving initial mono-dentate coordination of an amino acid which induces the labilisation of the *O,O*-chelate and leads ultimately to cleavage of lapachol. In contrast to **1c**, **1a** directly formed His and Met adducts and no other adducts were detected. For **1b**, Cys adducts are stable for more than 24 h and were observed besides His and Met adducts (Table S2, ESI[†]). The extent of His or Met adduct formation seems to be pH dependent (Fig. S2, ESI[†]), which is of relevance in certain slightly more acidic solid tumours due to hypoxia or upregulated glycolysis.¹² In such an environment, the organometallic Rh^{III} , Ru^{II} and Os^{II} compounds seem to favour thioether over imine binding. In addition, the reactivity of **1a-c** toward the model protein ubiquitin (ub) was investigated using ESI-TOF-MS. Incubation of **1a-c** with ub (2:1) for 24 h yielded primarily monoadducts accompanied by lapachol release from the metal centre (Fig. 2; Table S3, ESI[†]). These monoadducts were then subjected to in-source collision-induced dissociation (ISCID), in order to obtain information on the binding

Fig. 2 Ultra-high resolution ESI-TOF mass spectra of 2:1 reaction mixtures containing **1a** (A), **1b** (B) or **1c** (C) and after 24 h (left). ISCID top-down signals of the respective mono-adduct revealed Met1 as the primary metallation site (right).

site of the metal ion on the protein. Detection of $\text{Ru}^{II}(\text{cym})\text{A}_1$ and $\text{Os}^{II}(\text{cym})\text{B}_1$ fragments suggest Met1 as the primary binding site for **2a** and **2b**, as did the fragment $(\text{Cp}^*)\text{Rh}^{III}\text{B}_3$ for **2c** (Table S4, ESI[†]). To the best of our knowledge, this is the first report on binding site determination of a Rh-metallodrug on a protein in a top-down approach.

The cytotoxicity of the organometallic complexes **1a-c** was determined by means of the colorimetric MTT assay in the human cancer cell lines CH1 (ovarian carcinoma), SW480 (colon carcinoma), A549 (non-small cell lung carcinoma), HCT-116 (colon carcinoma) and HL60 (acute promyelocytic leukemia) and was compared to lapachol and cisplatin (Table 1 and Fig. S3, ESI[†]). Complexes **1a-c** exhibit antitumour activity in the low μM range. In general, the activity of **1b** was widely similar to that of lapachol (L), indicating that the ligand was the cytotoxicity-determining moiety of the compound. This may be related to ligand release in the presence of biomolecules as shown by the MS studies. The rhodium complex **1c** was less cytotoxic than lapachol and more stable under physiological conditions. The organoruthenium compound **1a** was the most potent compound of the series, especially in the otherwise less sensitive A549 and HCT-116 cells, where IC_{50} values suggest a synergistic effect of the metal ion. The complexes induced moderate but significant levels of apoptosis as determined by means of the annexin V assay in SW480 cells. The amount of annexin V/PI positive cells increased significantly after addition especially of **1a** and **1c**, where a more than 2-fold increase of apoptotic cells compared to the control was observed. In the cases of **1a** and **1c** but not **1b**

Table 1 *In vitro* anticancer activity (IC_{50} values in μM) of **1a-c** in CH1, SW480, A549, HCT-116 and HL60 cells compared to cisplatin and lapachol (L)^a

Fig. 3 Determination of the ROS level induced by lapachol and **1a–c** by the DCFH-DA-assay.

apoptosis induction was significantly enhanced as compared to **L** (Fig. S4, ESI[†]).

The cytotoxic activity of lapachol is related to the generation of ROS and interaction with nucleic acids.^{7,15} Thus the potential of **1a–c** to induce oxidative stress through ROS was investigated by means of the DCFH-DA assay in HL60 cells. **1a** was found to generate ROS to a higher extent than the free ligand and the Os and Rh compounds (Fig. 3). The induction of oxidative stress and apoptosis was accompanied by increased phosphorylation of the stress kinase p38 and enhanced levels of p53 in HCT-116 cells (Fig. 4). These observations confirm a synergistic effect of the organoruthenium coordination to the bioactive quinone. In addition, the impact of **L** and **1a–c** on the cell cycle was investigated by FACS analysis in CH1, SW480 and HCT-116 cells (Fig. S5 and S6, ESI[†]). Treatment of the more resistant HCT-116 cells caused a significant arrest in the G2/M phase, especially for the ruthenium complex **1a**. In the case of CH1 and SW480 cells, a substantial S phase arrest was observed in the IC₅₀ range (Fig. S5 and S6, ESI[†]). The G1/S checkpoint is partially regulated by p53 in response to DNA damage.¹⁶ SW480 cells have a mutated p53 in contrast to HCT-116 cells, explaining the different cell cycle arrests after treatment with **L** and **1a–c**. Furthermore, our data are comparable with lapachone induced S phase arrest in p53 mutated cell models.¹⁷ As a consequence of the cell cycle data, the dose-dependent expression changes in cyclins and the phosphorylation of cdc2 after 24 hours were elucidated by Western blot analyses in HCT-116 cells (Fig. 4). The G2/M arrest was accompanied by expression changes of cell cycle-related proteins, such as an increase in p21, cyclin B1 and E, while cyclin D1 expression was especially enhanced at

Fig. 4 Western blot analysis of HCT-116 cells incubated with **1a** and lapachol (**L**) for 24 h.

lower drug concentrations. These data indicate that **1a** interferes with cell cycle progression and induces apoptosis involving a p53 response.

In summary, organometallic lapachol complexes were prepared in high yields, which are activated by fast hydrolysis to the corresponding aqua species in aqueous solution. They are able to interact with biomolecules and show antiproliferative activity in the low μM range in human tumour cell lines. The first investigations of the underlying mechanisms showed an enhanced anti-cancer activity, especially in case of **1a**, based on ROS-induced apoptosis and cell cycle arrest. Further investigations will elucidate the mode of action in more detail. Overall, the Ru complex **1a** induced apoptosis to a higher degree compared to lapachol and its Rh and Os analogues, demonstrating a synergistic effect of the Ru centre and the bioactive ligand.
