## 1. Introduction

As a commensal microorganism *Staphylococcus aureus* does not normally cause harm to a healthy individual. Complications arise however with tissue damage<sup>1</sup> and a weakened immune system unable to fight off an opportunistic infection, for example in critically ill patients.<sup>2,3</sup> Rapid and early detection of *S. aureus* is critical to diagnose infection,

# Volatile metabolites differentiate air-liquid interface cultures after infection with *Staphylococcus aureus*<sup>†</sup>

Waqar Ahmed, <sup>[10]</sup> <sup>a</sup> Emmanuelle Bardin,<sup>b,c</sup> Michael D. Davis,<sup>d</sup> Isabelle Sermet-Gaudelus,<sup>b,e</sup> Stanislas Grassin Delyle <sup>[10] c,f</sup> and Stephen J. Fowler <sup>[10]</sup> \*<sup>a,g</sup>

Early detection of lung infection is critical to clinical diagnosis, treatment, and monitoring. Measuring volatile organic compounds (VOCs) in exhaled breath has shown promise as a rapid and accurate method of evaluating disease metabolism and phenotype. However, further investigations of the role and function of VOCs in bacterial-host-stress response is required and this can only be realised through representative *in vitro* models. In this study we sampled VOCs from the headspace of A549 cells at an air–liquid interface (ALI). We hypothesised VOC sampling from ALI cultures could be used to profile potential biomarkers of *S. aureus* lung infection. VOCs were collected using thin film microextraction (TFME) and were analysed by thermal desorption-gas chromatography-mass spectrometry. After optimising ALI cultures, we observed seven VOCs changed between A549 and media control samples. After infecting cells with *S. aureus*, supervised principal component-discriminant function analysis revealed 22 VOCs were found to be significantly changed in infected cells compared to uninfected cells (p < 0.05), five of which were also found in parallel axenic *S. aureus* cultures. We have demonstrated VOCs that could be used to identify *S. aureus* in ALI cultures, supporting further investigation of VOC analysis as a highly sensitive and specific test for *S. aureus* lung infection.

prescribe the right antibiotic at the right time, and reduce the risks associated with drug-resistant strains.<sup>4</sup>

Measuring exhaled volatile organic compounds (VOCs) offers potential for rapid non-invasive detection of lung infection.<sup>5,6</sup> To this end, several studies have explored VOC analysis with S. aureus infection from respiratory samples.7-9 However, VOCs from complex samples may contain several endogenous (e.g., host tissues and metabolism) and exogenous (e.g., sampling apparatus, environment, and other pathogens) sources, and these may likely confound VOCs directly associated with microbes. Investigating how these sources impact changes in the volatilome may provide novel insights into their metabolic pathway activation and role in infection pathogenesis. For example, studies have explored how changing the culture media environment can cause variations in the volatilome of bacterial cultures.<sup>10,11</sup> Confounders such as host response metabolic response to an infection may be responsible for poor reproducibility between in vitro and in vivo studies.12,13

Infection models of microbes and mammalian cells are more representative of the human lung environment than standard microbial cultures.<sup>14,15</sup> Air–liquid interface (ALI) culture models are widely used to emulate the cellular structure of lung disease in controlled environments and in

some cases reduce the dependence on animal models for experimentation.<sup>16</sup> Studies have also profiled the headspace from air-liquid interface (ALI) models, to investigate viral infection and the metabolic impact of oxidative stress from smoking.<sup>17–19</sup> These studies used either used stir-bar sorptive extraction or solid phase microextraction to sample VOCs from modified cell culture apparatus. All three studies used gas chromatography-mass spectrometry (GC-MS) for analysis of VOCs.

The aim of this study was to model epithelial damage caused by *S. aureus* and analyse the volatilome for potentially diagnostic biomarkers for *S. aureus*. The hypothesis was that VOC sampling could be used to profile potential biomarkers of *S. aureus* lung infection. We developed a method to sample VOCs using thin-film microextraction (TFME) from the apical compartment of an alveolar epithelial ALI culture, analysed offline by thermal desorption-gas chromatography-mass spectrometry (TD-GC-MS). Univariate and multivariate statistical comparisons will be presented between mammalian cells with and without *S. aureus* inoculation, using cell culture media and *S. aureus* culture as control samples.

## 2. Methods

#### 2.1. Strains and cell culture

The immortalised A549 alveolar epithelial cell line was used in this study, kindly donated from the Blaikley lab at the University of Manchester (passage no. 117). Cells were cultured in Dulbecco's Modified Eagle's medium (DMEM) supplemented with 4500 mg  $L^{-1}$  glucose (Sigma Aldrich, UK), 10% fetal bovine serum (PAA, UK), 2% 200 mM L-glutamine (Sigma Aldrich, UK), 1% 100 mM sodium pyruvate solution (Sigma Aldrich, UK), 1% penicillin–streptomycin (1000 µg m $L^{-1}$ –10 mg m $L^{-1}$  in solution with 0.9% NaCl, Sigma Aldrich, UK), and 0.1% 250 µg m $L^{-1}$  Amphotericin B (Gibco, UK).

Cells were incubated at 37 °C in 5% CO<sub>2</sub>, passaged when at least 80% cell confluence was reached using trypsin-EDTA (0.25% solution, Sigma Aldrich, UK), centrifuged at 100 RCF for 5 min, and the pellet resuspended in fresh media to a concentration of  $1 \times 10^6$  cells per mL. Cell concentration was determined using a trypan blue stain (0.4%, Sigma Aldrich, UK) and cells counted using a Fuchs-Rosenthal haemocytometer (C-chip DHC-F01, NanoEntek, South Korea).

To generate an ALI culture, approximately  $1 \times 10^5$  cells were seeded onto sterile 12-well plates with well inserts (ThinCert<sup>TM</sup>, PET transparent membrane, pore size  $3.0\mu$ m, pore density  $0.6 \times 10^6$  cm<sup>2</sup>, insert surface area 113.1mm<sup>2</sup>, Gibco, UK). Spent media in the apical compartment was removed after 24 h to generate a cell layer exposed to air on the apical side of the insert membrane. Basal compartment media was replenished every other day. Cell growth was visually inspected compared with control wells. In addition, transepithelial electrical resistance (TEER) measurements were carried out using an epithelial voltohmmeter according to manufacturer protocols (EVOM<sup>2</sup>, World Precision Instruments, USA). Cell monolayer TEER was calculated using the following equation: TEER ( $\Omega$  cm<sup>2</sup>) =  $R_{\text{Tissue}} \times S$ , where *R* is resistance ( $\Omega$ ),  $R_{\text{Tissue}} = R_{\text{blank}} - R_{\text{culture}}$ , and *S* is the insert surface area (cm<sup>2</sup>). Both apical and basal compartments were washed with phosphate buffered saline (PBS) before measurement.

#### 2.2. Infection with S. aureus and VOC sample collection

A reference strain of *S. aureus* (ATCC 29213) was initially subcultured in tryptic soy media. Apical compartments were inoculated with 100  $\mu$ L of *S. aureus* suspended in PBS and incubated for 24 h at 37 °C. Prior to this, basal media was replaced with DMEM without antibiotic supplementation and incubated at 37 °C for a further 24 h to confirm absence of contamination.

TFME was carried out using PDMS strips (20 mm × 15 mm × 0.45 mm, Goodfellow Cambridge Ltd, Huntingdon, UK), as previously described.<sup>20</sup> Strips were initially washed with water then methanol and conditioned in a stream of N2 at 350 °C for 1 h. Conditioned strips were stored in capped stainless-steel tubes until sample collection and analysis and were used within 24 h of conditioning. Strips were reused after reconditioning with the same parameters. VOCs were sampled by inserting a PDMS strip into the apical compartment of each well insert. Cultures were then incubated for a further 24 h before removing PDMS strips for VOC analysis. S. aureus was aspirated from the apical side with a 100 µL PBS wash and growth observed on tryptic soy agar plates using the drop plate method (10 µL of the PBS wash dropped on a segment of the agar plate and incubated at 37 °C for 18 h). Basal media was also collected to observe S. aureus migration through the cell layer and insert membrane. The PBS wash and basal media were diluted (1:10) up to a maximum of four dilutions.

Absorbance change of Phenol Red, a pH indicator and a constituent of DMEM, was measured as an orthogonal method to detect cell culture acidification by *S. aureus* infection. A standard curve of DMEM at different pH was created by adding citric acid, measured at 415 and 560 nm (Biochrom Asys UVM340, Cambridge, UK). The standard curve was calculated based on the 415/560 nm ratio for Phenol Red and used to interpolate pH levels of basal media ( $R^2$  0.96). This method was used as opposed to direct measurement using a pH probe due to the low volume of spent media available per well and risk of cross contamination between infected and uninfected samples.

# 2.3. Thermal desorption-gas chromatography-mass spectrometry (TD-GC-MS)

PDMS strips were dry purged with  $N_2$  at 50 mL min<sup>-1</sup> for 4 min to remove excess water on the sorbent before analysis by TD-GC-MS. Prior to thermal desorption, a gas standard (1 ppmV *p*-bromofluorobenzene in  $N_2$ ; Thames Restek, Saunderton, UK) was automatically spiked onto each tube. Tubes were then desorbed at 280 °C for 5 min (TD100, Markes International, Llantrisant, UK) then transferred with splitless injection to a cold trap (kept at 0 °C) for cryofocussing which was subsequently flash heated to 280 °C for 2 min. Desorbed

#### Paper

VOCs were transferred to the GC column (DB-5 ms, length 30 m × internal diameter 0.25 mm × film thickness 0.25 µm, Agilent Technologies, Cheadle, UK) using a constant helium flow of 1 mL min<sup>-1</sup>. The GC column oven (7890B, Agilent Technologies, Cheadle, UK) was set to a linear temperature programme starting at 30 °C and increasing to 250 °C at 7.5 °C min<sup>-1</sup> (total GC cycle time of 29.33 min). After GC separation, VOCs were transferred to the MS (7010, Agilent Technologies, Cheadle, UK) where they were ionised (EI 70 eV) in the source kept at 150 °C. Data was acquired in full scan mode with an acquisition rate of 5 scans s<sup>-1</sup> between *m*/*z* 40–300. In addition, validation of cell culture VOCs was performed on a different GC-MS method, as described previously.<sup>21</sup>

#### 2.4. Data analysis

Masshunter Quantitative Analysis software (version B.07.00, Agilent, Cheadle, UK) was used to automatically integrate peaks (Agile2) and identify VOCs in each sample to MSI level  $2^{22}$  using the NIST mass spectral library (version 2014, match factor > 70) and retention indices calculated using an alkane ladder. An aligned  $n \times p$  matrix was created of peak intensities. Missing values were imputed using Random Forest imputation (R package *missForest*). All samples were then normalised by the internal standard (p-bromofluorobenzene), and features were log transformed and mean centred (i.e. z-normalised). Statistical analyses were performed in Graphpad Prism (version 9.1) and R (v 4.1.1) and consisted of univariate tests including repeated measures ANOVA, non-parametric Mann-Whitney-U and multivariate analysis in the form of unsupervised principal component analysis (PCA) and supervised classification via principal component-discriminant function analysis (PC-DFA). PC-DFA was cross validated (80:20 training: test set) using stratified random sampling with 1000 repeats. Comparisons were made between culture media and

mammalian cells, and infected and uninfected cells. The Benjamini–Hochberg one way ANOVA was applied (q < 0.05) where appropriate to control the false discovery rate (FDR).

## 3. Results

#### 3.1. Blank PDMS strip reproducibility

Reproducibility of PDMS strip adsorption was assessed by calculating RSD for the internal standard purged onto blank PDMS strips. Repeated desorption of a single blank PDMS strip (n =10) resulted in an RSD of 1.35% whereas ten repeat desorption runs of a tube without sorbent material resulted in an RSD of 1.10%. Desorption of several individual PDMS strips (n = 10) resulted in an RSD 7.27%. The most consistently produced compounds associated with the sorbent background were hexamethylcyclotrisiloxane and octamethylcyclotetrasiloxane.

# 3.2. Optimal ALI culture time and CFU inoculum for *S. aureus*

To assess the formation of a A549 cell layer on the well insert, transepithelial integrity was measured by TEER (n = 11) on day 2, 5, 7, 9, and 12 after seeding (Fig. 1). A repeated measures ANOVA showed TEER increased on all days compared to the initial measurement on day 2 (p = < 0.001), whereas no difference was found between days 5, 7, 9, and 12. Day 9 was selected as the optimal time to infect cells based on the representative TEER ( $55.2 \pm 6.5$ ) and low RSD (11.7%), in comparison to other time points (day 5 =  $52.3 \pm 14.2$  RSD 27.2%, day 7 =  $56.1 \pm 16.8$  RSD 30.0%, day 12 =  $39.7 \pm 3.6$  RSD 9.1%). TEER measurements were also used to evaluate the impact of *S. aureus* on membrane integrity.

To select an infection CFU inoculum concentration for infection, A549 cells were cultured at ALI and the apical side

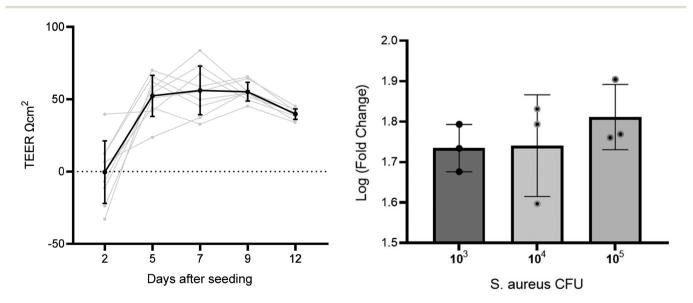

Fig. 1 Left: line graph with TEER measurements across several days on the same well inserts. Right: graph comparing three *S. aureus* CFU concentration of TEER fold change before and after inoculation.

was inoculated with *S. aureus* at three CFU concentrations –  $1 \times 10^3$ ,  $1 \times 10^4$ , and  $1 \times 10^5$  CFU (n = 3 per concentration). All *S. aureus* CFU concentrations decreased cell culture TEER after inoculation and incubation for 24 h (paired *t* test p < 0.001). Mean log fold changes for each CFU concentration were  $1 \times 10^3$  CFU mL<sup>-1</sup> = 1.7,  $1 \times 10^4$  CFU mL<sup>-1</sup> = 1.8, and  $1 \times 10^5$  CFU mL<sup>-1</sup> = 1.8. No significant differences were found between TEER measured before or after inoculation between CFU concentrations (p > 0.05). The lowest concentration tested ( $10^3$  CFU) was taken forward for infecting cells in the head-space sampling experiments. A low initial CFU was selected to reduce detection of saturated high-abundance VOCs from *S. aureus*, reducing the risk of sample carry over.

#### 3.3. Volatiles from A549 cells without infection

Headspace volatiles were sampled from A549 cells and mediaonly controls after 9 days in ALI culture, under standard growth conditions without infection. In addition, a validation experiment was carried out using the same culture methods but with a different analytical method as described in<sup>21</sup> (cells n = 6, media n = 3). All samples were confirmed free of microbial contamination after plate culture and visual inspection of the culture colour remaining red (media) or pink (cells) and absence of turbidity. After controlling for FDR, 107 features were significantly different between media and cells. For the validation experiment, 111 features were found significantly different between the two groups. Separation across PC1 was observed between sample groups for both original (Fig. 2A) and validation experiments (Fig. 2B).

Seven VOCs extracted from PCA loadings were significantly different between media and cells across both experiments as shown in Fig. 2. These included benzene 2-nitroethyl-(log 2 fold change [FC] 2.7, q < 0.001, validation experiment FC 5.2, q < 0.001), 1-hexanol 2-ethyl-(FC 2.0, q = 0.003 validation FC 2.3, q = 0.023) and a methylated furanone (Fig. 2C). The latter compound was identified as 2(3*H*)-furanone 5-methyl-(FC 2.5, q = 0.026) in the original experiment and as 2(3*H*)-furanone dihydro-4-methyl-(FC 2.9, q = 0.004) in the validation experiment. VOCs with a decreased abundance in cells (Fig. 2D) were benzeneacetaldehyde (FC -2.5, q = 0.003, validation FC -3.5, q = 0.001), benzaldehyde (FC -2.0, q = 0.003, validation FC -1.6 q = 0.007), 4-quinolinecarboxaldehyde (FC -8.1, q = 0.010, validation FC -1.2, q = 0.032, validation FC -2.7 q < 0.001).

#### 3.4. Infection of A549 cells with S. aureus

After 9 days of maintaining an ALI, cells were infected with  $10^3$  CFU of *S. aureus* (n = 6) on the apical side alongside cells without infection inoculated with 100µL PBS without *S. aureus* (n = 6) and control samples (media and *S. aureus* in media). After 24 h, leakage of media from the basal to the apical side was observed for A549 cultures with *S. aureus* infection, whereas no such leakage was seen for samples uninfected with *S. aureus*. TEER measurements decreased in *S. aureus* infected cells after 24 h (paired *t* test p = 0.0003), as shown in Fig. 3A. Basal media pH suggested increased acidity in infected cell

cultures compared to uninfected cells (Fig. 3B) which is consistent with bacterial contamination of mammalian cell culture. No visible *S. aureus* growth was observed for A549 cultures alone compared to infected A549 for both apical and basal samples (Fig. 3C). Saturated microbial growth was observed across all inoculated cultures, including the basal compartment cultures (>10<sup>7</sup>CFU) suggesting exponential growth of *S. aureus* in the presence of A549 cells.

#### 3.5. Volatile profile of A549 cells infected with S. aureus

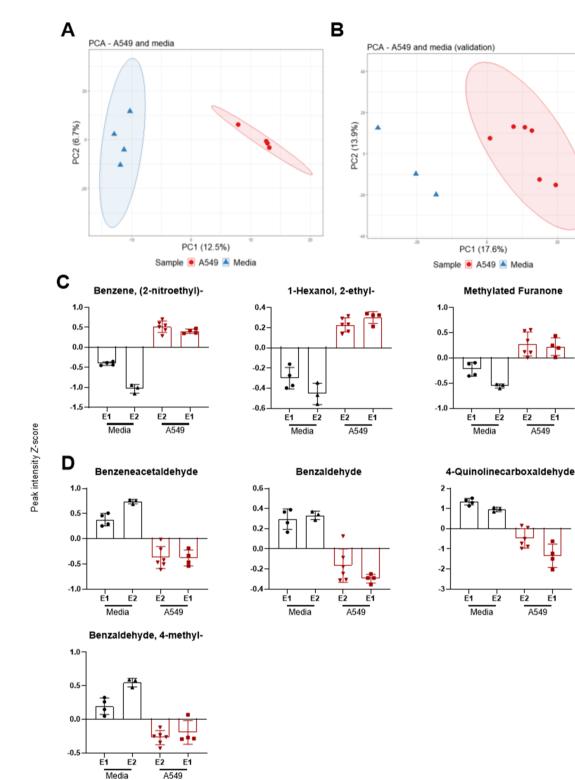

Data were initially assessed using PCA (Fig. S1<sup>†</sup>) and inspecting total ion current chromatograms, where no clear separation was found between groups. In addition, two samples failed analysis due to water retention. Therefore, to extract VOC features which differentiate infected and uninfected cells, a cross-validated PC-DFA (with eight PCs) was performed with A549 cells infected with *S* aureus (n = 4) in comparison to uninfected A549 cells (n = 6), media (n = 8), and S. aureus (n = 8)samples alone (Fig. 4). The PC-DFA model showed separation across the first discriminant function (DF1, S3) between samples with A549 cells (infected and uninfected) and those without (media and S. aureus alone). The second discriminant function (DF2, S4) showed separation of infected and uninfected sample groups. After applying an arbitrary noise cut off to the loadings (0.05), features that contributed to separation were extracted for DF1 (n = 70) and DF2 (n = 50).

Features from DF2, which indicated differences between infected and uninfected cells (n = 34, Table 1), were screened using the univariate non-parametric Mann–Whitney-*U* test and 22 were found to have statistically significant changes in abundance between the two groups (Fig. 5). Two VOCs were decreased in infected cells compared to uninfected. All other features were significantly increased (n = 20), five of which were also increased in axenic *S. aureus* cultures (see Table 1).

### 4. Discussion

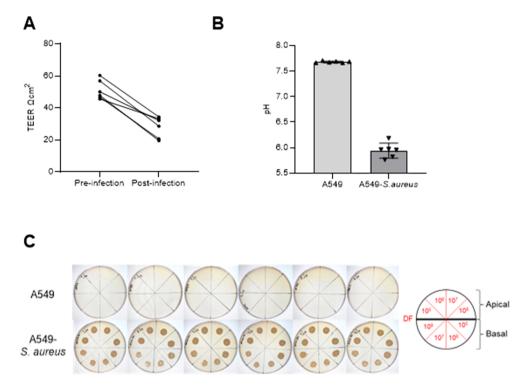

In this study, we found several VOCs associated with uninfected and infected alveolar epithelial cells in ALI cultures. VOCs were associated with the infection response alone and included VOCs also identified in axenic cultures of *S. aureus*. Therefore, these results demonstrate the diverse sources of VOCs in the infection process (*i.e.* bacterial infection and cell response) and are potentially good candidates as diagnostic biomarkers of the multiple contributors to infection pathogenesis.

An assessment of PDMS material adsorption showed good reproducibility without degradation after 10 sequential desorption cycles of the same PDMS strip. Desorption between different PDMS strips was less reproducible (higher RSD). This may be due to minor inconsistencies between strip length and width. To minimise the number of water-logged samples, the dry purge time would require optimisation in future studies. When sampling from cell headspace, only seven compounds were observed to be consistent between two experiments con-

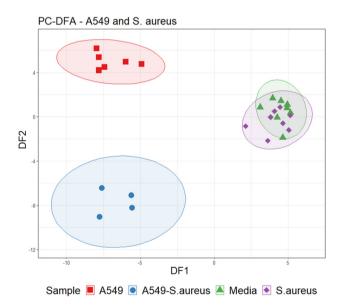

**Fig. 2** PCA scores plot showing PC1 and PC2 of headspace sampling experiments where VOCs were sampled after 24 h of incubation at 37 °C comparing (A) A549 and media, and (B) validation experiment comparing A549 and media using a different analysis method (see methods). *Z*-score plots of (C) of significantly increased (p < 0.05) VOCs in A549 and (D) significantly increased VOCs in media, across both original (E1) and validation (E2) experiments.

ducted at different times and with different GC-MS methods. This shows that different analytical methods can impact on the total number of VOCs observed. Furthermore, improving sampling and analytical parameters, such as introducing a secondary polar GC column, will increase the abundance and range of detectable VOCs. For sampling headspace, research-

**Fig. 3** (A) TEER measurements per well before and after infection of A549 cells with *S. aureus*. (B) Basal media pH after 24 h of infection (A549-*S. aureus*) compared to uninfected (A549) cells. ers have developed multi-bed TFME films which may also increase the range of VOCs sampled from cultures.<sup>23</sup>

Cells were successfully infected with *S. aureus* as demonstrated by increased CFU post-infection, reduced pH in coculture (*i.e.*, acidification due to aerobic bacterial contamination), and reduced TEER suggesting membrane damage. Epithelial damage by S. aureus and subsequent membrane rupture resulting in leakage in ALI culture is consistent with previous studies using a similar airway infection model.<sup>24</sup> Alcohol and fatty acid compounds were increased in the VOC profile of infected cells. Phenylethyl alcohol has previously been identified in S. aureus headspace.<sup>25</sup> The VOC 1-hexanol 2-ethyl in ALI culture was also shown by previous studies investigating A549 cells.<sup>26</sup> Fatty acids have been associated with the cell membrane phospholipid structure and their increased detection in infected cells may potentially be caused by membrane damage by S. aureus. Fatty acids are also found to control cell membrane integrity and biofilm dispersion in S. aureus.<sup>27-30</sup> Aromatic volatiles were decreased under normal cell growth suggesting uptake from the media and have been reported in previous studies investigating A549 cells.<sup>26,31</sup> Several methylated pyridine compounds were increased in infected cells compared to uninfected cells. Pyridine 3-methyl-2-phenyl was also detected in axenic S. aureus cultures. Pyridine is a potential marker for smoking and structurally associated with nicotine.32

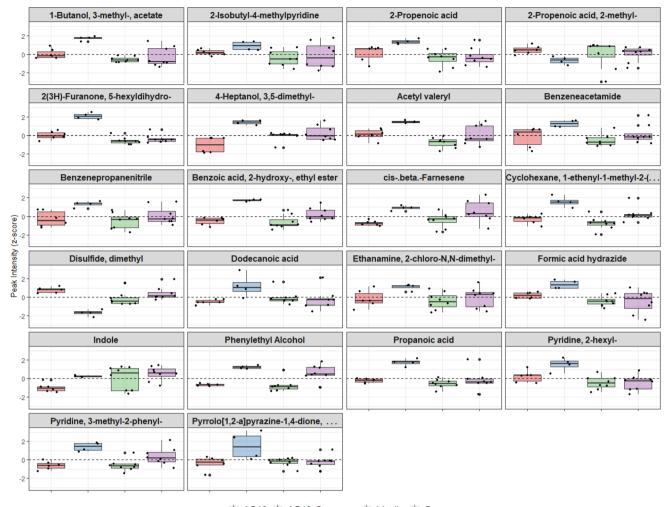

Although it was expected that VOCs which are very volatile will not be captured by the PDMS sorbent, not all VOCs within the detectable range were consistent with previous literature. For example, dimethyl disulfide (DMDS), a VOC known to be emitted by *S. aureus*, was comparatively low in infected cells, which suggests altered metabolism during infection. Furthermore, DMDS is a ubiquitous VOC produced by several microbial and plant species and therefore has little value as a

**Fig. 5** Boxplots of VOCs which are significantly different between infected and uninfected cells, showing all sample groups for comparison. Dashed line represents peak intensity mean after *z*-normalisation.

clinically useful diagnostic biomarker. However, further optimisation of the method (*e.g.* use of labelled sulfur-containing amino acids to track DMDS) is required to evaluate metabolic changes during infection. Culture conditions could be further improved by using primary cell culture, other cell types, by targeting specific bacterial and mammalian growth phases, and by collecting VOCs through dynamic or active sampling which has the advantage of measuring VOC metabolism in relation to VOC release time and rate.<sup>33,34</sup> Finally, we recognise the use of immortalised mammalian cells lines such as A549 may not represent normal mammalian cell metabolism and response to infection and a more representative model would include patient-derived primary cells.

We demonstrated for the first time a direct VOC sampling method for ALI cultures of bacterial infection and using standard 2D culture well inserts. TFME is a highly versatile method<sup>31,35</sup> and was applied to ALI cultures with minimal intervention, thus preserving routine mammalian lung cell propagation techniques. ALI culture is physiologically relevant and resembles the environment of the respiratory epithelium more closely than standard sedimented liquid cultures. Furthermore, ALI is an important tool to study the effects of nebulised drugs, exogenous pollutants and particulate matter on airway cells. Cultures can be further enhanced to develop a true lung infection model to include bronchial epithelial cells for cilia, goblet cells for mucus production, and include inflammatory cells for host response to xenobiotics.<sup>36</sup>

## 5. Conclusions

In this study we have detected VOCs characteristic of *S. aureus* infection in lung epithelial cells, using a novel approach which harnesses the adaptability of TFME to sample from a two-dimensional air-liquid interface culture model. We identified VOCs that are unique to *S. aureus*, and to infected and uninfected mammalian cells. These results demonstrate the poten-

tial for investigating VOCs as potential biomarkers of infection using complex two-dimensional culture models.

## Conflicts of interest

There are no conflicts to declare.

## Acknowledgements

We acknowledge the experimental support provided by Kai Wang and Professor Clare Mills at the Manchester Institute of Biotechnology and Dr John Blaikley and Dr Conal Hayton for donation of the immortalised cell line. E. B. also acknowledges the fellowship support of the European Cystic Fibrosis Society. W. A. and S. J. F. are supported by the NIHR-Manchester Biomedical Research Centre.
