New perspective crosslinking electrochemistry and other research fields: beyond electrochemical reactors†

Yu Zhang  and Yuen Wu *

Over the years, electrochemical reactors have evolved significantly, with modern reactors now able to achieve a high current density and power output in compact sizes. This leap in performance has not only greatly accelerated the rate of electrochemical reactions but also had a broader impact on the environment. Traditional research perspectives, focused primarily on the internal working systems of reactors, possibly overlook the potential of electrochemical systems in regulating their surrounding environment. A novel research perspective considering the interaction between electrochemical processes and their environmental context as a unified subject of study has gradually emerged alongside the dramatic development of electrochemical techniques. This viewpoint introduces a paradigm shift: electrochemical reactors are not isolated entities but rather are integral parts that interact with their surroundings. Correspondingly, this calls for an innovative research methodology that goes beyond studying the electrochemical processes in isolation. Rather, it integrates the design of the electrochemical system with its specific application environment, ensuring seamless integration for optimal performance under various practical conditions. Therefore, performance metrics should include not only the basic parameters of the electrochemical reactions but also the adaptability of the electrochemical system in real-world scenarios beyond the laboratory. By focusing on environmental integration and application-driven design, the applications of electrochemical technology can be more effectively leveraged. This perspective is exemplified by an electrochemical system based on coupled cathodic oxygen reduction and anodic oxygen evolution reactions. By adopting this new research paradigm, the applications of this electrochemical system can be extended to fields like medical treatment, food science, and microbial fermentation, with an emphasis on tailored designs for these specific application fields. This comprehensive and systematic new research approach aims to fully explore the potential applications of electrochemical technology and foster interdisciplinary collaboration in the electrochemical field.

Introduction

Electrochemical technology, powered by electrical energy to drive chemical reactions, plays a pivotal role in scientific research and holds vast potential in practical applications.^{1,2} Historically, the focus of research in the electrochemistry field has been primarily confined to electrochemical reactors, and investigating electrode reactions, product types, and yields. Such a limited scope was initially shaped by the early structure of electrochemical reactors, which led to low current densities and limited electrochemical reaction efficiency.^{3,4} Consequently, the subtle impact of the electrochemical processes at such low current densities often led researchers to overlook

their environmental interactions. Advancements in technology have since led to a considerable improvement in electrochemical reactors, now transitioning to flow-type electrolytic cells.^{3,5} This structure allows continuous reactant supply, especially supporting continuous gas-phase reactions with the introduction of gas diffusion electrodes (GDEs).^{6,7} Further progress includes the design of membrane electrode assembly (MEA) reactors with ion-exchange membranes between the anode and cathode.^{8–10} This near zero-gap structure minimizes internal polarization resistance, thus considerably boosting the electrochemical reaction efficiency.^{11,12} Modern electrochemical reactors have evolved into modular stacks based on MEA structures, maintaining a quite compact size while delivering high power and current density for prolonged, stable, and efficient electrochemical reactions.^{13–15} The ability to achieve high current densities reaching ampere levels for modern electrochemical reactors signifies the faster electrochemical reaction rates, but deepens their environmental footprints.¹⁶ It has

School of Chemistry and Materials Science, University of Science and Technology of China, Hefei 230026, China. E-mail: yuenwu@ustc.edu.cn

† Electronic supplementary information (ESI) available. See DOI: <https://doi.org/10.1039/d3sc06983d>

become evident that such a narrow focus on electrode reactions within the reactors is insufficient because it neglects the wider environmental and systemic impacts. Therefore, an in-depth exploration of electrochemical technology should not be confined only to the reactions inside reactors, but also encompass their roles and applications in a broader environmental context. Adopting such a holistic research perspective is pivotal to fully tap into the potential value of electrochemical technology across various domains.

In this new research paradigm, where electrochemical reactors and their surrounding environment are considered an interactive whole, an innovative research approach is required. Traditional strategies often follow a linear research process involving studies of the catalytic mechanism, catalyst, electrode reaction, and reaction product. However, such a research approach falls short in considering complex interactions between the reactor and its surrounding environment. The new research strategy emphasizes a practical application-oriented study, for designing everything from electrochemical mechanisms to reactor structures. As depicted in Fig. 1, this application-driven approach can ensure the seamless integration of electrochemical technology with its environment, achieving faster reactions and more effective environmental control. Furthermore, consideration must be given to the interplay between electrochemical reactions and external environments, as well as to the adaptability of reaction systems to the actual operating conditions. Performance assessments of designed electrochemical systems should extend beyond laboratory conditions towards real-world application environments, ensuring optimal overall performance in actual operations. In fact, even with the same electrochemical reaction mechanisms,

different application scenarios and objectives may lead to entirely different design considerations. In the following sections, an electrochemical system coupling a cathodic oxygen reduction reaction (ORR) and anodic oxygen evolution reaction (OER) is considered as an example to illustrate the design of electrochemical systems tailored to specific application goals. By adopting this new research perspective, the potential applications of the coupled ORR–OER system can be extended to medical treatment, food preservation, and microbial fermentation fields. While the applications of electrochemical technology in these fields are still in the nascent stages of exploration, it is expected that this perspective will encourage researchers in the domain of electrochemistry to explore these promising areas further. In conclusion, considering the electrochemical system and its environment as an integrated entity as well as a purpose-oriented research approach has the potential to propel electrochemical technology to the forefront of interdisciplinary intersections, and prompt new collaborative efforts across diverse research fields.

Discussion

Electrochemical system: coupling cathodic ORR and anodic OER

Oxygen (O_2), a crucial component of the earth's atmosphere, constituting approximately 21% of our breathable air, is omnipresent in our planet and plays a key role in numerous chemical and biological processes. In the field of electrochemistry, the ORR and the OER are two fundamental reactions. The ORR process involves the consumption of O_2 , reducing it to water or other oxygen-containing ions, while the OER is the

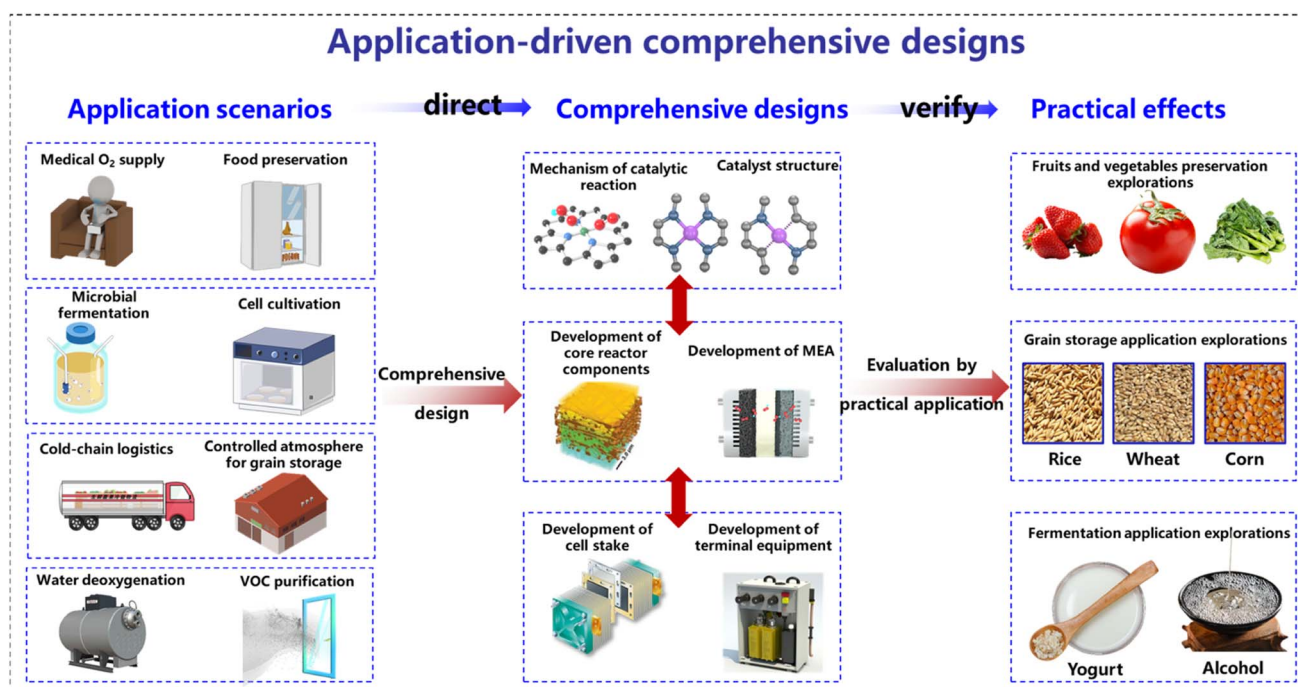

Fig. 1 Innovative research approach for application-driven comprehensive designs.

reverse process, electrochemically generating O₂ from water or oxygen-containing ions.¹⁰

By coupling these two electrochemical reactions, O₂ production, removal, or concentration modulation can be achieved. These are pivotal for various applications, such as O₂ production in the medical field, O₂ removal for food preservation, or manipulating the O₂ concentration to regulate microbial metabolism in microbial fermentation.

In the coupled electrochemical system of the cathodic ORR and anodic OER with a 4-electron transfer (4ET) pathway, the reactions at the cathode and anode for an acid system are shown as follows:^{17,18}

Cathode reaction:

Anode reaction:

In an alkaline system, the cathode and anode electrode equations are as follows:^{17,18}

Cathode reaction:

Anode reaction:

Upon combining the above cathodic and anodic half-reactions, the total electrochemical reaction can be derived as follows:

The above electrode reactions encapsulate the depletion of atmospheric O₂ at the cathode and the generation of an O₂ stream at the anode, which can be considered as the effective concentration of O₂ obtained from the air, as shown in the equation. This process, characterized by a reduction in entropy, requires energy input to the system for its activation. In electrochemistry, the energy necessary for initiating such an entropy reduction process is supplied in the form of electrical power. The relationship between the free energy change (ΔG) and potential in electrochemical reactions is defined by the equation:¹⁹

$$\Delta G = -nFE$$

where ' n ' represents the number of electrons involved in the reaction, ' F ' is the Faraday constant, and ' E ' denotes the electromotive potential of the cell. In thermodynamics, the

relationship between the ΔG of a system and its enthalpy change (ΔH) and entropy change (ΔS) is expressed as follows:²⁰

$$\Delta G = \Delta H - T\Delta S$$

where ' T ' is the temperature. Combining the above equations allows us to establish a relationship between the ΔS of a system and the input of electrical energy:

$$-nFE = \Delta H - T\Delta S$$

Assuming a constant temperature and driving a process where environmental entropy decreases (*i.e.*, $\Delta S < 0$) through electrical energy input, it is derived as follows:

$$T\Delta S = -nFE - \Delta H$$

The above equation delineates the relationship between electrical energy input and environmental entropy change in the electrochemical reaction process, unveiling its immense potential in precise environmental parameter control. Subsequent sections will delve into the potential applications of this ORR-OER electrochemical system across various domains. Furthermore, the following sections will specifically elaborate on guiding the overall designs of the electrochemical systems based on application scenarios.

Medical treatment field: electrochemical *in situ* production of high-purity medical O₂

Medical O₂, with a purity exceeding 99.5%, is extensively utilized in treating respiratory diseases, cardiac issues, emergency resuscitations, and as an adjunct in anaesthesia during surgeries.²¹ During the COVID-19 pandemic, medical O₂ became a critical healthcare resource, with severe shortages reported in many countries.^{22,23} This crisis primarily stemmed from the COVID-19 virus's severe impact on the lungs of patients, necessitating critically ill patients to rely on high-purity medical O₂ for assisted breathing.²⁴ The surge in patient numbers led to a drastic shortage in the supply of medical O₂. However, existing O₂ supply devices, such as O₂ cylinder and on-site pressure swing adsorption (PSA) equipment, exhibited inherent limitations.²⁵ O₂ cylinders are bulky, difficult to transport, and pose significant safety risks, while PSA equipment typically produces O₂ with a purity of only 93%,^{26,27} which fails to meet medical O₂ standards directly.²⁸ In this context, the application of electrochemical technology for the on-site production of medical O₂ presents itself as an innovative and viable solution, potentially alleviating the challenges of medical O₂ supply in hospitals.

Upon identifying hospital O₂ supply as the application scenario, it is imperative to design and optimize the entire electrochemical reaction system with the specific demands of this application. The primary application requirements are as follows: (1) high O₂ purity, as only O₂ with a purity exceeding 99.5% meets the standards for medical O₂; (2) high energy

efficiency, to ensure low energy consumption of the O₂ production equipment; (3) a high rate of O₂ production, which needs to reach at least 1 L min⁻¹ to satisfy practical application requirements.^{29,30} To meet the above criteria, it is essential to concurrently focus on optimizations and designs in terms of the catalytic mechanism, catalyst, and reactor structure. In a previous report,¹⁰ Zhang *et al.* designed a coupled ORR and OER electrocatalytic system to construct a high-performance electrochemical O₂ generator (EOG) for *in situ* medical O₂ production. As illustrated in Fig. 2, this EOG achieved a high O₂ purity (>99.9%), high O₂ production rate (>1.5 L min⁻¹), and high energy efficiency (496 L kW⁻¹ h⁻¹), along with offering other advantages, such as high portability (4.7 kg), instant start-up (<1 s), and low noise (<50 dB), demonstrating superior performance and significant potential to replace traditional PSA O₂ generators.

In the work, Zhang *et al.* conducted a series of designs and optimizations to enhance the performance of the electrochemical O₂ generator (EOG).¹⁰ In alkaline conditions, the ORR and OER can proceed through either a 4-electron transfer (4ET) mechanism adopting OH⁻ ions as intermediates or a 2ET mechanism applying HO₂⁻ ions as intermediates. The 2ET pathway, by halving the energy requirement per unit of O₂ produced, considerably enhances the O₂-generation efficiency compared to the 4ET pathway. In terms of catalyst optimization,

the development of ORR catalysts with high activity, stability, and 2ET selectivity was pursued to reduce the activation energy of the ORR, thereby decreasing the electrochemical polarization resistance and enhancing the reaction efficiency. In designing the electrocatalytic reactor structure, the cathodic ORR process is characterized as a three-phase-boundary reaction.³¹ This necessitates the incorporation of GDEs, which are instrumental in enhancing the mass-transfer efficiency of the O₂ reactant within the ORR process, thereby effectively mitigating concentration polarization. The use of an alkaline AEM in the MEA structure minimizes the anode-cathode gap, reduces ohmic resistance, and ensures high O₂ purity by allowing only ion transfer and preventing gas exchange between the anode and cathode. Through these optimizations and designs, Zhang *et al.* improved the O₂ production of a single MEA cell to 180 mL min⁻¹.¹⁰ However, this O₂-production rate still fell short of the applicable standard of >1 L min⁻¹. Their subsequent strategy involved assembling nine MEA units into an integrated stack and specifically improving the structure design of the polar plates. This highly integrated, series-connected stack structure enhanced the overall device's power output while minimizing the volume and weight, crucial for achieving the miniaturization and high portability of the electrochemical O₂-generation device (Fig. 2a and d).

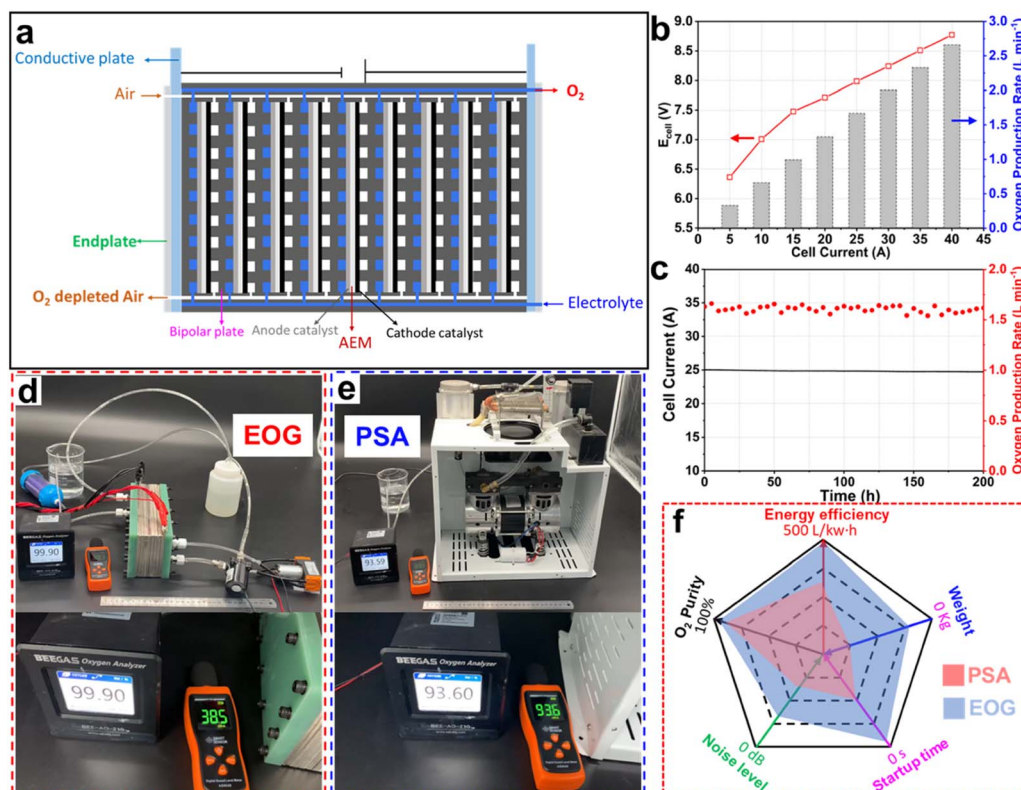

Fig. 2 (a) Structural schematic of the electrochemical O₂ generator (EOG) cell stack comprising 9-unit cells. (b) *I*-*V* curves and O₂ production rates of the EOG cell stack with a 100 cm² working area. (c) Stability test of the EOG cell stack. In electrochemical O₂ production, the aim is for a high rate anodic OER, thus ensuring the ORR process has an excessive supply of air-sourced O₂ over its consumption is crucial. An insufficient O₂ supply for the cathodic ORR may limit the OER rate in turn, thereby lowering the overall O₂ production. To address these issues, the design of the cathode flow channels should aim to maximize the air supply for the ORR side, reducing resistance to air mass transfer and accelerating the ORR reaction rates. Implementing multiple parallel straight channel-type flow fields and shortening the length of individual channels is an effective strategy to ensure sufficient gas flux for the ORR per unit time.³² Meanwhile, adjusting the land-to-channel ratio in the flow field is also crucial, as proper control of this ratio affects not only the flow rate and pressure drop of the gas reactants but also has great impacts on the water-removal efficiency, mechanical stability, temperature distribution, and overall conductivity of the cell stack.³³ During the electrochemical reaction process, the effective contact area between gas reactants and the electrode, *i.e.*, the land area, directly determines the distribution of the gas concentration within the electrode. This is vital for optimizing the entire electrochemical reaction process. For instance, Rajesh Boddu utilized computational fluid dynamics models to analyze the flow characteristics on bipolar plates with different serpentine flow field configurations.³⁴ Their findings revealed that increasing the number of parallel flow channels and reducing their size could achieve a more efficient and uniform contact surface area and lower pressure drops, thereby enhancing the fuel-cell cathode ORR rate. Furthermore, research by Kahraman *et al.* suggested that wide flow channels could facilitate reactant transport and water removal, while wide land areas could improve the conductivity, thermal conductivity, and mechanical stability. Based on the data and experimental results in the research work, the flow channel width should be maintained below 1.5 mm to ensure mechanical stability, while the land-to-channel ratio should be as low as possible to minimize voltage loss.³³ In summary, the importance of the flow channel design and land-to-channel ratio has been widely recognized in the fuel cells field.^{33–38} However, the design of novel, application-specific electrochemical reactors still requires tailored approaches. Variations in the viscosity and wettability of diverse reaction media necessitate unique land-to-channel ratios for each. Therefore, relying solely on existing design principles is insufficient for the design and optimization of future electrochemical reactors. This calls for researchers to not only deepen their understanding of existing principles but also to explore new design solutions.

On the anodic side, the rapid production of O₂ on the anode under high current densities often triggers drastic bubble release, leading to issues such as bubble shielding effects and catalyst detachment.³⁹ Numerous studies have demonstrated that self-supporting electrodes engineered through interfacial engineering techniques can effectively address these challenges.^{39–45} For instance, Hao *et al.* successfully deposited copper phosphide (Cu₃P) microsheets on nickel foam, significantly enhancing the catalytic activity for the hydrogen evolution reaction (HER) and the oxygen evolution reaction.⁴⁴ The

binder-free, hierarchical Cu₃P structure, with its super-hydrophilic and superaerophobic traits, enhanced electrolyte-electrode interactions and bubble release, reducing bubble-induced dead zones and boosting the catalytic performance. Yan *et al.* developed a universally applicable and efficient cathodic electrodeposition strategy to successfully prepare different metal hydroxides on conductive substrates, creating electrodes that not only boasted high-quality loading but also exhibited outstanding hydrophilicity and oxygen-repelling properties.³⁹ Zhang *et al.* elaborately constructed MOF-derived 2D nanosheet arrays loaded on a 3D porous Ni substrate.⁴⁵ This design could significantly improve the surface roughness and hydrophilicity, enhancing water contact and active material interaction over flat surfaces. This structure accelerated gas bubble release from the electrode surface, preventing the obstruction of active sites and ensuring uninterrupted electrochemical processes. The above research examples demonstrate that OER catalysts developed through interfacial engineering techniques commonly possess rough surfaces and can eliminate the requirement for hydrophobic binders. These characteristics endow the anode with an excellent degassing property, hastening O₂ bubble detachment, thus allowing achieving high activity and stability under high current density conditions.

Through these designs and improvements, the performance of the EOG finally met the preset objectives, achieving over 99.9% O₂ purity, with the highest O₂ production rate of over 2.5 L min⁻¹ (Fig. 2f), and 496 L kW⁻¹ h⁻¹ energy efficiency.¹⁰ In their study, Zhang *et al.* then examined the practical stability of the stack, confirming its continuous 200 h operation at 1.5 L per min O₂ production without degradation (Fig. 2c), demonstrating excellent prospects for practical application. Finally, to enhance the adaptability of the EOG to application environments, additional optimizations are necessary. For instance, give this EOG's reliance on alkaline electrolytes, the integration of an alkali vapor absorber at the anode outlet would be imperative for ensuring user safety. Moreover, to comply with hospital safety standards for electrical use, specific optimizations in the electrode area and cell unit number of the series-connected stack are required. These adjustments would allow for maintaining the overall current of the EOG device below the environmental maximum limitation without compromising its O₂-production ability.

The aforementioned study realized the development of an alkaline electrolyte-based EOG device with a 2ET reaction pathway. The designs of EOGs tend to focus on attaining a high O₂ purity, substantial O₂ production, and high energy efficiency. These features are specifically tailored to meet the demands of professional operation settings, such as hospitals and medical institutions, where reaching high working performance is required. However, for patients with chronic cardiopulmonary diseases who rely on medical O₂ in their daily lives, the design criteria for electrochemical O₂ generators in household applications differ significantly. In addition to ensuring basic application standards, like a high O₂ purity and production rate, safety also becomes a paramount consideration. The use of an alkaline electrolyte in the EOG system poses a risk of alkali leakage, which is unsuitable for non-professional, domestic

environments. This calls for specific designs tailored to the requirements of home settings. Our current goal is to engineer a system that functions without any electrolytes, operating only by pure water. This necessitates reconceiving the reaction mechanism, catalyst, and electrode structure. The elimination of electrolytes necessitates the exploration of alternative ion-conduction materials. A prime candidate is the use of proton-exchange membrane (PEM) to facilitate the ion conductivity between the anode and cathode by its inner high proton concentration. This requires a modification in the MEA fabrication method, favoring a catalyst-coated membrane (CCM) approach.⁴⁶ Here, the catalyst is directly adhered onto the PEM, ensuring robust bonding between the catalyst and the membrane. This greatly enhances the ion-transport efficiency, thereby enabling the electrochemical system to operate with pure water. However, the use of the PEM introduces a new challenge, where a harsh localized environment with a high proton concentration and strong acidity is formed on the catalyst interface. This leads to the need for a reconsideration of the catalyst selection, necessitating the development of stable, acid-resistant OER and ORR catalysts that can withstand acidic electro-corrosion. The above-discussed PEM-CCM technology has been extensively utilized in the fields of water electrolysis and fuel cells.^{47–56} In particular, such water electrolysis technology has been deeply developed for O₂ generation on space stations. Although traditional water electrolysis technology has been challenging for home O₂ generators due to the production of large amounts of explosive hydrogen at the cathode, adopting the ORR-OER coupled electrocatalytic system may effectively circumvent this issue. Given the similarities in the electrochemical environment of electrochemical systems based on PEM-CCM, one can draw on the advanced catalyst designs from the water electrolysis and fuel cell fields to optimize the ORR-OER system. Wu *et al.* introduced a nickel-stabilized ruthenium dioxide (Ni-RuO₂) catalyst as an efficient iridium alternative, enhancing acidic OER activity and durability significantly. The Ni addition notably improved RuO₂'s stability, achieving over 1000 h of operation at 200 mA cm⁻², indicating its practical application viability.⁵¹ For a PEM-based ORR catalyst design, Guo *et al.* utilized a gas-promoted dealloying technique to develop a Pt-skin Pt_{1.5}Ni_{1-x} alloy electrocatalyst with increased Ni site density. This hybrid catalyzed the ORR through a relay process, reducing Pt usage and boosting the ORR activity to 4.10 A mg_{Pt}⁻¹, about 15 times higher than commercial Pt/C.⁵⁶ Drawing on the latest advances in water electrolysis and fuel cell technologies is expected to enable overcoming the challenges associated with employing PEM-CCM structures in ORR-OER systems, thereby paving the way for safer, more efficient, and sustainable O₂-production solutions. However, the electrochemical ORR and OER mechanisms by adopting a PEM-CCM approach typically follow 4ET pathways. This can result in reduced energy efficiency compared to the alkaline EOG system that adopts the 2ET reaction pathway. However, the prioritization of safety in the design of home appliances necessitates certain trade-offs, including some degree of compromise in energy efficiency.

The above-outlined research strategy underscores the complexity and comprehensiveness inherent in designing electrochemical reaction systems and device structures tailored to specific application environments. This endeavor necessitates a holistic approach, where the design of individual components is not viewed in isolation but as part of an interconnected whole. Establishing definitive and clear requirements is crucial for guiding the design and optimization of each component within the system. In addressing the potential conflicts that arise between varying target needs and component designs, it becomes essential to prioritize key criteria while making strategic adjustments in other areas. Such a balanced and coordinated approach is fundamental to ensuring the adaptability of electrochemical system across diverse application scenarios and their successful implementation. This research methodology not only deepens the understanding of the interplay among various components within an electrochemical device and their collective impact on system performance but also highlights how these interactions shape the overall functionality of the system. Adopting this integrated design strategy, with a focus on practical applications, is pivotal for harnessing the full potential of electrochemical technology and aligning it seamlessly with the requirements of its intended application environments.

Food preservation field: electrochemical *in situ* deoxygenation

Numerous studies have confirmed that creating a low-O₂ environment can effectively extend the shelf life and improve the storage quality of fresh foods, including fruits, vegetables, and grains.^{57–59} Under low-O₂ conditions, the growth of bacteria and moulds is suppressed, significantly reducing microbial-induced spoilage.^{60,61} More importantly, such an environment restrains the aerobic respiration of produce, crucial for maintaining food freshness. The consumption of sugars and other key nutrients during aerobic respiration affects the taste and nutritional value of these plant foods;⁶² and a low-O₂ environment, by slowing down the respiration rate, helps reduce the loss of these nutrients, thereby extending the preservation time.⁶³ Moreover, a low-O₂ environment also reduces the production and accumulation of ethylene, a plant hormone that promotes fruit ripening and ageing, thus effectively helping delay the ageing process of produce.⁶⁴

Traditional methods of O₂ removal, such as using nitrogen (N₂) gas cylinders or *in situ* PSA N₂ generators, involve injecting high-purity N₂ into the preservation space to displace O₂.⁶⁵ However, these externally reliant N₂ source methods face multiple challenges, including high N₂ supply costs, large equipment size, and crucially, an inherently low O₂ removal efficiency. Also, the N₂-replacement O₂-removal strategy becomes less efficient as O₂ levels decrease, often resulting in huge N₂ wastage and an incomplete deoxygenation due to issues like dead corners and an uneven airflow. Typically, achieving complete O₂ displacement requires using N₂ gas several times the volume of the deoxygenation space, leading to high energy and time consumption. This not only escalates costs but also limits their practicality in broad-space or energy-

sensitive environments, highlighting the urgent need for a more cost-effective and efficient O₂-removal solution.

In the context of food preservation, the electrochemical ORR process may provide an effective means for efficiently diminishing environmental O₂ levels. In the above-discussed ORR–OER coupled electrochemical system, the focus was on utilizing electrical energy to drive the concentration process of O₂ from air by the electrochemical reactor, aimed at producing high-purity O₂ at the anode for medical applications. In contrast, for food preservation, the emphasis shifts to the ORR process at the cathode. This strategic focus is on enabling the rapid, energy-efficient, and effective *in situ* reduction of the O₂ concentration, thereby fostering a low-O₂ environment conducive to the extended preservation of fresh fruits, vegetables, and grains. As illustrated in Fig. 3a, for the design of an electrochemical O₂-removal (EOR) system, an air-tight space is directly linked to the cathode of the EOR device, to efficiently remove the O₂ in air by an ORR process under gaseous circulation. While the anode is exposed to the external environment, and discharges the OER-generated O₂ towards the external atmosphere. Considering the EOR device and the sealed space as an integrated system, the coupled ORR–OER electrochemical system facilitates a direct, *in situ*, and unidirectional transfer of O₂ from the preservation area to the external environment. This process, which reduces entropy, is powered by electrical energy,

standing in contrast to the traditional N₂-displacement strategy for O₂ removal. EOR offers a fundamentally superior approach by directly consuming O₂ on-site with the electrochemical device, thereby eliminating the need for external gas sources and reducing costs. Moreover, the advanced mechanism of EOR is characterized by its energy consumption being determined by the amount of O₂ removed, irrespective of the O₂ concentration. This characteristic makes the EOR more energy-efficient and potentially more cost-effective compared to traditional N₂-displacement methods, especially in scenarios where low O₂ levels need to be maintained consistently. To validate the above conclusions, a preliminary comparison was conducted on the energy consumption of different O₂-removal strategies. Actual experiments were performed with a 5 L sealed chamber using a PSA N₂ generator for O₂ removal, yielding specific data on the energy consumption. For electrochemical O₂ removal, a simulated electrochemical cyclic system was designed to estimate the energy consumption. As depicted in the structural configuration shown in Fig. 3b, O₂ removal was achieved by continuously circulating the air within the chamber into the electrochemical reactor. The specific calculation parameters and equations are shown in the ESI.† The energy consumption for the two O₂-removal strategies at various target O₂ concentrations are summarized in Fig. 3c. Energy consumption from N₂ displacement was observed to escalate quickly with

Fig. 3 (a) Illustrations of the working mechanism of the EOR when applied in food storage. (b) Simulation diagram showing the structural configuration of the designed EOR system. (c) Energy consumption of different O₂ removal devices: the results for PSA were obtained through practical measurements, while the results for EOR were calculated under simulation conditions.

decreasing the target O₂ concentrations, experiencing an exponential increase when the target O₂ level fell below 5%. This was attributed to the minimal gas concentration gradient at low O₂ levels, therefore significantly reducing the displacement efficiency. In contrast, the energy consumption for O₂ removal driven by the electrochemical ORR was markedly lower than that by N₂ displacement, exhibiting a linear increasing trend. This was due to the fact that the energy consumption for the ORR process depends on the amount of O₂ reacted, regardless of its concentration. In addition, employing a cyclic O₂-removal approach enables the repeated use of N₂, thereby further lowering the overall energy consumption. The above analysis preliminarily confirmed the energy efficiency advantages and technological advancements of electrochemical O₂ removal, providing a theoretical foundation for further studies in this area.

Upon identifying the application scenario for fresh food preservation, the establishment of specific application requirements is crucial for guiding the design of EOR devices. Despite sharing the same ORR–OER coupling mechanism with the EOG system previously discussed, the distinct application scenarios necessitate unique design considerations for the electrochemical O₂-removal apparatus. The primary application requirements include: (1) low energy consumption; (2) no pollution; and (3) a high O₂-removal rate. These criteria not only guide the design parameters but also shape the operational strategies of EOR devices, ensuring the efficacy and safety in fresh food preservation.

Following the above-established application requirements, comprehensive designs are required for EOR devices. Considering these in order: (1) low energy consumption: the catalytic mechanism employs a 2ET pathway for the coupled ORR–OER electrochemical system with HO₂[−] as an intermediate, consuming half the energy of the 4ET pathway, thereby significantly boosting the energy efficiency; (2) no pollution: given the direct connection between the cathode of the EOR and the sealed space with direct gas exchange taking place, it is necessary to ensure that the operation of the EOR does not result in any contamination of the fruits and vegetables, such as by electrolyte leakage, air outflow, or the dissolution of metal atoms from the catalyst. The choice and design of the catalyst play a crucial role in this process. An ideal catalyst should be non-toxic, exhibit high 2ET-ORR activity and selectivity, and possess excellent stability to avoid electro-corrosion. Single-atom catalysts represent a suitable choice, typically utilizing non-toxic carbon materials as substrates, offering excellent activity and selectivity, and high stability to effectively prevent metal atom dissolution under working potentials, thus avoiding contamination.^{65–68} Additionally, electrolytes should be eliminated to prevent potential leakage risk. The above-discussed CCM–MEA structure is well suited for this EOR device, as it can efficiently operate with only pure water; (3) a high O₂ removal rate: to enhance the efficiency of O₂ removal, optimization of the ORR process at the cathode is necessary to increase the current density and reaction rate. The optimizations can be divided into two aspects. First, since the ORR is a three-phase-boundary reaction involving gaseous O₂, liquid water, and

a solid catalyst, it is essential to ensure that the catalyst is in full contact with both the gaseous and liquid reactants, alongside sustaining efficient mass transfer of these reactants. In the MEA structure, introducing GDEs to the MEA may accelerate the rate of O₂ mass transfer.³ Current applicable GDEs typically comprise a current collector layer, a diffusion layer, and a catalyst layer, where the current collector layer possesses high electrical conductivity, sufficient mechanical strength, and a larger pore size and porosity; the diffusion layer is a conductive microporous layer with high hydrophobicity and air permeability; and the catalyst layer employs appropriate binders to achieve uniform catalyst loading. To further improve catalyst utilization, enhancing the wettability of the catalyst layer is suggested, such as by fabricating GDEs with hydrophobic polymer concentration gradient diffusion layers to adjust the balance between the hydrophobicity and hydrophilicity.⁶⁹ Through these methods, while accommodating the O₂ mass transfer and wetting needs of the ORR catalyst, the issue of increased internal resistance due to water evaporation on the ion-exchange membrane can be significantly mitigated. Second, to improve the O₂-removal efficiency, a shift of study emphasis is required, targeting ways to facilitate a complete depletion of O₂ in air by the cathodic ORR process. Besides increasing the gas pressure to enhance the contact of O₂ with the inner layer catalyst, redesign of the cathode flow channels to induce forced convection and turbulence is also required.⁷⁰ This can be achieved by integrating obstruction structures and using multiple serpentine channels with increased bends, thus ensuring better O₂ consumption. Such design alterations can not only enhance the O₂-reduction rates but also reduce the operational demands on air pumps and the O₂-removal time. In stark contrast to the above-discussed EOG that focused on O₂ generation, EOR systems prioritize maximizing the O₂ consumption, leading to fundamentally different design strategies for GDEs and for the flow channel of the polar plate to achieve better fruit and vegetable preservation in applications.

After finalizing the structural design of an EOR device, its practical application in fruit, vegetable, or grain storage is essential to validate the effectiveness of the EOR in real conditions. This step is crucial to evaluate the actual EOR performance and gather data for further improvements. Key considerations of the EOR device deployments include managing internal pressure changes of the storage space caused by O₂ depletion, and adjusting for variations in O₂-removal rates due to fluctuating O₂ levels. Necessary adaptations thus include the introduction of pressure balance valves to maintain pressure balance in the conservation space, as well as increasing the gas flow rate to compensate for lower O₂ concentrations. These modifications are crucial for optimizing the ultimate performance of EOR in real-world preservation scenarios.

The advantages of EOR devices in fresh food preservation merit extensive exploration, which may offer distinct advantages across the following three primary dimensions. (1) Energy-saving advantage: due to the intrinsic advancement of the electrochemical O₂-removal mechanism, EOR devices are inherently more energy efficient compared to traditional N₂-

replacement equipment; (2) humidity maintenance advantage: the traditional O₂-removal strategy often leads to significant humidity loss in the storage space due to the continuous injection of dry N₂ airflows, which can adversely affect the freshness of the fruits and vegetables. In contrast, an EOR device can effectively remove O₂ while maintaining humidity. It achieves this by removing electrolytes, enabling the device system with pure water loading to naturally humidify the space during gas circulation, thereby helping to preserve the freshness and taste flavour of the stored items; (3) further energy-saving advantages by combining with low-temperature storage: integrating EOR in low-temperature storage environments for fruits and vegetables could lessen the reliance on refrigeration. By creating a low-O₂ environment, it would be feasible to maintain produce freshness at relatively higher ambient temperatures, potentially leading to a significant reduction in energy use for cooling purposes. Moreover, the utility of the EOR system could be broadened to encompass the removal of dissolved O₂ from water, underscoring its potential to boost industrial efficiency. In critical industrial operations, like boiler water treatment and metal processing, eliminating dissolved O₂ is essential for preventing metal corrosion and extending the life of equipment. The adoption of EOR systems in these expanded fields highlights the wide-ranging application prospects of EOR systems in diverse settings.

The development of an EOR system is a comprehensive research process that requires careful consideration of various aspects, including the electrochemical mechanism, catalyst materials, and reactor structure design, for optimal efficiency and safety. Assessing the system's functionality in real-world conditions is vital to ensure it meets specific environmental needs. By efficiently bridging theory and practice, this strategy opens new avenues for applying EOR in food preservation.

Microbial culture and fermentation field: electrochemical O₂ concentration control

In modern biotechnology, the application of microorganisms has become a core technology, widely used in diverse fields including food production, pharmaceuticals, and energy generation.^{71–73} The growth and metabolic activities of microorganisms are critically influenced by the O₂ level of the environment. Microorganisms are categorized as aerobic, facultative anaerobic, or strictly anaerobic, depending on their different O₂ needs.⁷⁴ Precise O₂ control in microbial fermentation and culture is crucial for optimizing growth, enhancing the bioproduct yields, and directing metabolic pathways towards specific products.⁷⁵ Building on the deeply discussed ORR–OER coupled electrochemical mechanism above, this section delves into approaches to adapt this mechanism for precise O₂ regulation in the applications of microorganism cultivation and fermentation.

Traditional methods for environmental O₂ regulation typically use N₂ and O₂ supply systems, controlling O₂ levels through gas flow and gas route adjustments, as illustrated in Fig. 4a. However, these methods require separate O₂ and N₂ gas sources and suffer from low efficiency and poor mobility, as well

as being costly and space-consuming. The traditional principle for controlling the O₂ concentration lies in injecting pure O₂ or N₂ into a sealed space to either increase or decrease the O₂ level. Electrochemical technology may simplify the above processes by just switching electrode reactions between the OER and ORR, corresponding to the O₂-generation process to increase its level, and the O₂-consumption process to decrease its level, respectively (Fig. 4b). The direct use of conventional ORR–OER systems is, however, limited by the inconvenience of frequent switching between the cathode and anode gas routes and the system connect configuration, reducing the system efficiency and practicality. Developing an effective electrochemical O₂ control (EOC) device requires a design focused on precision, user-friendliness, portability, and adaptability to varied environments. This device should offer efficient O₂-concentration control, easy operation, and flexible application across different scenarios. The following section details these design requirements and their implementation.

For operational portability, the electrochemical system needs redesigning for continuous connection of one electrode to the O₂-controlled environment. This would allow seamless switching processes between O₂ removal and O₂ generation by altering the electrode reactions of the ORR and OER through only altering the voltage directions, without changing any gas routing or device deployment. However, this poses structural challenges for MEA due to the different reaction environments of the two electrodes. Addressing these challenges necessitates a specific design of the reaction mechanism of the EOC to accommodate the MEA structure. A novel approach involves connecting the GDE side of the EOC to a sealed space. In this configuration, the O₂-consumption process can be efficiently executed to continuously reduce the O₂ concentration within this sealed space. This set-up facilitates the following cathode and anode reactions to promote the O₂-removal function:

Cathodic ORR (GDE):

Anodic OER (in liquid solution):

To increase the O₂ level of the sealed space, altering the voltage direction may exchange the roles of the cathode and anode. In this way, the electrode connected to the environment, initially a cathode, becomes an anode to enable the OER, thereby raising O₂ levels. The opposite electrode, immersed in a liquid solution, now turns into a cathode. Although this cathode is unsuitable for the ORR due to the lack of a gas-transfer pathway, it may initiate the hydrogen evolution reaction (HER) to couple with the OER. In industrial settings for microbial cultivation and fermentation, exhaust gas-treatment systems allow the hydrogen produced by the HER to be properly managed, making the HER a viable choice in this

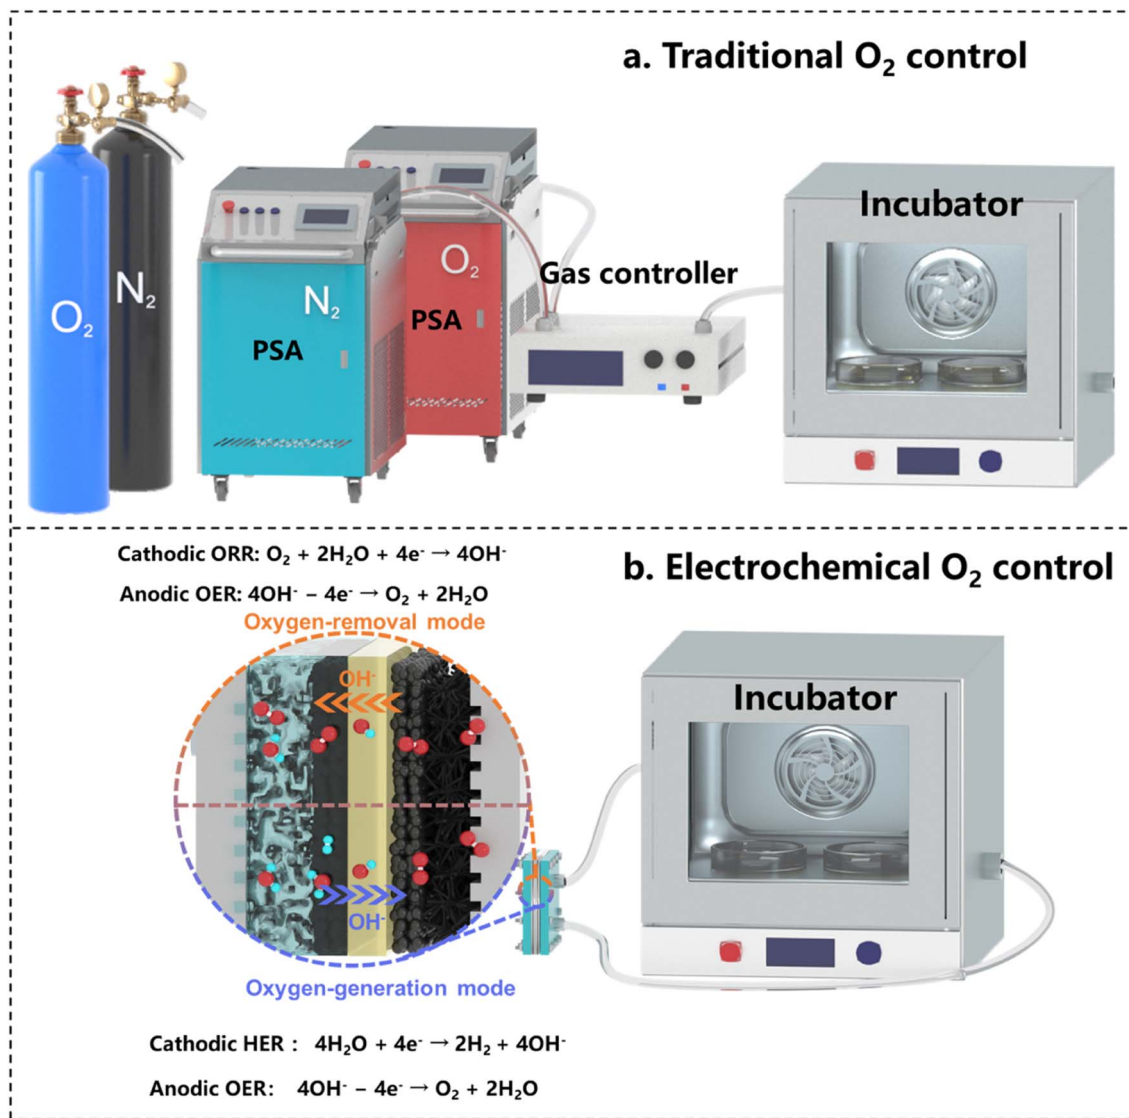

Fig. 4 Working mechanisms of different O₂-control methods: (a) traditional O₂-control method, and (b) electrochemical O₂-control method.

application. The specific cathode and anode reactions for facilitating the O₂-generation function are:

Cathodic HER (in liquid solution):

Anodic OER (GDE):

The design of the reaction mechanism outlined above enables the instantaneous switching functions of O₂ generation and O₂ removal, significantly optimizing the operational process with just a simple switch in the voltage direction (Fig. 4b). This electrochemical device achieves O₂-concentration control through the integration of electrochemical O₂ generation and removal functions. Therefore, based on the previous

discussions about the energy consumption of electrochemical O₂ generation and removal processes, it can be inferred that electrochemical O₂ control also has a significant advantage over traditional strategies.

To ensure efficient O₂ control performance, careful design of the catalyst is critical. Considering the O₂-control mechanism involves the coupling of the ORR, OER, and HER, we need to develop a multifunctional catalyst. This catalyst should be effective in catalyzing these three reactions at different potentials and be suitable for the bipolar use of the electrochemical reactor. Suitable candidates can be selected from dual single-atom catalysts that are reported to have excellent stability, activity, and low toxicity.^{76,77} The new catalytic mechanism fits perfectly with the gaseous and liquid environments of the two sides in the MEA structure. Finally, by assembling multiple MEA units into a stack, the oxygen-control efficiency can be significantly enhanced.

In specific application scenarios, such as microbial culture and fermentation, detailed modifications to the design of

electrochemical O₂-regulation devices are indispensable. This entails the integration of pressure balance valves to mitigate pressure fluctuations in the culture chamber attributable to O₂-concentration changes. To maintain a sterile environment, it is essential that all gas inlets and outlets be outfitted with bacterial filters, thereby preventing external microbial contamination. Considering the substantial CO₂ production from bacterial metabolism, the gas discharged from the chamber should be directed through a CO₂-absorption system prior to entering the EOC device, thus protecting the electrochemical device and prolonging its operational life. Moreover, if the EOC device employs an alkaline electrolyte, an alkali absorption unit must be installed to prevent any interference for the microbial culture environment. These customized designs for specific application scenario requirements are crucial for enhancing the compatibility of the EOC with the application environment and improving the overall functionality of the system.

Conclusions

Through an in-depth exploration of applications of the ORR–OER coupled electrochemical system in various research domains, it was demonstrated how the applications of the electrochemistry can be significantly broadened by shifting the research focus from being confined within the reactor to integrating with the surrounding environment. This perspective elaborately details how electrochemical reactors can be functionalized and customized for various application scenarios, encompassing overall design and detail adjustments. While these applications are all based on the same ORR–OER coupled electrochemical mechanism, they diverge into uniquely tailored designs responsive to different application needs. This research approach, centred around application objectives, places greater emphasis on feasibility and adaptability in real-world application scenarios. This shift in research perspective is not merely a technical evolution but also a progression in thinking methodology. It reflects a more comprehensive and systematic approach to problem-solving, particularly underscoring the importance of practical application and interdisciplinary integration. This trend will profoundly influence the field of electrochemistry, driving innovation in technology and diversifying applications. Furthermore, this comprehensive and systematic approach to research may bring new insights to other scientific fields, encouraging researchers to adopt a more integrated perspective, consider the interplay and impact across different disciplines, and thereby foster interdisciplinary collaboration, accelerating development and innovation in science and technology.
