Efficient electrocatalytic reduction of carbon dioxide by metal-doped β_{12} -borophene monolayers†

Jin-Hang Liu,^a Li-Ming Yang^{ID}*^a and Eric Ganz^{ID}^b

Electrochemical reduction of CO₂ to value-added chemicals and fuels shows great promise in contributing to reducing the energy crisis and environment problems. This progress has been slowed by a lack of stable, efficient and selective catalysts. In this paper, density functional theory (DFT) was used to study the catalytic performance of the first transition metal series anchored TM- β_{12} monolayers as catalysts for electrochemical reduction of CO₂. The results show that the TM- β_{12} monolayer structure has excellent catalytic stability and electrocatalytic selectivity. The primary reduction product of Sc- β_{12} is CO and the overpotential is 0.45 V. The primary reduction product of the remaining metals (Ti-Zn) is CH₄, where Fe- β_{12} has the minimum overpotential of 0.45 V. Therefore, these new catalytic materials are exciting. Furthermore, the underlying reaction mechanisms of CO₂ reduction *via* the TM- β_{12} monolayers have been revealed. This work will shed insights on both experimental and theoretical studies of electroreduction of CO₂.

1. Introduction

With the development of society and the economy, the energy crisis and the greenhouse effect have received more and more attention because of the serious impact on the environment.¹ The conversion of CO₂ into fuels and various chemicals would not only effectively alleviate the dependence on fossil fuels, but also potentially reduce the harm caused by the greenhouse effect.^{2–6} Carbon dioxide as a non-polar molecule is often considered an inert material with a unique linear structure. This determines the chemical reaction of CO₂ under special conditions (such as high temperature, high pressure with a catalyst). Based on factors such as energy requirements, process speed, and cost, electrochemistry is a promising method for these reactions due to its advantages such as mild reaction conditions.^{7–12}

Due to their high specific surface area, reduced dimensionality and exotic properties, two-dimensional (2D) nanosheets have become an ideal platform for the design of novel electrocatalysts for CO₂ reduction.^{13–16} Borophene is a novel 2D

material under active investigation with fascinating and diverse properties and potential.¹⁷ Recently, honeycomb borophene has been experimentally fabricated on an Al(111) substrate.¹⁸ This experimental work then triggered the theoretical discovery of a new 2D anti-van't Hoff/Le Bel ptAl array AlB₆ which is predicted to have rare triple Dirac cone electronic structure as well as superconductivity.¹⁹ This is an example of how the properties of borophene can be enhanced and extended by alloying with other elements. This may provide new opportunities to design functional materials or catalysts.

To the best of our knowledge, the application of TM- β_{12} monolayers as new single-atom catalysts for electrocatalytic CO₂ reduction reaction (CRR) has not been achieved. Therefore, we performed a systematic study on the catalytic performance of TM- β_{12} (TM = Sc-Zn) monolayers for CRR using density functional theory (DFT). The results show that for the 10 materials studied, all have good stability and CRR selectivity. For Sc, the primary reduction product is CO. For the other materials, the primary product is CH₄, with the overpotential as low as 0.45 V. We predict that these monolayers will be promising CRR catalysts.

2. Computational methods

Structural optimization, total energy and electronic properties (density of states, charge analysis) were calculated using spin polarized density functional theory. All of the calculations were carried out using the DMol³ module of Materials Studio 2016.²⁰ Exchange correlation used the generalized gradient

approximation (GGA).²¹ Exchange correlation functions used Perdew, Burke and Ernzerhof (PBE), and basis sets used double numerical polarization (DNP) basis sets and all-electronic methods to process the electrons in the system.²² In order to better describe the adsorption of molecules on the catalyst surface, the van der Waals Correction (DFT-D2) was added to the calculation.²³ Since electrochemical catalysis is carried out in aqueous solution, the conductor-like screening model (COSMO) was used as the solvation model for better agreement with the experiment, and the dielectric constant of water (ϵ) is set to 78.54.²⁴ In order to eliminate the interactions between adjacent images, the vacuum layer thickness was selected to be 15 Å. In order to improve the accuracy of the calculations, the energy convergence criterion was 10^{-6} eV, and smearing of 0.005 Ha was added to accelerate the energy convergence. In structural optimization and electronic structure calculations, Monkhorst-Pack k -point grids of $5 \times 5 \times 1$ and $12 \times 12 \times 1$ were used respectively.

The adsorption energy is a measure of the interaction between intermediates and the TM-B $_{\beta 12}$ monolayer. Formula (1) defines the adsorption energy (for example, for CH₄):

$$E_{\text{ads}} = E_{\text{TM-B}_{\beta 12}\text{-CH}_4} - E_{\text{TM-B}_{\beta 12}} - E_{\text{CH}_4} \quad (1)$$

where $E_{\text{TM-B}_{\beta 12}\text{-CH}_4}$, $E_{\text{TM-B}_{\beta 12}}$ and E_{CH_4} represent the total energy of CH₄ adsorbed on the TM-B $_{\beta 12}$ surface, the energy of the TM-B $_{\beta 12}$ monolayer, and the energy of a single CH₄ molecule, respectively. The concept of Gibbs free energy is introduced in order to determine the optimal reaction paths of CRR. Formula (2) defines the Gibbs free energy:

$$\Delta G = \Delta E + \Delta E_{\text{ZPE}} - T\Delta S + \Delta G_{\text{pH}} + \Delta G_{\text{U}} \quad (2)$$

The electrocatalytic reduction of CO₂ involves electron transfer, so the energy of this reaction can be calculated by the

reference standard hydrogen electrode method proposed by Nørskov and co-workers.²⁵ In the formula ΔE is the reaction energy of each protonation step, ΔE_{ZPE} and ΔS are the change of zero point energy and entropy value, and T is the thermodynamic temperature of the reaction (298.15 K). ΔG_{pH} is due to the effect of different pH values of the solution on the Gibbs free energy of reaction ($\Delta G_{\text{pH}} = 2.303k_{\text{B}}T\text{pH}$). The pH value in acidic solution is assumed to be 0. ΔG_{U} is due to the influence of different electrode potentials on the free energy of reaction. ΔG_{U} can be produced by the formula

$$\Delta G_{\text{U}} = -neU \quad (3)$$

In this formula, n is the number of transfer electrons, and e is the electron charge, and U is the electrode potential. The catalytic performance of the TM-B $_{\beta 12}$ monolayers can be evaluated using the limit potential (U_{L}) and the overpotential (η). The limit potential is calculated by the formula

$$U_{\text{L}} = -\Delta G_{\text{max}}/ne \quad (4)$$

where ΔG_{max} is the change of free energy of the decisive step. The overpotential is calculated by the difference between the equilibrium potential and the limit potential. The formula is

$$\eta = U_{\text{equilibrium}} - U_{\text{L}} \quad (5)$$

The higher the overpotential, the more difficult the reaction. Therefore, a good CRR catalyst must have a small overpotential.

3. Results and discussion

3.1 Structural features of the TM-B $_{\beta 12}$ monolayer

Fig. 1 shows top and side views of the TM-B $_{\beta 12}$ monolayers in the 3×3 computational supercell. In this paper, we studied

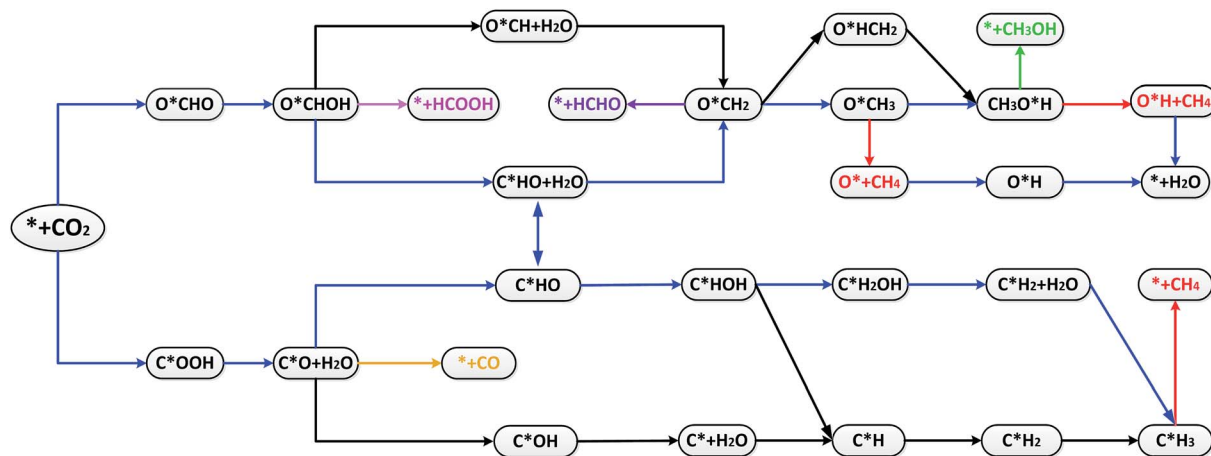

Fig. 1 Optimized geometric structure of the TM-B $_{\beta 12}$ monolayers in the 3×3 computational supercell. (a) Top view, (b) and (c) side views. The pastel pink, orange and purple balls represent B, TM (TM = Sc, Cu and Zn) and TM (TM = Ti–Ni), respectively. R_{out} is the distance between the metal atom and the plane of the B $_{\beta 12}$ sheet.

Scheme 1 Most likely reaction pathways for the electroreduction of CO_2 on $\text{TM-B}_{\beta 12}$.

If the absolute value of the binding energy ($E_b^{\text{SAC}1}$) is larger than the absolute value of the cohesive energy (E_c) of the corresponding bulk metal, this means that the metal atom is more likely to bind with the $\text{B}_{\beta 12}$ monolayer, thus indicating that the $\text{TM-B}_{\beta 12}$ monolayer has excellent stability. It can be seen from Table S1† that the absolute value of $E_b^{\text{SAC}1}$ (except Sc and Ti) are smaller than the absolute value of E_c . Considering the binding energies of the clusters of 3 and 4 metal atoms with $\text{B}_{\beta 12}$ monolayer ($E_b^{\text{CL}3}$ and $E_b^{\text{CL}4}$), the absolute values of $E_b^{\text{CL}3}$ and $E_b^{\text{CL}4}$ (except Zn) are smaller than the absolute value of $E_b^{\text{SAC}3}$ and $E_b^{\text{SAC}4}$ of the corresponding 3 and 4 dispersed metal atoms with $\text{B}_{\beta 12}$ monolayer (as shown from Fig. 2 and Table S2†), which indicates that the dispersed metal atoms have stronger binding ability to the $\text{B}_{\beta 12}$ monolayer than the metal clusters (except for Zn). Therefore, the metal atoms are more likely to bind to the $\text{B}_{\beta 12}$ monolayer. Furthermore, the binding energy for individual atoms is relatively large and ranges from 3 to 6 eV (other than Zn) so the $\text{TM-B}_{\beta 12}$ monolayers (other than Zn) have strong stability.

3.3 First hydrogenation: selectivity for CRR vs. HER

Since CO_2 reduction occurs in aqueous solution, the proton-electron pair ($\text{H}^+ + \text{e}^-$) required for CRR is mainly derived from water. The metal atom directly accepts a proton-electron pair to produce H^* ($* + \text{H}^+ + \text{e}^- \rightarrow \text{H}^*$). If the reaction continues, H_2 will be desorbed from the surface of the catalyst. This is called the hydrogen evolution reaction (HER). HER as a side reaction of CRR could potentially reduce the efficiency of the catalysts, so the selectivity of these new materials for CRR *versus* HER must be considered. The first step of the protonation of CRR is based on the path $\text{CO}_2 + \text{H}^+ + \text{e}^- \rightarrow \text{C}^*\text{OOH}$ or O^*CHO to produce two intermediates, C^*OOH or O^*CHO . The Gibbs free energy change for the first hydrogenation step can be used to determine whether the monolayer binding with C^*OOH or O^*CHO (or with H^*) is stable. The more negative the Gibbs free energy change, the more stable the binding. Because the metal

active sites of the $\text{TM-B}_{\beta 12}$ monolayer surface are limited, if the monolayer binds to C^*OOH or O^*CHO stably, the active site will be occupied, which will make H^* difficult to form. Thus, the catalyst has a good CRR selectivity. It can be seen from Fig. 3, that for the monolayers considered, all metals are below the dotted line, indicating strong CRR selectivity (see Table S2†).

3.4 Reaction pathway analysis of CRR

The optimal reaction paths and catalytic products of these materials during CRR will now be discussed. Scheme 1 shows the most favorable reaction pathways of CRR. Fig. 4 shows the important intermediates for the whole 8e^- reaction process. Each step in the protonation of CRR has two different H-adding positions (onto the C atom, or onto the O atom). Therefore CRR has many possible reaction paths. In addition, it is possible for CO_2 to produce different reduction products by accepting different numbers of proton-electron pairs. The most likely reaction paths and reaction products for CRR on these materials, will be determined by the reaction Gibbs free energy change, the overpotential, the adsorption energy, and other factors.

The intermediates C^*OOH and O^*CHO can continue to protonate and then follow the path $\text{C}^*\text{OOH} + \text{H}^+ + \text{e}^- \rightarrow \text{C}^*\text{O}$ and $\text{O}^*\text{CHO} + \text{H}^+ + \text{e}^- \rightarrow \text{O}^*\text{CHOH}$ to produce C^*O and O^*CHOH , respectively. If the adsorption energy of CO and HCOOH are small enough, they will become products and desorb from the surface ($\text{C}^*\text{O} + \text{H}_2\text{O} \rightarrow * + \text{CO}$ or $\text{O}^*\text{CHOH} \rightarrow * + \text{HCOOH}$). Conversely, if the adsorption energy of CO and HCOOH are large, it makes them difficult to desorb, but then they can continue to be reduced as reaction intermediates. Table S3† shows that the adsorption energy of Sc- $\text{B}_{\beta 12}$ for CO and HCOOH are -0.40 and -1.02 eV, respectively, which indicates that the adsorption energy of CO is smaller than that of HCOOH, and it is therefore easier to desorb from the surface to become a reduction product. Therefore, the reduction product of CRR for Sc is mainly CO (as shown in Fig. 5a). In addition, for Ti through Zn, the adsorption energy

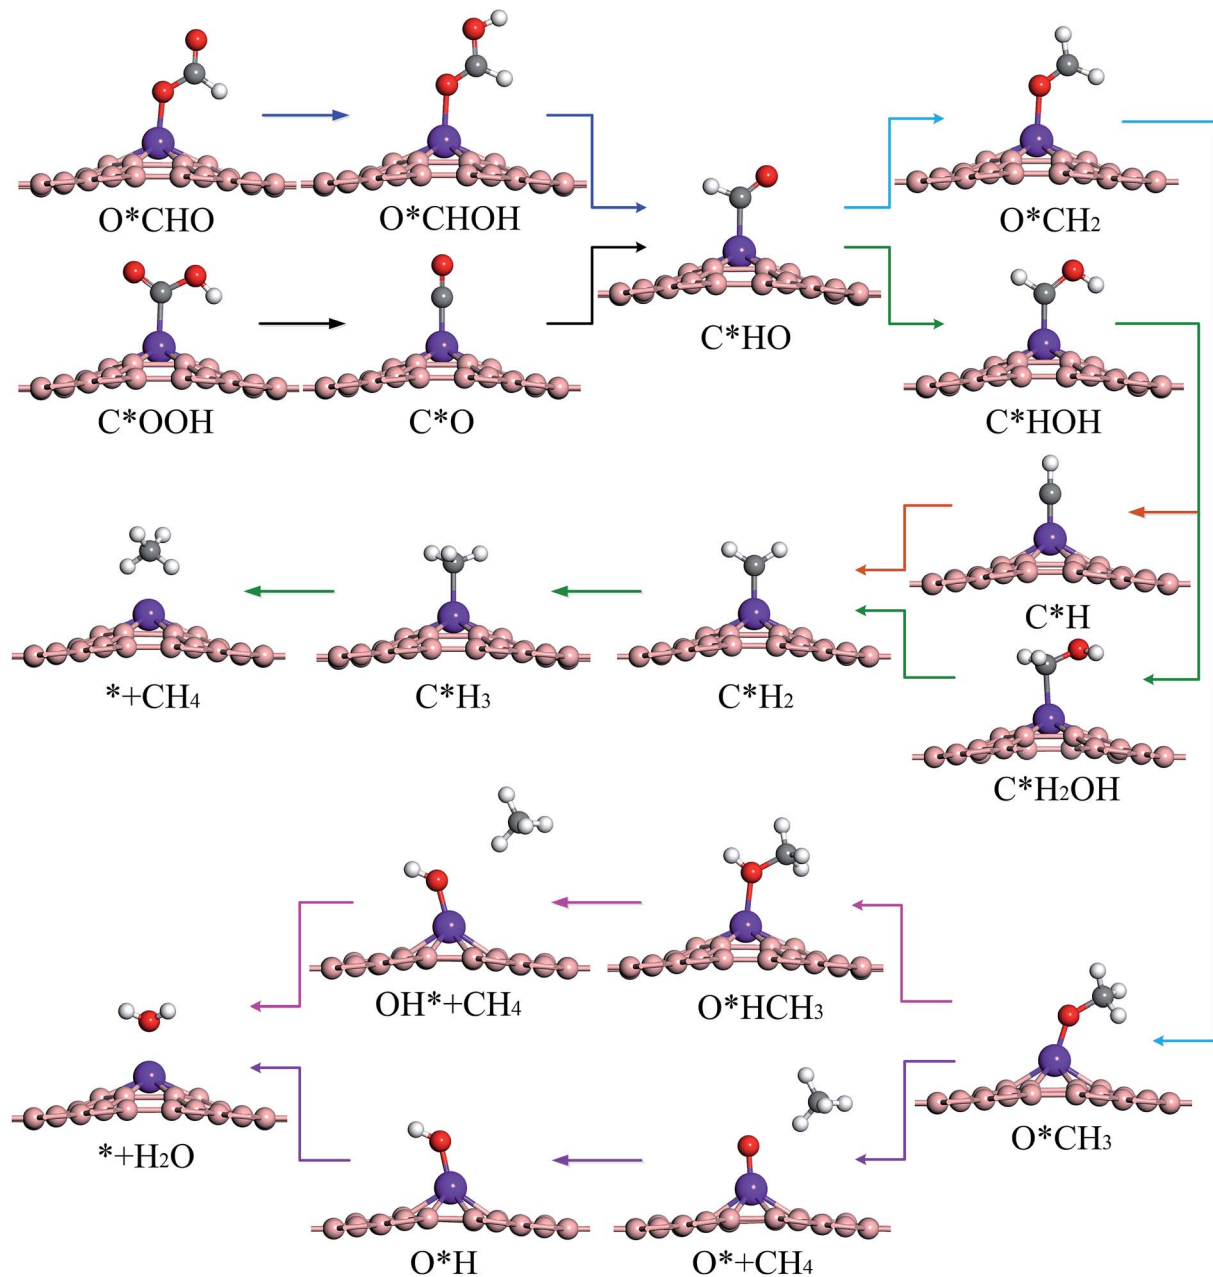

Fig. 4 Optimized geometric structures of key reaction intermediates of CRR.

of CO and HCOOH are in the range of -0.92 to -2.24 eV and -0.78 to -1.35 eV, respectively, indicating that it is difficult to get $2e^-$ products from these materials, for both CO and HCOOH. Therefore, CO and HCOOH can continue to participate in the reaction as reaction intermediates.

CO and HCOOH can continue to be protonated to produce three intermediates: C^*HO , C^*HO and O^*CH . Compared to C^*OH and O^*CH , the Gibbs free energy change for C^*HO is smaller, so it is easier to form C^*HO . It can be seen from Fig. 5b, c, d, g, i and j that Ti, V, Cr, Co, Cu and Zn are more likely to follow the path $C^*OOH \rightarrow C^*O \rightarrow C^*HO$ to produce C^*HO . On the other hand Mn, Fe, Ni are more likely to produce C^*HO

according to the path $O^*CHO \rightarrow O^*CHOH \rightarrow C^*HO + H_2O$ (as shown in Fig. 5e, f and h). Scheme 1 shows that C^*HO can continue to hydrogenate to give the products HCHO ($4e^-$), CH₃OH ($6e^-$) and CH₄ ($8e^-$). Table S3[†] shows the adsorption energies of HCHO and CH₃OH for Ti through Zn are in the range of -0.73 to -2.24 eV and -0.78 to -1.35 eV, respectively. The adsorption energy of CH₄ is in the range of -0.12 to -0.52 eV, which indicates that the products of these 9 catalysts from Ti to Zn are mostly CH₄. As can be seen from Scheme 1, creating CH₄ from the intermediate C^*HO has four main pathways:

Fig. 5 Gibbs free energy profiles for CRR along the most favorable pathways for (a) Sc-B₁₂, (b) Ti-B₁₂, (c) V-B₁₂, (d) Cr-B₁₂, (e) Mn-B₁₂, (f) Fe-B₁₂, (g) Co-B₁₂, (h) Ni-B₁₂, (i) Cu-B₁₂ and (j) Zn-B₁₂ at zero potential. A CO₂ molecule in the gas phase with a clean catalyst surface sets the free energy zero point.

Table 2 Calculated potential determining steps (PDS), limiting potentials (U_L/V), equilibrium potential of different reduction products (U_{eq}/V , vs. SHE, pH = 0) and overpotentials (η/V) for the CRR

TM- $B_{\beta 12}$	PDS	U_L	U_{eq} (product)	η
Sc- $B_{\beta 12}$	C*OOH \rightarrow C*O + H ₂ O	-0.552	-0.106 (CO)	0.446
Ti- $B_{\beta 12}$	C*HO \rightarrow C*HOH	-1.232	0.169 (CH ₄)	1.401
V- $B_{\beta 12}$	C*HOH \rightarrow C*H + H ₂ O	-0.681	0.169 (CH ₄)	0.850
Cr- $B_{\beta 12}$	C*O \rightarrow C*HO	-0.547	0.169 (CH ₄)	0.716
Mn- $B_{\beta 12}$	O*CHOH \rightarrow C*HO + H ₂ O	-0.520	0.169 (CH ₄)	0.689
Fe- $B_{\beta 12}$	O*CHOH \rightarrow C*HO + H ₂ O	-0.281	0.169 (CH ₄)	0.450
Co- $B_{\beta 12}$	O*H \rightarrow * + H ₂ O	-0.329	0.169 (CH ₄)	0.498
Ni- $B_{\beta 12}$	O*CHOH \rightarrow C*HO + H ₂ O	-0.387	0.169 (CH ₄)	0.556
Cu- $B_{\beta 12}$	C*O \rightarrow C*HO	-1.149	0.169 (CH ₄)	1.318
Zn- $B_{\beta 12}$	O*H \rightarrow * + H ₂ O	-0.513	0.169 (CH ₄)	0.682

- (1) C*HO \rightarrow C*HOH \rightarrow C*H + H₂O \rightarrow C*H₂ \rightarrow C*H₃
 \rightarrow * + CH₄
- (2) C*HO \rightarrow C*HOH \rightarrow C*H₂OH \rightarrow C*H₂ + H₂O
 \rightarrow C*H₃ \rightarrow * + CH₄
- (3) C*HO \rightarrow O*CH₂ \rightarrow O*CH₃ \rightarrow O* + CH₄ \rightarrow O*H
 \rightarrow * + H₂O
- (4) C*HO \rightarrow O*CH₂ \rightarrow O*HCH₂ \rightarrow O*HCH₃
 \rightarrow O*H + CH₄ \rightarrow * + H₂O

According to the principle that the lower the energy barrier, the more likely the reaction, V will primarily follow path (1), Ti, Cr and Mn will primarily follow path (2), Fe will primarily follow path (3), and Co, Ni, Cu and Zn will primarily follow path (4).

The overpotential determines how efficient these catalysts will be in practical application. The smaller the overpotential, the smaller the applied voltage required for CRR, and the easier the reaction. Therefore, in order to have a strong catalytic effect, these new materials must have a small overpotential. Table 2 summarizes the potential determining steps, limit potential, and overpotential of these materials. The results show that the primary catalytic product of Sc is CO and its corresponding overpotential is 0.45 V. The remaining 9 materials primarily produce CH₄, with overpotentials from 0.45 to 1.40 V. Only the overpotentials for Ti and Cu are greater than 1 V, while the other overpotentials are all less than 0.85 V. This is comparable to or even lower than the 1 V overpotential of CRR by polycrystalline copper that has been studied extensively in the past.^{27–29} The performance of the new TM- $B_{\beta 12}$ monolayers is comparable to that of Cu atomic chain decorated boron nanosheets.³⁰ In addition, the overpotential of the CRR catalyst designed in this paper is comparable to or even smaller than that of other promising experimentally known catalysts in the literature. Examples include: monodisperse Au nanoparticles ($\eta = 0.26$ V),³¹ the modified Cu electrode from the reduction of thick Cu₂O films ($\eta = 0.50$ V),³² N-doped carbon nanotubes ($\eta = 0.54$ V),³³ and nanoporous Ag ($\eta < 0.50$ V).³⁴ Therefore, we predict that the TM- $B_{\beta 12}$ monolayer will have excellent catalytic activity for CRR.

3.5 Electronic structure analysis

For these new catalysts, the interaction between the transition metal atoms and the β -type B monolayer will greatly affect the CRR catalytic performance. From the PDOS diagram of Fig. S1,[†] it can be seen that the 3d orbitals of the metal atoms in the monolayer overlap with the 2p orbitals of the B atoms, which indicates that there is a strong interaction between the metal atoms and the B monolayer. For the 9 monolayers with primary reduction product CH₄, the 3d orbitals of Cr, Mn, Fe, Co and Ni overlap better with the B-2p orbitals. This indicates that their interaction with the B monolayer is stronger than for the other metals. Moreover, it can be seen from Table 2 that the overpotentials are also smaller than for the other metals (except for Zn). Thus, we can conclude that the stronger the interaction of the metal atoms with the B monolayer, the lower the overpotential for catalytic CO₂ reduction. In addition, it can be seen from Table 2 that the overpotentials of Fe, Co and Ni are relatively close and lower than for the other metals. Table 1 shows that Fe, Co and Ni carry much less charge than the other metals. We see that the amount of electrons transferred when the metal atom interacts with the B monolayer correlates with the catalytic ability of these materials.

In addition, the strength of the interaction between the reaction intermediates and the monolayers has a great influence on whether CRR can proceed smoothly. If the monolayer binds the intermediates too strongly, the catalyst can lose its activity and the so-called poisoning phenomenon can appear. Conversely, if the binding is too weak, the intermediate will easily fall off the surface of the catalyst, which will make the reduction reaction not likely to continue. Therefore, it is necessary to have a suitable adsorption energy for the intermediates on the catalysts. In addition, the interaction between the reaction intermediates and the TM- $B_{\beta 12}$ monolayers has a great influence on the magnitude of the overpotential of CRR. If the interaction is too strong, the Gibbs free energy of the protonation reaction at the potential determining step will increase, and the energy barrier of the reaction will also increase. The higher the energy barrier of the potential determining step, the bigger the overpotential of the reaction. According to the organometallic catalyst metal coordination theory, the intermediate and TM- $B_{\beta 12}$ mainly interact through the σ -bond and the π -bond. Fig. 6 show the PDOS diagrams of the reaction intermediates in the potential determining step of different TM- $B_{\beta 12}$ monolayers catalyzed CO₂ reduction reactions. The 3d orbitals of the metal atoms in the TM- B_{β} monolayers and the carbon or oxygen in the intermediates overlap with different degrees. For Ti, V, and Cu (Fig. 6b, c and i), the metal atom states overlap with the 2p orbitals of carbon or oxygen in the intermediates more than the other metals. This indicates that Ti, V, and Cu monolayers interact more strongly with the intermediates of the potential determining step. Table 2 also shows that their corresponding overpotentials are higher than the other metals. This can explain that why Ti, V, and Cu monolayers have relatively high energy barriers for CRR.

Fig. 6 Projected partial density of states (PDOS) of (a) C*OOH adsorbed on Sc-B $_{\beta 12}$, (b) C*HO on Ti-B $_{\beta 12}$, (c) C*HOH on V-B $_{\beta 12}$, (d) C*O on Cr-B $_{\beta 12}$, (e) O*CHOH on Mn-B $_{\beta 12}$, (f) O*CHOH on Fe-B $_{\beta 12}$, (g) O*H on Co-B $_{\beta 12}$, (h) O*CHOH on Ni-B $_{\beta 12}$, (i) C*O on Cu-B $_{\beta 12}$ (j) O*H on Zn-B $_{\beta 12}$. The dotted line denotes the Fermi level. The red, blue and green lines represent the 3d orbital of the metal atom, and the 2p orbital of the oxygen and carbon atom, respectively.

4. Conclusions

In summary, this paper used density functional theory to study the catalytic properties of TM-B_{β12} monolayers. The results show that the metal atoms can be stably combined with the β-type boron monolayer. The catalysts show excellent CRR selectivity. The primary reduction product for Sc is CO, with 0.45 V overpotential. The primary product for the other metals (Ti–Zn) is CH₄ and the overpotentials are all lower than 0.90 V (except for Ti and Cu which are greater than 1.30 V). Remarkably, the overpotential for Fe is only 0.45 V. Therefore, these new TM-B_{β12} materials are predicted to be remarkable CRR catalysts. Our results also provide theoretical support for future experimental study of these materials.
