Structural studies on proteins directly in their native environment are required for a comprehensive understanding of their function. Electron paramagnetic resonance (EPR) spectroscopy and in particular double electron–electron resonance (DEER) distance determination are suited to investigate spin-labeled proteins directly in the cell. The combination of intracellular bioorthogonal labeling with in-cell DEER measurements does not require additional purification or delivery steps of spin-labeled protein to the cells. In this study, we express eGFP in *E. coli* and use copper-catalyzed azide–alkyne cycloaddition (CuAAC) for the site-directed spin labeling of the protein *in vivo*, followed by in-cell EPR distance determination. Inter-spin distance measurements of spin-labeled eGFP agree with *in vitro* measurements and calculations based on the rotamer library of the spin label.

The understanding of protein function and structure is crucially linked to the ability to study proteins in their native environment. Effects of not only molecular crowding but also post-translational modifications and the presence of a variety of specific or non-specific interaction partners or chaperones have a great impact on proteins, yet are only incompletely understood through *in vitro* studies.¹

Facing the challenge of highly complex cellular compositions, in-cell electron paramagnetic resonance (EPR) spectroscopy in combination with site-directed spin labeling (SDSL)² has emerged as a valuable tool to provide structural information³ as many cellular components are diamagnetic and therefore EPR-silent. Pulsed techniques such as double electron–electron resonance (DEER) provide access to long-range distance restraints in the nanometer range by measuring the dipole–dipole interactions between paramagnetic spin labels.^{4,5}

So far, *in vivo* DEER studies on spin-labeled proteins have either been conducted on outer membrane proteins upon

cysteine-based spin labeling on the cellular surface^{6–8} or relied on the delivery of spin-labeled protein into the cell, *e.g.* by microinjection into oocytes^{9–12} or permeabilization of the membrane *via* hypo-osmotic shock or electroporation.^{13–18} Non-canonical amino acid (ncAA) incorporation and bioorthogonal *in vivo* spin labeling offer a more direct and elegant approach for in-cell EPR studies as they may combine expression, labeling and the EPR study of the protein of interest directly inside the same cell without additional delivery steps. While a number of studies on bioorthogonal spin labeling have been published in recent years,^{19–27} the corresponding DEER measurements were limited to *in vitro* measurements. Even in cases with confirmed *in vivo* labeling, purification and concentration of spin-labeled protein were required prior to a DEER measurement. The Steinhoff group has advanced nitroxide spin labeling *via* copper-catalyzed [3+2] azide–alkyne cycloaddition (CuAAC) and reported labeling of eGFP at one site between the ncAA *N*- ϵ -propargyl-L-lysine (PrK) and a nitroxide spin label in *E. coli*. However, for DEER distance determination, the protein was purified and conventional cysteine labeling with MTSSL was used to introduce the second spin label.²⁴

In our previous work,²⁷ we have identified the ncAA *para*-ethynyl-phenylalanine (*p*ENF) as a suitable choice for bioorthogonal spin labeling with CuAAC. *p*ENF was incorporated into *E. coli* thioredoxin with high labeling yields and exhibited favorable linker properties for DEER distance determination in *in vitro* measurements.

Here, we extend this approach to bioorthogonal double spin labeling and DEER measurements directly *in vivo* (Fig. 1). We report the incorporation of *p*ENF at two sites of eGFP *via* amber stop codon suppression in *E. coli*, develop conditions for CuAAC with an azide-bearing nitroxide spin label and combine it with in-cell DEER distance determination without any additional protein purification step. In-cell inter-spin distances of spin-labeled eGFP are comparable to *in vitro* measurements and calculated distances based on the rotamer library of the label.

Due to the reductive environment of the cell, in-cell EPR studies benefit from the use of reduction-resistant spin labels,

Fig. 1 Schematic overview of the *in vivo* spin labeling approach via copper-catalyzed [3+2] azide–alkyne cycloaddition followed by in-cell EPR distance determination. The nCAAs pENF are incorporated site-specifically into eGFP using amber stop codon suppression. The eGFP-expressing *E. coli* cells are subjected to CuAAC-based spin labeling and subsequent, DEER distance determination is performed directly inside the cell.

such as gadolinium spin labels²⁸ or nitroxides shielded with ethyl groups.^{29,30} Nevertheless, we decided to use an uncharged, small nitroxide spin labels with a five-membered ring structure and shielding methyl groups in our study because of its known cell permeability.²⁴ EGFP was chosen as a model protein for our study since *in vivo* CuAAC-based spin labeling of this protein has previously been shown²⁴ and the fluorescence properties of eGFP facilitate in-cell monitoring of the protein. The positions Y39TAG in the β_2 – β_3 loop region and L221TAG in the β_{11} -strand of the barrel were chosen as labeling sites.³¹ We co-transformed plasmids pBAD_GFP_Y39/L221-TAG and pEVOL_pCNF (encoding a polyspecific *Methanocaldococcus jannaschii* tRNA^{Tyr}(CUA)/tyrosyl-tRNA-synthetase (YRS) pair evolved for the genetic encoding of *para*-cyano-L-phenylalanine, pCNF)^{32,33} into BL21-Gold (DE3) *E. coli*, induced the culture and purified Y39/L221pENF eGFP by Ni-NTA chromatography via its C-terminal His6-tag. ESI-MS data confirmed the correct incorporation of pENF at two positions (Fig. S1, ESI[†]). *In vitro* labeling reactions were performed as previously described²⁷ with 1 mM CuSO₄, 3 mM 2-(4-((bis((1-(*tert*-butyl)-1*H*-1,2,3-triazol-4-yl)methyl)amino)methyl)-1*H*-1,2,3-triazol-1-yl) acetic acid (BTAA), 1 mM sodium ascorbate (NaAsc) and 1 mM 3-(azidomethyl)-2,2,5,5-tetramethyl-1-pyrrolidinyloxy (az-proxyl) and yielded Y39/L221pENF-L eGFP with an averaged labeling efficiency of approximately 70% per site based on the ratio of spin concentration to protein concentration. Incorporation of pENF and labeling did not significantly affect the function of eGFP as *in vitro* excitation and emission fluorescence spectra of Y39/L221pENF before and after labeling did not differ from eGFP wild-type spectra (Fig. S2, ESI[†]). *In vitro* DEER measurements of spin-labeled Y39/L221pENF-L eGFP resulted in a narrow distance distribution (HWHM: 0.5 nm) with a mean peak at 2.3 nm (Fig. S3, ESI[†]) and agree well with the calculated distances based on the crystal structure of eGFP (PDB structure 4EUL) and our previously published rotamer library²⁷ of the pENF-L spin label.

A major concern of *in vivo* applications of CuAAC is copper-mediated cytotoxicity. Copper ions are linked to the formation of reactive oxygen species (ROS)³⁴ and are known to impair

Fig. 2 Toxicity of CuAAC labeling reagents for *E. coli*. (A) *E. coli* growth after treatment with CuAAC reagents: 1 mM sodium ascorbate (red), labeling mix Cu(II)SO₄, BTAA, NaAsc (1/3/1 mM) (blue), 1 mM Cu(II)SO₄ (green), 10 mM Cu(II)SO₄ (orange), untreated control (gray) ($n = 2$) (B) plate sensitivity assay. Diluted *E. coli* suspensions of cells treated with Cu(II)SO₄, BTAA, NaAsc (1/3/1 mM) (blue), and untreated control sample (gray) were plated, incubated overnight and the number of colony-forming units (CFU) was counted ($n = 3$). (C) Dead cell/alive cell identification with flow cytometry. *E. coli* cells expressing Y39/L221pENF eGFP were either treated with ethanol (EtOH), subjected to CuSO₄, BTAA, NaAsc (1/3/1 mM, labeling mix) or treated with 30 mM Cu(II)SO₄. Untreated cells (control) served as alive control sample. Dead cell detection was facilitated by PI staining and the indicated numbers represent the percentage of dead cells.

cytoplasmic proteins with Fe–S clusters due to their thiophilic tendency.³⁵ However, it has been shown that this toxicity is greatly reduced by adding chelators to the copper species with BTAA being a ligand that shows especially promising properties for *in vivo* CuAAC applications.³⁶ To investigate the effects of *in vivo* CuAAC on *E. coli*, we monitored the bacterial growth immediately after CuAAC treatment as well as the long-term growth behavior with a plate sensitivity assay (Fig. 2). Cells were treated with the labeling reagents copper(II)sulfate, BTAA and sodium ascorbate (in a 1:3:1 ratio), diluted, and the optical density of the cells at 600 nm (O.D. 600) was measured over time and compared to an untreated control sample (Fig. 2A and Fig. S4, ESI[†]). The growth rate of *E. coli* cells treated with CuAAC labeling reagents under labeling conditions did not differ from the untreated controls (only under far higher copper concentrations of 10 mM a reduction of growth rate was observed). In addition, we investigated the long-term growth behavior of treated and untreated cells by plating out diluted *E. coli* suspensions onto LB agar plates and incubating overnight at 37 °C. After counting the number of colony-forming units, we concluded that CuAAC treatment did not impact the number of viable cells (Fig. 2B and Fig. S5, ESI[†]). Finally, to evaluate the integrity of the bacterial membrane after CuAAC labeling, we performed dead cell/alive cell discrimination via FACS analysis (Fig. 2C and Fig. S6, ESI[†]). Events were pre-gated based on their forward (FSC-A) and sideward scattering

(SSC-A) to exclude cell debris and buffer crystals. *E. coli* cells were then gated based on SSC-A and eGFP fluorescence, and the fraction of dead cells was detected *via* staining with propidium iodide (PI). Untreated cells and cells treated with 75% ethanol were used as controls to determine the level of PI intensity characteristic for live and dead cells, respectively. We did not observe an increase in the dead cell fraction in the CuAAC-treated compared to the untreated cells. For higher copper(II)sulfate concentrations of 30 mM, FACS data suggested the onset of copper-mediated cell death. The FACS analysis was conducted approximately 60–65 minutes after the start of the labeling reaction, the time point at which samples intended for in-cell EPR distance determination were frozen in liquid nitrogen as part of the DEER sample preparation. We therefore expect a similar level of integrity as seen in FACS measurements for the respective DEER samples.

Next, we were interested in studying possible nitroxide reduction inside *E. coli* (Fig. 3). Proxyl-based spin labels as employed in this study are prone to fast biological reduction and it has been shown that they can be rendered EPR-inactive on a minute timescale.²⁹ However, it is possible to prolong the time scale on which nitroxide signal is still detectable by adding a large excess of the spin label to the cells and thereby practically overloading cellular reduction mechanisms.^{9,30}

In case of CuAAC-based spin labeling, Kucher *et al.* have already reported on the successful *in vivo* nitroxide labeling at a single labeling site,²⁴ while sufficient double-labeling *in vivo* has yet to be proven. We limited the labeling times for the *in vivo* labeling approach to 40 minutes at room temperature, followed by additional washing steps to remove unbound nitroxide spin labels (see ESI† for details). In total, approximately 60 minutes passed between the addition of the nitroxide spin labeling reagent to *E. coli* cells and the start of the EPR measurement. Time-dependent EPR spectra are shown in Fig. 3A. For a qualitative description of the signal reduction, we plotted the amplitude of the nitroxide center field peak

against the time (Fig. 3B). Upon performing the CuAAC-based spin labeling procedure, *E. coli* cells expressing Y39/L221pENF eGFP show a typical nitroxide EPR spectrum that prevails up to 120 minutes after the addition of azido-proxyl spin labeling reagent. In principle, EPR signals in *E. coli* can stem from several possible species. Besides spin-labeled Y39/L221pENF-L eGFP, the free spin label from the labeling reaction, as well as labeled pENF, both in free form and esterified to tRNA^{Tyr}(CUA) might contribute to the signal. To limit off-target labeling, protein-expressing cells were transferred to fresh LB medium without pENF and protein expression was prolonged for 90 minutes prior to CuAAC labeling. In addition, approximately 9% of *E. coli* proteins are terminated with an amber stop codon (TAG)³⁷ and pENF might also eventually be incorporated into these proteins. To investigate potential sources of signal, we co-transformed *E. coli* cells with plasmids for eGFP wild-type and the tRNA^{Tyr}(CUA)/YRS pair and expressed eGFP wild-type in the presence of pENF in the medium. In this scenario, the EPR signal after CuAAC labeling procedure can only arise from free or tRNA-esterified spin-labeled pENF or from labeled pENF incorporated at amber sites of off-target proteins. However, we did only observe neglectable signal intensities in this sample (Fig. 3A, black). In addition, we tested our washing protocol after CuAAC-based spin labeling with *E. coli* cells treated with CuAAC labeling reagents and azido-proxyl in the absence of pENF and found that free spin-label is effectively removed from the bacterial solution (Fig. S7, ESI†). We therefore assumed that the main contribution to the signal stems from spin-labeled Y39/L221pENF-L eGFP. The CW EPR spectra of Y39/L221pENF-L after *in vitro* or *in vivo* labeling were not identical which might be attributed to different ratios of spin labels attached to the individual labeling sites or differences in the mobility of the spin label within the cytoplasm (Fig. S8, ESI†).

For pulsed EPR experiments, *E. coli* cells expressing Y39/L221pENF eGFP were labeled as described above and shock-frozen in liquid 60 minutes after the start of the labeling reaction. The overall protein content was estimated by Western Blot analysis to be in the range of 200–800 μM with a spin concentration of approximately 20 μM , resulting in less than 5% EPR-active spin label per site. Echo-detected field sweeps of *E. coli* samples after CuAAC spin labeling contained spectral contributions from Cu(II) species as a result of the incomplete removal of the catalyst after labeling (Fig. S9, ESI†). The phase memory time of the spins was reduced to 0.66 μs for protonated cellular samples compared to 2.44 μs from the *in vitro* experiment in partially deuterated aqueous solution (Fig. S10, ESI†). The dipolar evolution time of in-cell DEER measurements was limited to 1.3 μs due to the reduced phase memory time in the cellular environment, but still long enough to provide reliable information about distance distributions in the range of the *in vitro* experiment.⁴ For background correction, we recorded in-cell DEER traces with the two singly labeled eGFP variants Y39pENF-L and L221pENF-L eGFP which could be completely described by a homogeneous background model (Fig. S11, ESI†). A similar background model was then used for the background correction for doubly-labeled eGFP. The form factor and the derived distance distribution were

Fig. 3 In-cell nitroxide stability after CuAAC spin labeling. (A) CW EPR spectra of *E. coli* cells expressing the tRNA^{Tyr}(CUA)/YRS pair for the incorporation of pENF as well as eGFP wild-type (black) or Y39/L221pENF eGFP (green) after *in vivo* CuAAC spin labeling. A detailed explanation is given in the text. Spectra were averaged over 5 scans. Indicated time points refer to the passed time after the addition of the nitroxide labeling reagent to the cells. $t = 60$ min marks the end of the labeling procedure and the start of the EPR measurement. (B) For a qualitative description of the nitroxide reduction, the amplitude of the centerline from averaged CW spectra was plotted against the time. The signal intensity at $t = 60$ min was set to 100%.

Fig. 4 In-cell DEER distance determination after bioorthogonal CuAAC spin labeling (A) Comparison of the form factors of Y39/L221pENF-L eGFP from DEER measurements conducted *in vitro* (orange) or *in vivo* (green). The modulation depth decreased from 38% for *in vitro* DEER to approximately 2% for *in vivo* DEER. (B) Derived distance distribution from form factors for DEER measurements *in vitro* (orange) and *in vivo* (green). The gray area indicates the expected distance distribution based on MMM³⁸ calculations with the rotamer library of pENF-L and a crystal structure of eGFP (C) The crystal structure of eGFP with indicated labeling sites and expected label conformers based on the rotamer library of pENF-L.

compared to the *in vitro* measurement of Y39/L221pENF-L eGFP and the expected distances based on the rotamer library (Fig. 4 and Fig. S12, ESI†).³⁸ The shape of the in-cell form factor was strikingly similar to the *in vitro* measurement and both experimental distance distributions contained the main distance constraint at 2.3 nm, while a second maximum at 2.6 nm could not be evaluated in the in-cell experiment. The in-cell measurement yielded a low modulation depth of roughly 2%, compared to 38% for the *in vitro* sample. We suspect that the large background contribution is a result of incomplete labeling of eGFP in the cellular environment as well as fast nitroxide reduction during the labeling procedure, while the presence of unbound spin label only plays a minor role.

In conclusion, we have demonstrated CuAAC-based spin labeling of an alkyne-bearing protein *in vivo* without apparent toxicity in *E. coli*. Moreover, we observe minimal background signal from nitroxides not attached to our target protein positions. Stability of the nitroxide spin label is a limiting factor of *in vivo* labeling that requires a large excess of spin label reagent and high cellular protein concentrations. Despite fast nitroxide reduction in the cytoplasm, double labeling of Y39/L221pENF eGFP and subsequent in-cell DEER measurements were performed that argue for a similar conformation that eGFP adopts in the *E. coli* cytoplasm and *in vitro*. Taken together, our approach combines natural translation, folding, and processing of a target protein with bioorthogonal double labeling and DEER distance measurements directly in the natural environment of a

bacterial cell. It overcomes the necessity for introducing spin-labeled proteins into cells, e.g. *via* electroporation or hypo-osmotic shock and thus represents a new access point to in-cell EPR studies of protein structure and function.
