Aqueous assembly of a (pseudo)rotaxane with a donor– π –acceptor axis formed by a Knoevenagel condensation†

Laurent Jucker,^a Yves Aeschi^a and Marcel Mayor ^{a,b,c}

The incorporation of a linear D– π –A “push–pull” chromophore synthesized by a Knoevenagel condensation as axle of a rotaxane is reported. While the introduction of the mechanical stoppers by the reversible and thermodynamically controlled Knoevenagel reaction turned out to be challenging, mechanical fixation of the superstructure is achieved by “click” chemistry in aqueous solution. The isolated rotaxane with a red- to NIR-emitting dye as axle displays enhanced emission in aqueous buffered media compared to the unthreaded model chromophore.

Introduction

The influence of macrocyclic hosts on the optical properties of their guests (and *vice versa*) has been investigated in a wide range of supramolecular systems with various emerging applications. Depending on the particular implementation, fluorescence enhancement, electron and/or energy transfer mechanisms can be incorporated in optical triggered molecular switches, typically as a function of the proximity of the components involved.^{1–4} Commonly employed dyes include rylene diimides,^{5–7} naphthalene imides,⁸ azo dyes,^{9–11} squaraines,^{12,13} and poly-aromatic hydrocarbons like anthracene^{14,15} or pyrene.¹⁶ Despite the growing library of rotaxanes, only very few examples comprising linear donor– π –acceptor “push–pull” chromophores are reported.^{17–23} An even more surprising fact considering their synthetic accessibility and tunability of their optical properties.²⁴

The decoration of a pseudorotaxane with a bulky substituent as stopper to mechanically fix the macrocyclic host is a common assembly strategy for rotaxanes, often referred to as “capping” or “stopping”. A variety of coupling reactions have been employed, with the copper(I)-catalysed azide–alkyne 1,3-cycloaddition (CuAAC) as “click” reaction being particularly popular,^{10,16} combining mild conditions and the concomitant

tolerance for a large variety of functional groups with high yields, especially in (metal)-templated assembly strategies.^{25–28} However, in contrast to the irreversible CuAAC, only stopping by reversible transformations might provide thermodynamic control over the formed superstructures. So far mainly imine condensations^{29,30} and olefin metatheses³¹ have been used for this purpose. To the best of our knowledge, examples taking advantage of the dynamic nature of the Knoevenagel condensation³² are limited to the syntheses of two rotaxanes^{22,23} comprising cyclodextrin-encapsulated cyanine dyes under aqueous basic conditions. More frequent use of the Knoevenagel condensation is observed in the field of covalent organic frameworks^{33,34} and macrocyclizations.³⁵

We thus explored the potential of the Knoevenagel condensation as stopping reaction for pseudorotaxanes assembled in water (Scheme 1a). We not only hoped for the reversible, thermodynamically controlled assembly of rotaxanes, but also wanted to profit from the strong electron accepting nature of the formed olefin decorated with a pair of electron-withdrawing groups (EWG). Our focus was set on the formation of linear donor– π –acceptor (D– π –A) “push–pull” chromophores as axles with emission in the red to near-infrared region (NIR). This emission range is not only of interest for bioimaging,^{13,36} but also particularly appealing for spectroscopy experiments enhanced by gold nanostructures.^{37,38}

As macrocycle forming (pseudo)rotaxanes with these axes, the Diederich-type cyclophane **2**^{39–41} combining strong complexation of hydrophobic guests with water-solubility was considered. Previously, **2** has been employed in rotaxanes comprising oligo(phenylene-ethynylene) (OPE) molecular wires,^{39,42,43} azo dyes,⁹ or naphthalenes⁴⁴ as guests. We have previously used an OPE-functionalized modification of **2** to assemble

Scheme 1 (a) Both strategies to assemble rotaxanes with a D-π-A chromophore as axis considered. (b) Rotaxane **1eC2** obtained via strategy B.

dimeric, zwitterionic daisy chains in water⁴⁵ and studied the slow association of **2** with carboxylate-terminated OPE structures forming kinetically inert pseudorotaxanes.⁴⁶ Interestingly, the changes observed in the emission intensity upon complexation with **2** strongly depend on the nature of the guest and seem not to be fully understood yet. This further motivated the here reported approach, as axes assembled *via* Knoevenagel condensation might provide access to a series of (pseudo)rotaxanes incorporating “push-pull” D-π-A systems of various acceptor strengths.

Here we report our attempts to assemble water-soluble linear “push-pull” chromophores by Knoevenagel condensations as potential axes of rotaxanes. We present our initial struggles to balance reactivity, stability and solubility in water together with the first “proof-of-existence” rotaxane **1eC2** (Scheme 1b) with the desired axis structure. While this mechanically interlinked model compound enabled preliminary investigations of the physical properties of this class of rotaxanes, it was obtained applying a stepwise strategy, assembling first the axis with a Knoevenagel condensation and subsequently fixing the supermolecule by CuAAC “click” chemistry (strategy B in Scheme 1a).

Results and discussion

Precursor synthesis and pseudorotaxane formation

With the intention to profit from the Knoevenagel condensation as a stoppering reaction, the aldehyde decorated precursor **3** combining multiple key components was designed (Scheme 2). Its biphenyl backbone acts as both, π-system of the chromophore bridging donor and acceptor substituent and as hydrophobic station complexing the cyclophane. The electron-donating nitrogen is functionalized with two triazol units bearing sulfonates, which have a double role too, serving

as mechanical stopper and as water-solubilizing groups at the same time.

Starting from 4-iodoaniline **4**, two-fold alkylation with propargyl bromide in acetonitrile gave **5** in 66% yield. Formation of 3-azidopropane-1-sulfonate by S_N2 of 1,3-propanesultone with sodium azide and subsequent CuAAC gave the water-soluble **6** as the disodium salt in 45% yield after decomposition of excess azide, purification by reverse-phase column chromatography, and precipitation from water with EtOH. After unsuccessful attempts in commonly employed mixed aqueous-organic media, we found suitable conditions⁴⁷ for the Suzuki-Miyaura cross-coupling of **6** with 4-formylphenylboronic acid in water in absence of a ligand to give the desired aldehyde **3** as the ammonium salt in 78% yield after reverse-phase column chromatography.

The interaction between the one-sidedly stoppered water-soluble biphenyl **3** and the cyclophane **2** was investigated by ¹H-NMR spectroscopy (Scheme S1†). Addition of an equimolar amount of **2** to a solution of **3** in D₂O displayed the typical up-field shift of the protons encircled by the host expected for the formation of **3C2**, along with a broadening of the signals. The aryl signals of the biphenyl system are shifted up-field by 0.5–2.2 ppm, with the central two protons experiencing the strongest shielding effect (as determined by NOESY, Fig. S1†). The aldehyde singlet only shifts up-field by 0.36 ppm and the triazole and propyl signals of the stopper are slightly deshielded. According to the extent of the experienced shielding we hypothesized the macrocyclic host in **3C2** to be mainly located around the centre of the biphenyl subunit, with the terminal aldehyde accessible for further reactions. A dilution series of **3C2** in D₂O (Fig. S2†) in the range of 1 mM to 0.1 mM only showed a slight shift of the signals, indicating a high association constant (*K*_a) in aqueous solution (*K*_a > 10⁵ M⁻¹).⁴⁸ This is in line with previously published pseudorotaxanes comprising **2**.⁴⁶

Aqueous Knoevenagel condensations

Having confirmed the formation of **3C2** by ¹H-NMR spectroscopy, we investigated conditions for the Knoevenagel condensation in aqueous media (Scheme 3). Inspired by literature procedures,^{49,50} we tested the condensation of malononitrile with **3** in water at room temperature in absence of any catalyst and were delighted to obtain **1a** in 69% yield after simple precipitation of the product by addition of acetonitrile. The “push-pull” dye **1a** showed interesting optical properties (Fig. S14†) with an absorption maximum of λ_{abs} = 420 nm and emission extending into the NIR with a maximum of λ_{em} = 710 nm in H₂O. The large Stokes’ shift of approx. 9700 cm⁻¹ observed for **1a** was particularly appealing for both, biological applications and the optimization of superstructures for single molecule experiments profiting from the field enhancement in gold nanostructures.

Motivated by both, the encouraging preliminary synthesis and the exciting optical properties of the Knoevenagel product

1a, a large variety of sterically more demanding precursors were synthesized. From a molecular design view point, it seemed that the required methylene subunit trapped between a pair of EWGs was ideally suited to be decorated with bulky substituents, providing the option to profit from the Knoevenagel condensation to introduce the stopper required for the mechanically interlocked rotaxane structure. The overview and evaluation of considered methylene precursors comprising in part the stopper function is summarized in Scheme 3. Diester **b** was synthesized in an acid-catalyzed esterification of malonic acid; barbituric acid derivative **c** was obtained in two steps from a literature known urea derivative⁵¹ (Scheme S4†). Unfortunately, the diester **b** turned out to be unserviceable for the intended purpose in preliminary experiments. The compound was not reactive at room temperature and its ester moieties were prone to hydrolysis at elevated temperatures under all reaction conditions investigated (acidic, basic, and uncatalyzed aqueous conditions). At the first glance, preliminary experiments with the barbituric acid derivative **c** were more promising, as the colour of the reaction mixture changed immediately to red upon addition of acetic acid to an aqueous solution of the reactants, pointing at the successful product formation. However, reaction control by LC-MS and reverse-phase TLC merely showed the starting materials. Repeating the experiment in D₂O, addition of CD₃CO₂D provided the expected red colour, yet it was not accompanied by any change in the ¹H-NMR spectrum, likely due to the formation of only negligible amount of the intensely coloured desired product. Unfortunately, reaction conditions pushing the equilibrium towards the formation of **1c** could not be found and we suspected the product to be of limited stability in aqueous medium.

We thus considered the less electron-withdrawing but likely more stable, commercially available 4,4'-methylene-dibenzoic acid **d** next. Its reactivity was very poor even at elevated temperatures and reactions under more classic Knoevenagel conditions (DMF/piperidine) did not proceed either.

Puzzled by the refusal of the so far investigated methylene precursors to form the Knoevenagel product in aqueous media, we wondered whether their bulkiness or their charged state compromised either their reactivity or the stability of their condensation products. In a last attempt we developed the less symmetric precursor **e**, which features a bulky stopper on only one side of the active methylene component. In this compound the conjugation between the active methylene group and the stopper is broken by the methylene bridge between the amide and the triazole, thus the charged stopper is not participating in the electron withdrawal, unlike in molecules **b–d**. Of course we hoped that this variation in the molecular design will improve the reactivity of **e** and the stability of the resulting product **1e**.

The synthesis of **e** was performed in three steps from the literature-reported⁵² aniline **7** (Scheme 4). First, a diazotation-azidation procedure gave **8** in 98% yield, followed by basic ester hydrolysis in THF/MeOH/H₂O to produce the stopper **9** in 96% yield after centrifugation and removal of excess NaOH. In a final step, CuAAC with **f** led to the formation of **e** in 65% yield.

Scheme 3 Series of methylene precursors **a–f** activated by electron-withdrawing groups (EWGs) for the Knoevenagel reaction with **3** with the intention to form **1a–f**. Answer statements together with ticks and crosses show the success in the search for suitable conditions for the formation of the corresponding Knoevenagel products in isolable yields.

Scheme 4 Synthesis of the stopper **9** in 2 steps and CuAAC “click” reaction providing **e**. Reagents and conditions: (i) TMSN_3 , tBuONO , DMF, 0 °C to rt, 6 h, 98%; (ii) NaOH, THF–MeOH– H_2O (4 : 4 : 1), 50 °C, 1 h, 86%; (iii) $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, sodium ascorbate, H_2O –MeOH (2 : 1), rt, 1 h, 65%.

However, the Knoevenagel condensation of **e** and **3** to form **1e** (Scheme 3) remained challenging in aqueous conditions. In absence of catalyst the reaction did not proceed towards the product even at elevated temperatures, while addition of Na_2CO_3 led to amide hydrolysis already at room temperature. By adjusting pH to ~ 7 – 8 with a phosphate buffer, decomposition at elevated temperature was slowed down, however, the formation of the desired condensation product **1e** was not observed. Acidic reaction conditions turned out to be even more challenging as the solubility of **e** decreased, substantially handicapping the formation of condensation product.

The reaction sequence forming the methylene precursor **e** with stopper potential by CuAAC “click” chemistry first and its subsequent engagement in the Knoevenagel condensation could also be inverted. The condensation could also be performed with the alkyne-bearing **f** and the obtained product exposed to the CuAAC “click” conditions to be further decorated by the bulky stopper. And indeed, the desired condensation product **1f** was obtained, even so not in aqueous conditions. However, **1f** profits from rather compact olefin substituents introduced by the Knoevenagel reaction, which should allow the subsequent rotaxane formation. As aqueous conditions are only required to unleash hydrophobic interaction to trigger the pseudorotaxane formation, the use of alternative solvents to obtain **1f** is less an issue than in the case of bulkier methylene precursors. The formation of **1f** was observed in DMF with piperidine as catalyst. However, under these conditions **1f** was prone to react further in a Michael addition. To our delight, omission of piperidine led to the *E*-selective (as evidenced by the NOESY NMR spectrum, Fig. S13[†]) formation of **1f** in 36% isolated yield.

The absorption and emission spectra of **1f** in H_2O (Fig. S15[†]) show a hypsochromic shift with respect to **1a**, with maxima of 396 nm and 693 nm for the absorption and emission of **1f**, respectively. The Stokes’ shift is, with a value of approximately $10\,800\text{ cm}^{-1}$, even larger than the one observed for **1a**.

As already mentioned above, due to the relatively compact **f**, we anticipated that **2** should readily thread onto **1f**. And

indeed, the $^1\text{H-NMR}$ analysis of a 1 mM 1:1 mixture in D_2O displayed the expected shifts of the aromatic signals of **1f** (Scheme S2†). In similarity to **3C2**, the central protons of the biphenyl system in **1fC2** experienced the largest shift, suggesting the centre of the biphenyl subunit to be the most prevalent position of the host **2** in the superstructure. This is further corroborated by NOE signals of these central protons to the aromatic signal of **2** (Fig. S4†). $^1\text{H-NMR}$ spectra of a dilution series (Fig. S5†) showed no significant changes in the chemical shift down to concentrations of 50 μM , indicating a K_a beyond the range suited for determination by NMR spectroscopy ($>10^5 \text{ M}^{-1}$). The association of **1fC2** in water was determined by recording the emission intensity during the titration of **1f** against **2** (Fig. S11†). The obtained K_a of $1.5 \times 10^7 \text{ M}^{-1}$ is larger than previously reported association constants with the same cyclophane,^{42,46} which might be the result of supporting electrostatic attractions between the negatively charged sulfonate groups of the axis and the piperidinium moieties of the macrocycle.

With the successful syntheses of **e** and **1f**, together with its strong association with **2**, our focus moved away from the original idea of using a Knoevenagel condensation as stoppering reaction (strategy A in Scheme 1a) to the stepwise assembly strategy (strategy B in Scheme 1a). Finally accepting that aqueous conditions are a challenging environment to push a reversible condensation reaction to completion, we wondered if a rotaxane with an axle assembled by a Knoevenagel condensation might be stable in water at all. Furthermore, we hoped to access the model compound to be able to assess the influence of the integration of the $\text{D}-\pi\text{-A}$ dye systems into the rotaxane superstructure on its optical properties.

[2]Rotaxane

With the confirmed formation of the pseudorotaxane **1fC2**, the stoppering with **9** via CuAAC “click” reaction was envisioned (Scheme 5).

To simplify purification, classical conditions with CuSO_4 and sodium ascorbate in absence of a ligand were chosen. The reaction was performed at 2 mM concentration of **2** in H_2O , to prevent its self-aggregation.³⁹ Higher host concentrations led to the formation of precipitate during the reaction. After 30 min, we were delighted to observe the formation of new species with masses of the desired [2]rotaxane **1eC2** and the unthreaded side product **1e** by LC-MS. While the ratio of both products could not be determined, we proceeded with the challenging isolation of the [2]rotaxane.

The solubility of **1eC2** was lower in H_2O than that of its precursors, however it turned out to be well soluble in mixed solvents of $\text{H}_2\text{O}/\text{CH}_3\text{CN}$ and $\text{H}_2\text{O}/\text{DMF}$, as well as in DMSO. While reverse-phase HPLC on C18-functionalized silica using $\text{H}_2\text{O}/\text{CH}_3\text{CN}$ as eluent allowed to remove most impurities like **1e**, **2**, and **9** over multiple consecutive runs, some remaining impurities could also not be removed using $\text{H}_2\text{O}/\text{MeOH}$ eluent mixtures. Numerous alternative purification attempts like precipitations and crystallizations by vapour diffusion failed. Dialysis against water showed no significant improvement by $^1\text{H-NMR}$ spectroscopy. Purification by gel permeation chromatography (GPC) using polystyrene beads (BioBeads SX-1) was considered, but the low solubility of **1eC2** in pure DMF and the poor swelling behaviour of the beads in polar protic media rendered the method ill-suited for this purpose. Finally, GPC using Sephadex LH-20 in a mixture of DMF and aqueous NH_4OAc buffer, followed by a second dialysis, provided the rotaxane **1eC2** in 0.9% isolated yield with only minor impurities remaining. **1eC2** was characterized by $^1\text{H-NMR}$ and 2D-NMR in $\text{D}_2\text{O}/\text{CD}_3\text{CN}$, and high-resolution mass spectrometry. The sparse availability of the mechanically interlinked model compound did neither allow to record $^{13}\text{C-NMR}$ spectra showing all expected signals nor its characterization by elemental analysis, however, the chemical shifts of the missing ^{13}C peaks were extracted from HMQC and HMBC measurements.

Scheme 5 Mechanical fixation in the rotaxane **1eC2** via CuAAC “click” reaction of **1f** and **9** in presence of host **2** in aqueous environment. Reagents and conditions: (i) $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, sodium ascorbate, H_2O , rt, 1.5 h, 0.9%.

The low yield of the mechanically interlocked product led us to investigate the reaction further and $^1\text{H-NMR}$ studies revealed the formation of undesired pseudorotaxane **9C2** when **9** and **2** were mixed in D_2O (Fig. S6†). Furthermore, equimolar competition experiments of **1f**, **9**, and **2** in D_2O (Fig. S9†) revealed the partial formation of both **1eC2** and **9C2**, pointing towards similarly high K_a values. Unfortunately, higher ratios of **2** led to precipitation during the CuAAC reaction and formation of impurities which were inseparable by HPLC, GPC, or precipitation.

To exclude that deslipping of the macrocycle off the axle in the [2]rotaxane occurred during purification, we heated solutions of **1eC2** in acetonitrile and DMSO to $75\text{ }^\circ\text{C}$ and $120\text{ }^\circ\text{C}$, respectively. Qualitative analysis by HPLC-MS (Fig. S27†) showed neither the formation of **1e** nor **2** after 16 h of heating, confirming sufficient bulkiness of both stopper moieties.

The unthreaded reference compound **1e** was prepared by CuAAC between **1f** and **9**, and obtained in 81% yield after precipitation from the reaction mixture with an excess of CH_3CN (Scheme S6†). Interestingly, **1e** turned out to be better soluble in water than the [2]rotaxane. However, $^1\text{H-NMR}$ spectra of **1e** displayed broad signals in both, D_2O and $\text{D}_2\text{O}/\text{CD}_3\text{CN}$ solutions, presumably due to the presence of different protonation states. Reasonably sharp NMR spectra were obtained in DMSO after addition of acetic acid.

To exclude solvent effects, the $^1\text{H-NMR}$ spectra of **1e** and **1eC2** were compared in $\text{DMSO-}d_6$ with acetic acid as additive (Fig. 1). Akin to the NMR spectra of pseudorotaxanes **3C2** and **1fC2** measured in D_2O , the aromatic protons of the biphenyl moiety are most affected by the cyclophane, showing a significant upfield shift. The protons of the stoppers remain largely unaffected, further corroborating the biphenyl bridge as the preferred resting position of the cyclophane in the superstructure.

Fig. 1 Comparison of $^1\text{H-NMR}$ spectra of **1e** (top, 400 MHz) and **1eC2** (bottom, 500 MHz) in $\text{DMSO-}d_6$ with AcOH as additive.

We are mainly interested in the effects the cyclophane exercises on the optical properties of the D- π -A chromophore, with the intention to develop model compounds for experiments investigating single molecule motions spectroscopically. Thus the optical properties of **1e** and **1eC2** (Fig. 2a) were recorded in aqueous solutions containing $0.1\text{ M Na}_2\text{HPO}_4$ adjusted to pH 6.4 with H_3PO_4 to guarantee similar ions and comparable protonation states. In the UV-Vis absorption spectra, the longest wavelength absorption maxima are 420 nm and 406 nm for **1eC2** and **1e**, respectively, showing a bathochromic shift in the [2]rotaxane. Exciting both samples at their absorption maxima for the emission spectra, displayed a hypsochromically shifted emission for **1eC2** compared to **1e** with maxima at 655 nm and 669 nm , respectively. More importantly, when corrected for the different absorptions, we noticed that the signal intensity at the emission maximum is significantly higher in the [2]rotaxane than in the unthreaded chromophore in the buffered aqueous solution. Intrigued by this result, we determined the absolute quantum yields (QY) in buffered aqueous solution to be below 1% for **1e**, while an efficiency of $11.0\% (\pm 0.5\%)$ was observed for **1eC2** under the same conditions (see ESI†). In DMSO, the effect seemed to persist (Fig. S16†) and indeed, both molecules showed higher

Fig. 2 (a) Absorption (solid lines) and emission (dashed lines) spectra of **1eC2** (black) and **1e** (red) in aqueous $0.1\text{ M Na}_2\text{HPO}_4$ solution adjusted to pH 6.4 with H_3PO_4 . Absorption spectra are normalized. Emission spectra were corrected for differences in absorption at the excitation wavelength (420 nm for **1eC2**; 406 nm for **1e**). Photographs of **3**, **1a**, **1f**, **1e**, **1eC2** (left to right) under ambient (b) and 366 nm wavelength light (c). Photographs in (c) were slightly edited to decrease the blue discoloration caused by the lamp, unedited photographs can be found in the supporting information (Fig. S22–S26†).

QY in DMSO with values of 19.0% ($\pm 0.9\%$) and 58.5% ($\pm 1.5\%$) for the rod and [2]rotaxane, respectively. The mechanisms determining the extent of emission enhancement upon threading are not fully clarified yet and various factors might contribute like *e.g.*, reduced solvent interaction or decreased rotational freedom. Aggregation-induced emission quenching of **1e** seems unlikely as potential mechanism, as all the synthesised chromophores **3**, **1a**, **1e**, **1f**, and **1eC2** even emit in the solid state when irradiated with light of 366 nm (Fig. 2b and c). The emission spectra of the finely ground solids of **3**, **1a**, **1e**, and **1f** in between two glass slides were recorded in an integrating sphere, while **1eC2** was measured as a film on glass due to the lack of material. Interestingly, the emission spectra of dyes **1a**, **1e**, **1f**, and **1eC2** (Fig. S21[†]) show no significant differences, sharing an emission maximum at roughly 600 nm. This hypsochromic shift can be explained by the absence of solvent interaction.

Knoevenagel reversibility

During experiments examining the pH-dependence of **1e** in NMR spectroscopy, we observed the instability of **1e** in D₂O/CD₃CN (1 : 1) in the presence of Na₂CO₃, as expected based on our previous results with **e**, which showed decomposition in Knoevenagel condensation attempts performed under basic conditions. Over time, an aldehyde signal arose, along with the characteristic peaks of the biphenyl moiety present in our chromophore design. To our delight, the ¹H-NMR spectra of the formed species and **3** (in D₂O/CD₃CN, 1 : 1, Scheme S3[†]) share identical chemical shifts. Further examination by LC-MS corroborated **3** as the main species formed after 20 h (Fig. S28[†]). While **e** decomposed under these conditions, the experiment nonetheless indicated the reversibility of the Knoevenagel condensation in water, a prerequisite for its employment as a stoppering reaction for the formation of rotaxanes under thermodynamic control.

Conclusions

The challenges we faced during our ongoing journey studying the potential of the Knoevenagel condensation as stoppering reaction in water for the formation of rotaxanes are reported. The rigid-rod type water-soluble aldehyde precursor readily associated with the macrocyclic host in water and was suited for the synthesis of push-pull red to NIR-emitting dyes with solid-state emission. While we have not yet succeeded in finding a suitable reaction system enabling stoppering *via* Knoevenagel condensation, we synthesized and characterized a first “proof-of-existence” [2]rotaxane with a Knoevenagel product as axle. Significant emission enhancement was observed for the encapsulated dye in comparison to the unthreaded dye when measured in buffered aqueous solution and solid-state emission was preserved.

We are currently working on mechanically interlocked model compounds for externally triggered single molecule experiments.
