New hybrid architectures and composites that incorporate 2D materials optimise energy storage devices, increasing metrics such as energy density and cycling stability. Moreover, integrating 2D materials into flexible, wearable devices addresses the needs of portable electronics and IoT. The review links the structure, synthesis, and characterisation to the electrochemical behavior of each material and also captures recent advances in the last decade related to battery and supercapacitor applications. 1. Introduction

The modern world is witnessing an unprecedented surge in the demand for efficient energy storage systems driven by the rapid

growth of renewable energy sources, the electrification of transportation, and the increasing reliance on portable electronic devices. To facilitate the integration of renewable energy into the grid and to meet the rising energy demands, there is an urgent need for advanced energy storage technologies that can store and deliver energy effectively, reliably, and sustainably.¹ Despite the remarkable progress in energy storage research, current technologies still face several limitations, such as low energy density, slow charging rates, limited cycle life, high cost, and environmental concerns² associated with the use of conventional materials.

In response to these challenges, the exploration of novel materials with exceptional properties and tailored functionalities has become imperative.³ One class of materials that has emerged as a game-changer in the field of energy storage is two-dimensional (2D) materials. Unlike conventional bulk materials, 2D materials possess atomically thin structures, exhibiting unique electronic, mechanical, and chemical characteristics⁴ that make them promising candidates for addressing the limitations of current energy storage technologies. This review serves as an overview of the growing demand for efficient energy storage systems and the constraints faced by

conventional technologies. Subsequently, we delve into the significance of 2D materials in mitigating these challenges, highlighting their exceptional properties and potential applications in various energy storage devices. Moreover, we will discuss recent advances in the utilization of 2D materials, focusing on batteries and supercapacitors, and outline the organization of this review paper.

1.1. Growing demand for efficient energy storage systems

The transition towards sustainable and low-carbon energy systems has led to a dramatic increase in the deployment of renewable energy sources, such as solar and wind power. While these renewable sources offer abundant energy, their intermittency poses a significant challenge to grid stability and reliability.⁵ Energy storage systems play a pivotal role in overcoming this intermittency, enabling efficient energy capture during surplus periods and discharge when demand peaks or renewable energy production is low.⁶ Additionally, the electrification of the transportation sector has also amplified the need for high-performance energy storage solutions to power electric vehicles (EVs) with extended driving ranges and reduced charging times.⁷

Furthermore, the exponential growth of portable electronic devices, ranging from smartphones to wearables, has heightened the demand for compact and long-lasting energy storage systems.⁸ The increasing reliance on these devices in daily life has accentuated the necessity for high-energy-density batteries that can sustain prolonged usage without frequent recharging.⁶ Thus, there is an urgent need to develop energy storage technologies that not only meet the rising energy demands but also address the environmental concerns associated with conventional fossil-fuel-based energy sources and materials.

1.2. Limitations of current energy storage technologies

Although several energy storage technologies exist today, each with its strengths and limitations, none are without compromise. Conventional lead-acid batteries, widely used in automotive applications, suffer from low energy density and limited cycle life.⁹ Lithium-ion batteries (LIBs), which dominate the portable electronics market and are increasingly being utilized in EVs, offer relatively higher energy density and longer cycle life.⁷ However, they still fall short of meeting the escalating energy storage demands for large-scale applications.

The high cost and limited availability of certain raw materials, especially those used in LIBs, such as cobalt, raise concerns about the long-term sustainability of current energy storage technologies.¹⁰ Additionally, the safety of LIBs, with their propensity for thermal runaway and fire hazards, necessitates the development of safer alternatives for energy storage.

On the other hand, supercapacitors, offer fast charging and discharging rates but generally have lower energy densities compared to batteries.¹¹ The use of traditional carbon-based electrodes in supercapacitors limits their specific capacitance and energy storage capacity. As a result, there is a pressing need to explore novel materials and structures that can enhance the energy storage capabilities of supercapacitors.

1.3. Necessity of 2D materials in energy storage applications

Two-dimensional materials have emerged as a promising class of materials that could revolutionize the field of energy storage. These materials are composed of single or a few layers of atoms, resulting in their unique physicochemical properties and large surface area-to-volume ratios. One of the most well-known 2D materials is graphene, a single layer of carbon atoms arranged in a two-dimensional honeycomb lattice. Graphene exhibits exceptional electronic conductivity, mechanical strength, and thermal stability, making it a prime candidate for various energy storage applications.¹²

Apart from graphene, other 2D materials, such as transition metal dichalcogenides (TMDs), hexagonal boron nitride (h-BN), and MXenes, have also garnered significant attention for their potential in energy storage devices.¹³ TMDs offer a diverse range of electronic and electrochemical properties, making them suitable for both anode and cathode materials in batteries. h-BN, with its wide bandgap and excellent insulating properties, has been explored as a dielectric material in capacitive energy storage systems.¹⁴ MXenes, a family of 2D transition metal carbides and nitrides, exhibit tunable electronic properties and high surface area, making them attractive candidates for supercapacitors and batteries.¹⁵ However, challenges such as large-scale synthesis, cost-effectiveness, and long-term stability need to be addressed to unlock the full potential of 2D materials in commercial energy storage applications.

1.4. Scope

This review provides a consolidated and comparative overview of the major classes of two-dimensional (2D) materials that have emerged as promising electrode candidates for electrochemical energy storage, with a primary focus on graphene-based materials, MXenes, and transition metal dichalcogenides (TMDs). These material families are examined as representative platforms encompassing metallic, semiconducting, and surface-functionalized 2D systems, thereby enabling a balanced assessment of their structure–property relationships and electrochemical behaviour in batteries and supercapacitors. Particular attention is given to how atomic structure, surface chemistry, phase composition, and defect engineering govern ion transport, charge storage mechanisms, and cycling stability across different device configurations.

The review is structured to systematically link material structure to synthesis strategy to physicochemical properties to electrochemical performance, allowing direct comparison across the three 2D material families within a unified framework. Following an introduction to the fundamental characteristics and synthesis routes of each material class, their performance in lithium-ion, sodium-ion, and emerging multivalent batteries, as well as in electric double-layer and pseudocapacitive supercapacitors, is critically evaluated. Comparative tables are used to benchmark key performance metrics such as specific capacity, capacitance, rate capability, and cycling durability, highlighting both strengths and persistent limitations associated with each class.

In addition to established material systems, the review emphasizes emerging hybrid and composite architectures that

integrate 2D materials with metal oxides, conductive polymers, carbon nanostructures, and molecular redox species to overcome challenges related to restacking, limited active sites, and long-term stability. Forward-looking perspectives are provided on strategies such as surface termination control, phase engineering, heterostructure design, and oxidation-resistant architectures, which are increasingly important for translating laboratory-scale performance into practical energy storage technologies. By combining comparative analysis with a materials-design perspective, this review aims to serve as a useful reference for guiding future development of robust, high-performance 2D-material-based electrodes. In addition to established 2D material systems, this review includes a dedicated forward-looking section that examines emerging electrode concepts such as single-atom catalysts on 2D supports, hydrogen-bonded polyoxometalate hybrids, and oxidation-resistant wide-band-gap architectures. This section critically positions these future materials within the broader landscape of energy storage research, emphasizing stability-driven design, hybridization strategies, and durability under high-voltage and long-term cycling conditions.

2. An outlook into the different 2D materials' properties and synthesis routes

2.1. Graphene

Graphene is a fascinating allotrope of carbon characterized by a monolayered distribution of carbon atoms arranged in a 2D layered honeycomb lattice structure. Each lattice of graphene is made up of three sigma bonds and exhibits sp^2 hybridization, resulting in a robust hexagonal structure. The carbon-carbon bond length within a graphene layer is approximately 0.142 nm, while the overall thickness of the graphene is approximately 0.35 nm (Fig. 1).¹⁶

One of the most intriguing features of graphene is its exceptional electrical conductivity, primarily attributed to the presence of pi bonds perpendicular to the lattice plane. These pi bonds enable efficient electron mobility through the material, making graphene an outstanding conductor of electricity. This

property is particularly beneficial in energy storage devices where fast electron transfer is important for performance. Additionally, the unique arrangement of carbon atoms in the hexagonal lattice confers remarkable mechanical strength and flexibility to the material, making it a promising candidate for various applications.¹⁷

When multiple layers of graphene are stacked together, they form other materials such as graphite, carbon nanotubes, fullerenes, and large aromatic molecules. Among these, few layer graphene and graphene-based composites are frequently utilised in batteries and supercapacitors to enhance conductivity, structural integrity, and ion diffusion pathways. Graphite, for instance, is composed of numerous graphene layers stacked on top of one another, with weak van der Waals forces holding the layers together. This arrangement allows the layers to slide over each other, giving graphite its characteristic lubricating properties.¹⁸ Carbon nanotubes are elongated cylindrical structures formed by rolling up a single layer of graphene.¹⁹ They possess extraordinary strength and unique electronic properties, making them valuable in a wide range of nanotechnology and materials science applications. Fullerenes, on the other hand, are spherical molecules consisting of carbon atoms arranged in a cage-like structure. Certain fullerenes, like buckminsterfullerene (C₆₀), contain 60 carbon atoms, forming a geodesic dome-like shape.²⁰ These fascinating molecules have captivated researchers due to their intriguing physical and chemical properties.

Graphene, with its sp^2 hybridized carbon atoms and strong hexagonal lattice structure, lays the foundation for an array of remarkable carbon-based materials. Its exceptional electrical conductivity and mechanical properties, coupled with the ability to stack and form various structures, open up endless possibilities for applications in fields such as electronics, nanotechnology, and materials engineering.

2.1.1. Properties of graphene. Graphene's excellent electrical conductivity, reaching around 10^6 S m^{-1} , makes it perfect for high-performance energy storage, enabling rapid charge and discharge in supercapacitors and batteries.²¹ Its outstanding mechanical strength, with a tensile strength near 125 GPa, maintains structural integrity in electrodes and prevents

damage during repeated use. Moreover, graphene's very high in-plane thermal conductivity ($\sim 5000 \text{ W m}^{-1} \text{ K}^{-1}$) helps dissipate heat effectively, enhancing thermal management and safety in battery systems.⁷ As a gapless semiconductor, its electronic properties can be precisely adjusted, making it suitable for hybrid energy devices. Additionally, graphene's impermeability to gases improves its role as a protective barrier in encapsulation layers and separators, boosting the lifespan and stability of energy storage systems. These qualities make graphene a key material for next-generation energy storage technologies.

- **Optical transparency:** due to its monolayered atomic structure and minimal thickness, graphene exhibits high optical transparency across a wide range of wavelengths.²¹ This property makes it an attractive candidate for transparent conductive films used in electronic devices, displays, and solar cells.

- **Electrical conductivity:** graphene stands out as the most conductive material known at room temperature, boasting a remarkable electrical conductivity of 106 S m^{-1} and a low sheet resistance of $31 \text{ } \Omega \text{ sq}^{-1}$.²² This outstanding conductivity makes it highly suitable for use in electrical and electronic applications.

- **Mechanical strength:** graphene showcases extraordinary mechanical strength, making it the toughest crystal structure among all known materials. With a tensile strength of 125 GPa and an elastic modulus of 1.1 TPa,²³ graphene exhibits exceptional resilience and robustness.

- **Thermal conductivity:** graphene's high in-plane thermal conductivity results from the strong covalent sp^2 bonding between carbon atoms, enabling efficient heat transfer within the material.²⁴ However, out-of-plane heat flow is restricted due to weak van der Waals coupling between graphene layers.

- **Gapless semiconductor:** one of the unique electronic properties of graphene arises from its gapless semiconductor nature. Charge carriers in graphene follow a linear dispersion relation, resembling massless relativistic particles.²⁵ This leads to several intriguing electronic phenomena, contributing to their potential in electronic and optoelectronic devices.

- **Transparent conductive membrane:** the combination of optical transparency and electrical conductivity makes graphene an excellent candidate for transparent conductive membranes, used in applications like flexible touchscreens and wearable electronics.²⁶

- **High strength limit:** graphene's impressive strength limit, reaching 42 N m^{-1} , ensures its stability and resilience even under extreme conditions, making it suitable for various structural applications.²⁷

- **Gas barrier properties:** single layers of graphene have shown excellent gas barrier properties, making it useful in applications where gas permeation needs to be controlled,²⁸ such as in packaging and environmental protection.

2.1.2. Different synthesis methods of graphene. Graphene can be synthesized through various methods, including both top-down and bottom-up approaches (Table 1):

Graphene has shown impressive electrochemistry in many forms of energy storage technology. Hybrid graphene/MnO₂ electrodes showed a capacitance of 350 F g^{-1} at a current

density of 1 A g^{-1} with 92% cycling retention, which can be indicative of their ability to function well as high power supercapacitors.³⁶ The same was true for nitrogen-doped graphene, which produced a high reversible capacity of 875 mAh g^{-1} at a low rate of 0.1 A g^{-1} as an anode in a lithium-ion battery due to its increased conductivity, as well as its defect induced active sites.³⁷ Additionally, three-dimensional (3D) porous graphene aerogels created a high energy density of 22 Wh kg^{-1} in symmetric supercapacitors by allowing for better ion transport pathways as well as providing greater structural integrity.³⁸

2.2. Graphene oxide (GO)

Graphene Oxide (GO) is a unique monolayer material composed of carbon, hydrogen, and oxygen molecules.³⁹ Its sp^2 hybridization is disrupted, leading to properties that align more with those of an insulator rather than a conductor. Despite its insulating behavior, GO exhibits high hydrophilicity and can form stable aqueous colloids.⁴⁰

This adjustable chemistry makes GO a promising precursor for energy storage uses. When partially reduced to reduced graphene oxide (rGO), it restores electrical conductivity while maintaining oxygen groups, enabling it to act as a conductive and chemically active matrix for battery electrodes and supercapacitors materials.

Several structural models have been proposed to describe the composition and arrangement of functional groups in GO:

- > Hoffman and Holst's model: they suggested a structure with epoxy groups dispersed across the basal planes of graphite, leading to a net molecular formula of C₂O.

- > Reuss' variation:⁴¹ Reuss incorporated hydroxyl groups into the basal plane, accounting for the hydrogen content in GO. Additionally, the basal plane structure was altered to a sp^3 hybridized system.

- > Scholz and Boehm's model:⁴² this model removed the epoxide and ether groups completely and introduced regular quinoidal species, resulting in a corrugated backbone.

- > Nakajima and Matsuo's assumption:⁴³ They relied on the assumption of a lattice framework similar to poly(dicarbon monofluoride), a stage 2 graphite intercalation compound (GIC).

The various models proposed reflect the complexity and diversity of functional groups and hybridization patterns present in GO. The structural understanding of GO is crucial for tailoring its properties and optimizing its applications in areas such as energy storage, sensing, and biomedical devices. Despite its insulating nature, GO's unique hydrophilicity and colloidal stability make it a versatile material for various applications, including water purification, drug delivery, and as a precursor for the synthesis of reduced graphene oxide (rGO), which exhibits enhanced electrical conductivity compared to GO (Fig. 2).

2.2.1. Properties of graphene oxide (GO). • **Mechanical properties:** monolayer graphene oxide exhibits a lower effective Young's modulus ($207.6 \pm 23.4 \text{ GPa}$ at 0.7 nm thickness) than pristine graphene. GO membranes made *via* solution-based deposition have a lower prestress (39.7–76.8 MPa) than

mechanically cleaved graphene, indicating reduced mechanical strength and flexibility.³¹

- **Electrical properties:** GO's electrical resistance can be reduced through thermal annealing, chemical reduction, or the use of reducing agents.⁴⁵ These processes restore the sp^2 bonding orbitals and remove surface functional groups, increasing electrical conductivity. This improvement in electrical properties enhances GO's performance in electronic applications.

- **Thermal properties:** GO synthesized from graphite exhibits a low thermal conductivity of $0.5^{-1} \text{ W m}^{-1} \text{ K}^{-1}$.⁴⁶ While high thermal conductivity is desirable for many applications, GO's low thermal conductivity can be advantageous in specific situations. For example, it can be used to provide high thermal insulation in applications such as home insulation and flame retardants. GO has been shown to be an effective filler in polymer nanocomposites to improve their flame-retardant properties.⁴⁷

GO possesses oxygen functional groups that enhance its dispersion in water and organic solvents, facilitating easy integration with active materials like metal oxides and conductive

polymers.^{48,49} These groups also promote strong interfacial interactions, improving the stability and performance of composites. Although GO is initially insulating, a controlled reduction converts it into reduced graphene oxide (rGO), which has tunable electrical properties—important for boosting electrode efficiency in energy storage devices. Its high surface area provides abundant active sites for ion adsorption in supercapacitors and improves electrode–electrolyte contact in batteries. Additionally, their mechanical flexibility makes them ideal for next-generation flexible and wearable energy devices, where durability and adaptability are essential.⁵⁰

GO and reduced graphene oxide (rGO) composites are essential for enhancing energy storage device performance. In supercapacitors, combining GO/rGO with pseudocapacitive materials like MnO_2 , $\text{Ni}(\text{OH})_2$, or conductive polymers such as polyaniline and polypyrrole significantly boosts charge storage and energy density through synergistic effects.⁵¹ For lithium and sodium-ion batteries, GO acts as a stabilizing backbone for silicon and metal oxide anodes, minimising damaging volume expansion during cycling. It also serves as a conductive scaffold in sulfur-based cathodes, improving charge transfer in Li–S and Na–S batteries.⁵² In emerging zinc-ion and aluminum-ion systems, GO/rGO promotes faster ion diffusion and prevents metal dendrite formation at electrodes. Recent advances demonstrate these composites' promise, with GO-enhanced Li-ion anodes achieving capacities over 1000 mAh g^{-1} and supercapacitor electrodes surpassing 300 F g^{-1} , all with excellent long-term cycling stability, making them promising for next-generation energy storage.^{53,54}

2.2.2. Different synthesis methods of graphene oxide. The synthesis of graphene oxide (GO) can be categorized into two main methods: bottom-up and top-down approaches. Bottom-up methods involve constructing pristine graphene from simple carbon molecules, while top-down methods extract graphene derivatives from a carbon source, typically graphite.

Bottom-up synthesis: techniques like chemical vapor deposition (CVD)⁵⁵ and epitaxial growth on silicon carbide wafers are considered bottom-up approaches for GO synthesis. However, these methods have been found to be time-consuming and face challenges in scalability.

Top-down synthesis: the first synthesis of GO is credited to Brodie, Staudenmaier,⁵⁶ and Hummers and Offeman. Hummers and Offeman's method,⁵⁷ in particular, became widely used due to its safer and more scalable nature. It involves the oxidation of graphite using KMnO_4 as the oxidizer, followed by the addition of sodium nitrate to form nitric acid *in situ*. The resulting Hummers' method, or slightly modified versions of it, are commonly employed for generating GO (Fig. 3).⁵⁸

In the Hummers' method, a carbon source (typically graphite flakes or powders) is placed in a protonated solvent (*e.g.*, sulfuric acid or phosphoric acid) with the introduction of a strong oxidizing agent (usually KMnO_4). The mixture is then diluted, treated with H_2O_2 to remove metal ions from the oxidizer, resulting in a yellow–brown liquid. The solids are separated, treated with dilute hydrochloric acid to further remove any metal species, and then washed and centrifuged with water until the solution's pH is nearly neutral.

Fig. 3 Schematic of the most common GO synthesis methods reproduced from ref. 59 with permission from the American Chemical Society, *ACS Nano*, D. C. Marcano, D. V. Kosynkin, J. M. Berlin, *et al.*, 2010, © 2010 American Chemical Society.

Novel approaches to GO synthesis have been proposed, such as stationary oxidation mechanism,⁶⁰ which leads to larger GO sheets. Another popular modification is the “improved Hummers” method,⁶¹ which omits sodium nitride and incorporates phosphoric acid and a higher amount of KMnO_4 . This modification eliminates toxic gases, enables easy temperature control, and produces GO powders with a higher degree of oxidation. The diverse methods of GO synthesis allow researchers to tailor the material's properties for specific applications, from electronics and energy storage to biomedical devices and composites.

As well as showing good energy storage properties, rGO and GO are promising materials in composite and hybrid forms. rGO/ Fe_3O_4 composite nanomaterials showed high capacities (1120 mAh g^{-1}) at low rates (0.1 A g^{-1}), when tested as anode materials in lithium-ion batteries, thanks to both redox reactions and conductivity provided by the rGO network;⁶² similarly, GO hydrogel electrodes showed 210 F g^{-1} specific capacitance in aqueous supercapacitor systems because of their open pore structure and connectivity;⁶³ Finally, rGO/polyaniline film electrodes displayed long term cycling capabilities, retaining more than 85% of their capacitance through 10 000 cycles, and thus could be considered for use in flexible or wearable devices.⁶⁴

2.3. Reduced graphene oxide

Graphene oxide (GO) is a form of graphene that contains oxygen functional groups. When GO is subjected to reduction, these functional groups are eliminated, resulting in the formation of reduced graphene oxide (rGO). Although rGO still possesses some oxide functionalities, its structure becomes more similar to graphite, with much wider interlayer spacing (ranging from 6 to 12 Å) due to the insertion of water molecules.^{65,66}

The reduction process of GO to rGO involves the removal of oxygenated functional groups, leading to a material that retains the basic graphene framework but with improved electrical conductivity and other desirable properties. The wider interlayer spacing in rGO allows for enhanced interactions with various molecules and ions, making it a promising material for various applications, including energy storage, sensors, and catalysis. The unique combination of graphene-like structure and residual oxide functionalities in rGO makes it a versatile and valuable material for emerging technologies (Fig. 4).

The removal of oxygen functional groups during reduction leads to the restoration of sp^2 hybridization in the graphene lattice, resulting in improved electrical conductivity compared to GO. This enhanced conductivity makes rGO a promising candidate for

Fig. 4 Reduction of GO to rGO reproduced from ref. 67 N. Balqis, B. M. Jan, H. S. C. Metselaar, A. Sidek, G. Kenanakis and R. Ikram, *Materials*, 2023, 16, 3726, © 2023. The authors (CC BY 4.0).

applications in electronics, such as flexible and transparent conductive films and electrodes for energy storage devices.

Furthermore, the wider interlayer spacing in rGO allows for greater accessibility and diffusion of molecules and ions, making it advantageous for applications in gas sensing, water purification, and electrochemical catalysis. The residual oxide functionalities in rGO also provide sites for chemical functionalization, enabling tailored surface modifications and improved compatibility with other materials.

2.3.1. Properties of reduced graphene oxide (rGO).

- **Mechanical properties:** Gomez-Navarro⁶⁸ reported that an rGO monolayer, produced by the original Hummers' method followed by thermal annealing in a hydrogen environment, exhibited a Young's modulus of 250 ± 150 TPa. The reduced GO sheets also demonstrated remarkable stability in their electrical properties against deformation. Electrical resistance measurements before and after repeated deformation showed that the resistance of the monolayers remained unchanged as long as the indentation depth was less than 10 nm. This mechanical and electrical stability makes rGO an attractive material for applications where consistent and reliable electrical contacts are required during deformation.⁶⁹

- **Electrical properties:** reduction of GO improves its electrical conductivity. However, the presence of residual sp^3 -bonded carbon to oxygen in rGO restricts the movement of charge carriers through the sp^2 clusters. As a result, the electrical transport in rGO occurs mainly through hopping, which is different from mechanically exfoliated graphene. Despite this, the improved electrical properties of rGO make it a promising conductive filler in polymer matrices for various applications, especially in electronic devices.^{70,71}

- **Thermal properties:** rGO exhibits enhanced thermal conductivity, primarily due to its high conductivity, providing a low-resistance path for phonons owing to the large aspect ratio and interfacial contact area. Annealing GO at high temperatures (1000 °C) to produce rGO films can significantly improve in-plane thermal conductivity, increasing it from 3 to 61 W ($m^{-1} K^{-1}$). These films also display anisotropic thermal conductivity, with a notable cross-plane thermal conductivity of 0.09 W ($m^{-1} K^{-1}$) and an in-plane to cross-plane thermal conductivity ratio of 675. This anisotropy can be advantageous for applications that require directional heat conduction.⁷²

rGO provides several key advantages for energy storage thanks to its unique structural and electronic properties. By restoring part of its conjugated carbon network, it significantly boosts electrical conductivity compared to GO, facilitating efficient charge transfer in battery electrodes and supercapacitor films. Its larger interlayer spacing ($\sim 6\text{--}12$ Å) enables rapid ion intercalation, which is particularly beneficial for multivalent batteries like zinc-ion and aluminum-ion types, where larger ions must move freely. The material also maintains mechanical flexibility and stability, ensuring long-lasting performance in flexible and wearable energy storage devices.^{70,71} Additionally, the remaining oxygen groups on rGO act as anchoring sites for nanoparticles, metal ions, and polymers, allowing for the creation of tailored composites that improve electrochemical performance.

rGO plays a key role in improving lithium-ion and sodium-ion batteries by forming a conductive network around high-capacity electrode materials like Sn, Si, and Fe_3O_4 . Its flexible yet strong structure helps buffer the significant volume changes these materials undergo during charge and discharge cycles, boosting the electrode's stability and lifespan. In some cases, rGO acts as an anode material itself, offering reversible capacities ranging from 300 to 600 mAhg⁻¹. Its performance is influenced by factors such as porosity and the number of layers stacked.^{73,74}

In supercapacitor applications, rGO enhances both electric double-layer capacitance (EDLC) and pseudocapacitance when paired with metal oxides or conductive polymers. This dual role allows for specific capacitances between 200 and 350 F g⁻¹, while also providing excellent rate capability, which is essential for high-power uses.⁵¹

Beyond conventional energy storage devices, rGO functions as a flexible conductive framework in hybrid systems. It forms the foundation for advanced ternary composites like rGO/metal oxide/polymer and acts as lightweight current collectors in flexible electronics, highlighting its adaptability for future energy storage technologies. These diverse roles make rGO an essential element in modern electrochemical energy storage systems.

2.3.2. Different synthesis methods of reduced graphene oxide.

Synthesis of reduced graphene oxide (rGO) involves the removal of oxygen functional groups from Graphene Oxide (GO) through thermal, chemical, or electrochemical methods. Several key factors must be considered during GO reduction, including achieving the desired C/O ratio, selectively removing oxygen groups, repairing surface defects, and preserving the physical and chemical properties of GO, such as mechanical strength, conductivity, optical properties, and solubility/dispersibility of nanosheets.^{75,76}

Thermal reduction: GO can be thermally reduced through annealing in an oxygen-free environment or unconventional methods like microwaving GO powder or flash reduction of GO films using high-intensity light. These approaches offer simplicity and scalability but require careful control to avoid over-reduction and preserve the desired properties of rGO.⁷⁶

Chemical reduction: chemical reducing agents are commonly added to GO solutions for reduction, and several well-supported techniques are available in the literature. These agents can include hydrazine, metal hydrides, hydrohalic acids, and other suitable chemicals. Careful selection and control of the reducing agent are essential to achieve the desired reduction level while minimizing unwanted side reactions.⁷⁷

Photocatalyzed reduction: rGO can also be synthesized through photocatalyzed reactions. UV light in the presence of a TiO_2 catalyst has been shown to effectively reduce GO, as demonstrated by the previous study.⁷⁸ This approach provides a green and energy-efficient alternative to traditional reduction methods.

Electrochemical reduction: electrochemical reduction of GO is a chemical-agent-free process that relies on electron exchange between GO and the electrodes of an electrochemical cell. This approach offers precise control over the reduction process and

has been explored as a promising method for producing rGO with tailored properties.⁷⁹

In recent years, there has been growing interest in “green” reducing agents for synthesizing rGO, such as ascorbic acid, sugars, amino acids, and even microorganisms. These green methods offer environmentally friendly alternatives and reduce the generation of chemical waste. The choice of reduction method depends on the specific requirements of the application, scalability, energy usage, and waste management considerations. Researchers are continually exploring and optimizing various reduction strategies to tailor the properties of rGO for diverse applications, including electronics, energy storage, sensors, and composites.

2.4. MXenes

MXenes are a family of transition metal carbides, nitrides, or carbonitrides that are derived from the chemical delamination of 3D ternary (or quaternary) compounds known as MAX phases. These MAX phases serve as precursors to MXenes and have the general stoichiometry $M_{n+1}AX_n$, with $n = 1, 2, \text{ or } 3$. Here, “M” represents a d-block transition metal, “A” denotes group 13 and 14 elements like Si, Al, Ge, or Sn, and “X” consists of carbon, nitrogen, or a combination of both.⁸⁰

The structure of MAX phases features a hexagonal arrangement with space group $P6_3/mmc$, where layers of “M” and “A” elements are interleaved, and “X” atoms occupy the octahedral sites formed by “M” elements. This layered structure allows for the exfoliation of MAX phases into 2D MXenes by selectively removing the “A” layer, leaving behind the transition metal carbide or nitride layers.^{81,82}

MXenes are denoted by the general formula $M_{n+1}X_nT_x$ ($n = 1-3$), where “M” represents various transition metals like Sc, Ti, Zr, Nb, and others, “X” represents carbon and/or nitrogen, and “ T_x ” accounts for the hydroxyl, oxygen, or fluorine terminations that result from the synthesis procedures.⁸²

In addition to being derived from MAX phases, MXenes can also be obtained from other layered compounds such as $Zr_3Al_3C_5$ and Mo_2Ga_2C . With more than 70 known MAX phases and new discoveries being made regularly, MXenes present a rich and diverse family of 2D materials with fascinating properties and potential applications in various fields, including energy storage, catalysis, and electronics.⁸³

The unique properties of MXenes, stemming from their 2D layered structure and tunable surface terminations, make them highly versatile and promising materials for a wide range of applications. Due to their excellent electrical conductivity, MXenes have found applications in energy storage devices, such as supercapacitors and lithium-ion batteries, where they demonstrate superior performance compared to conventional materials. Their high surface area, tunable surface chemistry, and catalytic activity have also led to their use as efficient catalysts in various chemical reactions.⁸⁴

Moreover, MXenes exhibit exceptional mechanical strength and flexibility, making them attractive candidates for use in flexible electronics and wearable devices. Their tunable electronic band structures, ranging from metallic behavior to

semiconducting properties, offer opportunities for designing novel electronic and optoelectronic devices. Additionally, the large interlayer spacing in MXenes enables facile intercalation of different ions and molecules, making them promising candidates for ion sieving membranes, sensors, and gas separation applications.

2.4.1. Properties of MXene. MXenes are a revolutionary class of materials for energy storage, showcasing exceptional versatility in various device designs. In supercapacitors, they uniquely blend electric double-layer capacitance with redox-based pseudocapacitance, reaching industry-leading volumetric capacitance over 1500 F cm^{-3} and specific capacitance between $400-700 \text{ F g}^{-1}$. Their inherent flexibility, ease of processing in solutions, and compatibility with aqueous electrolytes make them ideal for next-generation wearable devices and micro-supercapacitors integrated on chip.⁸³

When used as anodes in lithium-ion and sodium-ion batteries, MXenes provide outstanding rate capability and long-term stability, retaining reversible capacities of $300-500 \text{ mAh g}^{-1}$ over thousands of cycles.⁸⁵ This is due to their expanded interlayer spacing and highly conductive surfaces, facilitating fast ion intercalation—crucial for high-power applications. Their usefulness extends to multivalent systems, effectively preventing zinc and aluminum dendrite formation and boosting ion transport at electrode interfaces. The materials’ adjustable interlayer chemistry and high charge density make them especially suited for hosting divalent and trivalent ions.

Beyond individual applications, MXenes excel in hybrid systems. When combined with polymers or metal oxides, they form composites that integrate the strengths of batteries and supercapacitors—offering greater stability, higher capacitance, and enhanced mechanical properties. These hybrid configurations push energy storage technology forward, enabling devices with unmatched energy and power densities.

- **Structural properties:** MXenes typically possess surface groups such as F, OH, and O after being extracted from the MAX phase. Among these terminations, O- and OH- terminated MXenes are considered the most stable, as F terminations tend to transform into OH groups through rinsing or water storage. Notably, OH terminations can be further transformed into O terminations through high heat or metal adsorption processes. However, O-terminated MXene may break down into bare MXene when in contact with certain metals like Mg, Ca, or Al. Understanding the stability of different surface terminations is crucial in tailoring MXene properties for specific applications.^{83,85}

- **Electric properties:** the electric properties of MXenes depend on their composition and surface terminations. Bare MXene species with the general formula $Ti_{n+1}X_n$ exhibit metallic behavior. However, as the value of “ n ” increases, the metallic properties become weaker due to the addition of Ti-X bonds. For example, titanium nitrides generally have stronger metallic properties than titanium carbides due to the N atom having one more electron than the C atom. On the other hand, terminated MXene sheets can exhibit either narrow-band-gap semiconducting or metallic behavior, depending on the type and

orientation of surface groups. The tunability of the electronic structure in MXenes is essential for applications in optoelectronics and optics, where achieving a direct band gap is of particular interest.⁸²

- **Chemical properties:** MXenes can undergo oxidation in certain environments, leading to the formation of TiO₂ nanocrystals embedded in amorphous carbon sheets (TiO₂-C hybrid structure). The oxidation mechanism can result in the formation of different TiO₂ phases, such as anatase or rutile, depending on factors like reaction time and temperature. These chemical properties provide valuable insights into the stability and reactivity of MXenes, influencing their potential applications in catalysis, energy storage, and other fields.^{86,87}

2.4.2. Different synthesis methods of MXenes. MXenes are synthesized from MAX phases through a series of chemical reactions that involve dissolving the MAX phase in specific acids. The process requires precise corrosion times and agitation to break the M-A bonds and remove the A atom layers, resulting in the formation of MXenes, which are transition metal carbides, nitrides, or carbonitrides. One of the first MXenes to be synthesized was Ti₃C₂T_x, achieved by treating Ti₃AlC₂ powders with 50% HF for 2 hours at room temperature. This process replaced the Ti₃AlC₂ with Ti₃C₂T_x, as confirmed by X-ray diffraction (XRD) patterns.⁸⁴

The XRD pattern after HF etching displayed shifts that were consistent with the presence of functional groups in the resulting MXene. The method of HF etching was successfully applied to various other MAX phases, leading to the discovery of numerous new MXenes with different compositions, such as Ti₂CT_x, V₂CT_x, Nb₂CT_x, Ti₂NT_x, (V_{0.5}Cr_{0.5})₃C₂T_x, (Ti_{0.5}Nb_{0.5})₂-CT_x, Mo_{4/3}CT_x, Nb_{4/3}CT_x, W_{4/3}CT_x, Ti₃C₂T_x, Ti₃CNT_x, Nb₄C₃T_x, Ta₄C₃T_x, V₄C₃T_x, Mo₂TiC₂T_x, and Cr₂TiC₂T_x.^{84,88,89}

The distinction between M-X and M-A bond strengths is crucial for the synthesis of MXenes. The weaker M-A bonds allow for the removal of A atom layers from the MAX phase, leaving behind the desired carbides, nitrides, or both. The initial synthesis process involved treating the MAX phase with HF and exfoliating the resulting multi-layered structure through ultrasonication in alcohol solvents. The chemical reactions during the synthesis led to MXene termination with hydroxyl, fluorine, and later oxygen atoms, replacing the original Ti-Al bonds.

The prepared MXene samples typically consist of stacked multilayer flakes held together by weak interlayer interactions, allowing for easy exfoliation through ultrasonication. The discovery and synthesis of various MXenes have opened up exciting possibilities for their applications in diverse fields, including energy storage, catalysis, electronics, and more. Continued research and exploration in the field of MXenes hold the potential for further advancements and novel applications of these fascinating 2D materials.^{88,90,91}

MXene is a new family of high performance electroactive material that have been shown to be good electrodes because of their excellent electrical conductivity and highly hydrophilic surface properties. Ti₃C₂T_x MXene thin film was able to demonstrate one of the highest reported values of volumetric capacitance (*i.e.*, 1500 F cm⁻³) at low scan rates in aqueous

supercapacitor systems.⁹² The enhanced lithium storage ability of the MXene/graphene hybrid was also demonstrated by achieving 320 mAh g⁻¹ at 1 A g⁻¹ through the improvement of structural stability and enhancement of ion diffusion.⁹³ Furthermore, Ti₃C₂T_x based supercapacitors were able to exhibit long term cyclic durability with 70% capacitance retained over 100 000 charge/discharge cycles, indicating that these materials are suitable for high frequency applications.

2.5. Molybdenum disulfide (MoS₂)

Transition Metal Dichalcogenides (TMDs) are an intriguing class of 2D materials with the formula MX₂, where M is a transition metal like molybdenum or tungsten, and X is a chalcogen such as sulfur or selenium. They have a distinctive sandwich-like structure, with metal atoms between two chalcogen layers (S-M-S or Se-M-Se), held together by weak van der Waals forces. This allows for easy mechanical or chemical exfoliation into atomically thin sheets. TMDs are especially interesting because their electronic properties can be tuned—they can act as semiconductors (MoS₂, WS₂), metals (NbSe₂), or superconductors, depending on their composition and layer thickness. Their versatile electronic features, large surface area, and ability to intercalate ions make them highly promising for energy-related applications. They are used as high-capacity battery electrodes with enhanced cycling stability, contribute to pseudocapacitive energy storage in supercapacitors, and serve as efficient electrocatalysts for hydrogen production. Molybdenum disulfide (MoS₂) is a well-studied example, widely researched for uses ranging from lithium-ion batteries to hydrogen evolution, because of its well-understood properties, ease of synthesis, and strong electrochemical performance across various energy systems.⁸⁵⁻⁸⁷

Molybdenum disulfide (MoS₂) is an inorganic compound that belongs to Transition metal dichalcogenides (TMDCs). It consists of two atoms of sulphur and one atom of molybdenum. Transition metal dichalcogenides are chemical compounds consisting of a transition metal (Groups 4–12) and a chalcogen (Group 16). The monolayer MoS₂ is a semiconductor with bandgap of 1.8 eV and its distinctive structure makes it a promising material to substitute graphene and making it feasible for 2D materials to be used in the future and optoelectronic devices. MoS₂ is an excellent material for making thin-film transistors, because its fabrication is simple which means large production yield and low cost. The covalent bonds between molybdenum and sulphur and the van der Waals bonds between its layers make it optimal for gas sensing. MoS₂ has achieved primary progress in the fields including energy conversion and storage and hydrogen evolution reaction (HER). In addition, MoS₂ with odd number of layers could produce oscillating piezoelectric voltage and current outputs, indicating its potential applications in powering nano-devices and stretchable electronics.^{86,94}

2.5.1. Properties and structure of MoS₂. The chemical formula of MoS₂ is MX₂ where M means transition metal and X means chalcogen, and their family belongs to superconducting, semiconducting and metallic. The single layer of

Fig. 5 MXene preparation by MAX phase etching.

MoS₂ is arranged in a sequence of S–Mo–S by valent bonds in a sandwich like structure (M (+4) S(–2)). Although the relatively weak van der Waal forces influences the interaction of the sandwich like structure and these sandwich layers are approximately 0.65 nm in thickness.⁹⁵

The bulk (3D) structure of MoS₂ possibly tetragonal (T), hexagonal (H) and rhombohedral (R), where 2H MoS₂ means 2-layer hexagonal shape MoS₂. MoS₂ has basically three main structures such as 1T, 2H and 3R, where the 1T is octahedral structure and 2H and 3R is trigonal prismatic in structure (Fig. 5). The 1T structure is metallic and 2H, 3R are semi-conducting and these two are used as dry unguent (Fig. 6).⁹⁶

Every TMD polymorph possesses incomparable structures and electrical properties from where dissimilar catalytic properties are able to come out. Hence, it is crucial to make a contrast of distinct TMD polymorphs, intending to understand the effect of polymorph structure on the catalytic characters of TMD materials. When TMD materials subjected to chemical exfoliation, 2H → 1T phase change occurs and the catalytic characteristic of 1T and 2H has been exfoliated. The metallic 1T phase of MoS₂ exhibits a greater level of HER activity than does the semiconducting 2H phase of MoS₂, as a result of increased conductivity, more accessible surface sites and thinner flake size. This was explicated by the enhanced edge-

exposed surface, reduced sheet size and improved electrical conductivity of the 1T phase.⁹⁸

Transition Metal Dichalcogenides (TMDs), such as MoS₂, feature a distinctive layered structure with van der Waals gaps that enable efficient ion intercalation and diffusion. This behaviour is similar to graphite but offers additional functionalities. Their electronic properties differ significantly between phases: the naturally occurring 2H phase acts as a semiconductor suitable for optoelectronics, while the chemically induced 1T phase becomes metallic, greatly increasing conductivity and electrocatalytic activity. With a very high specific surface area, these materials enhance electrolyte contact, improving charge storage. Their tunable bandgap and defect chemistry also allow precise manipulation of charge transport and redox processes.⁸⁷

In lithium and sodium-ion batteries, MoS₂'s layered structure enables efficient Li⁺/Na⁺ insertion, providing theoretical capacities close to 670 mAh g⁻¹. When combined with conductive additives like graphene or carbon nanotubes, it achieves impressive cycling stability, with the metallic 1T phase offering better rate capability compared to its semiconducting form. For supercapacitor applications, MoS₂ delivers substantial pseudocapacitance through reversible redox reactions at molybdenum centres, often exceeding 300 F g⁻¹ when nanostructured into flower-like shapes or combined with conductive supports.⁹⁸ These materials excel in hybrid devices, where MoS₂-based composites combine faradaic storage with electric double-layer capacitance, creating asymmetric systems that optimise energy and power density while maintaining mechanical strength. The ability to precisely control phase, morphology, and composite formation makes MoS₂ a highly versatile platform for next-generation energy storage technologies.

- **Optical properties:** the response of a material when a certain wavelength passes through it can be determined by the absorption coefficient and refractive index. The distance of spectrum passes inside the material before getting absorbed is determined by absorption coefficient. If the absorption coefficient is high, the attenuation to the wave applied will be high. The semiconductors have high absorption coefficient for short wavelengths and low absorption coefficient for long wavelengths. MoS₂ has a comparatively large absorption coefficient for the wavelengths from 400 nm to 500 nm with a sharp decay at 500 nm. The reason behind the wide use of MoS₂ in optoelectronics is its tunable bandgap that changes with size and structure; different bandgaps mean tunable photoresponsivity (R), specific detectivity, and response time, and thus, a wide range of applications. The MoS₂ multilayers and monolayers have a high refractive index of more than 2, where it can be used in coating. Since the photoluminescence (PL) spectra are affected by the band gap, doping, and structure of the material, MoS₂ has different PL activity. It has a peak exciton (A) in a single layer MoS₂. The PL properties of monolayer MoS₂ are enhanced by adding H₂O₂ solution, where it acts as a strong oxidizer without changing the crystalline structure of MoS₂.^{83,86,98}

- **Electronic properties:** the multilayer MoS₂ has an indirect band gap of 1.2 eV, which increases with decrease in the

number of layers until we get a monolayer of MoS₂ with a direct band gap of 1.8 eV. However, band gap value of MoS₂ is excellent. Due to the mechanical strain the band gap of MoS₂ changes from direct to indirect band gap and transfers the material from a semiconducting material to metallic.^{99,100}

The properties of MoS₂ are determined by the 4d and 3p orbitals in Mo and S respectively. For the bulk and monolayer MoS₂, the projected density of state is nearly the same but in the monolayer it shows some peaks. When the monolayer MoS₂ is doped with chromium, copper and scandium it changes to an n-type semiconductor and to a p-type when doped with nickel and zinc. Doping with titanium (Ti) transfers MoS₂ to a p-type or n-type semiconductor according to the levels and sites of doping. At low doping levels of Ti below 2.04%, MoS₂ behaves as a p-type. In case of interstitial doping of Ti at 3.57% doping levels, the covalent bond between MoS₂ and Ti are strong which increases the surface dipole moment that induces a reduction in electron affinity of 0.49 eV, where it behaves as an n-type. At high doping levels of 7.69%, the Fermi level shifts towards the conduction band and merges into the conduction band, where the surface dipole moment declines and the electron affinity rises, pinning Fermi level over the conduction band. In this case, MoS₂ changes to a ferromagnetic half-metal with spin polarization equals to 1, that is promising for spintronics. On the other side the substitutional doping of Ti did not show any change in electronic properties for the three doping concentrations (2.04%, 3.57%, 7.69%).⁸⁹

2.5.2. Different synthesis methods of MoS₂. Hydrothermal method under acid condition is used to synthesize MoS₂ materials with distinct structure. Here molybdenum oxide (MoO₃) and potassium thiocyanate (KSCN) were used as the starting materials. In this synthesis process, 1.5 mmol of MoO₃ (0.2159 g) and 4.5 mmol of KSCN (0.4373 g) were dissolved in 40 mL of deionized water and sonicated for 30 min. After the first step, by adding 1 mol L⁻¹ HCl the pH value of the solution is reconciled to 2.0, after that this solution is stirred for 30 min. For hydrothermal treatment, the well mixed solution was transferred to a 50 mL Teflon-lined stainless-steel autoclave about 240 °C for 37 h and cooled to room temperature. After cooling, the solution was centrifuged at 4000 rpm for 10 min, a black powder of MoS₂ was collected. The black powder is then washed with deionized water and ethanol several times and dried in the vacuum oven at 60 °C for 12 h.¹⁰¹

Top-down methods and bottom-up methods are used to synthesize MoS₂, and its end result is in different shapes, size and quantity. The top-down method is actually decided by engraving crystal planes from a substrate that has the crystals set down over it, and the crystals are layered over the substrate in the bottom-up method. The top-bottom methods to get MoS₂ layers is by exfoliation. The weak van der Waals forces between layers of TMDs clear the way at the fore of disparate exfoliation synthesizing methods. A sticky tape is used to rub out the MoS₂ by mechanical exfoliation and the MoS₂ flakes were over it. This method is practically useful in laboratory synthesis but the yield is low. Liquid phase exfoliation is possible by adding chemicals and stirring, foaming or by milling. Liquid phase exfoliation is easy, quick economical and finish in 30 minutes, the carbon

aerogels were used to avert the low yield of this method. This method enhances the electrical conductivity and porosity of MoS₂ and avert the pyrophoric materials that are commonly used in liquid exfoliation. The dangerous materials used in the liquid phase method were cast out by sonication and this technique is easiest. In the sonication from a probe in a shape of bubbles ultrasonic waves produced and when it burst MoS₂ layers will peel. The MoS₂ nanosheet produced by sonication have dispute in practical applications. Commonly, top-down methods are said to have low controllability, and scalability and high cost. When using ultrasound sonication with supercritical carbon in with an intercalating solvent *N*-methyl-2-pyrrolidone (NMP) enhances yield >90% (Fig. 7).^{83,86,98}

- Physical layer deposition (PVD) is a bottom-up method which is applied only in thin layer of MoS₂ and grain size are variable. This method includes ion implantation like molecular beam epitaxy (MBE).

- Chemical vapour deposition (CVD) method is possible to thin and thick layers, where Mo is laid over a substrate and sulfur vapor passes over it. This method has good quality, but low yield.

- The atomic layer deposition (ALD) method is used to fabricate thick and thin films. The method is considered efficient and the layers have fewer impurities that can be used in different applications, including electronics and sensors.¹⁰²

2.4.3. MoS₂ dispersion preparation. MoS₂ dispersions were created by liquid phase exfoliation as has been reported previously.^{86,98} Briefly, MoS₂ powder (10 mg mL⁻¹) was dispersed in *N*-methyl-2-pyrrolidone (NMP) and ultrasonically processed in a bath sonicator (Elmasonic P70H) operating at 37 kHz and 40% amplitude for 12 h while cooling to maintain a stable temperature of 20 °C. After this sonication, the dispersions were centrifuged at 6000 rpm (3139 g) for 30 min to remove any unexfoliated material, the supernatant was then decanted and fresh solvent added before repeating the centrifugation to ensure a narrow distribution of flake dimensions and thickness. The resultant MoS₂ suspensions were stable in solution for several months with no detectable sedimentation.

Because of their layered nature, and the ability to tune phases, MoS₂ and other TMDs are demonstrating promising

energy storage properties. MoS₂ nanosheet anodes (in 1T phase) reached a capacity of 700 mAh g⁻¹ after 200 cycles for LIBs, due to their electrically conductive nature and availability of many sites on which electrochemical reactions may occur.¹⁰³ In addition, supercapacitor electrodes made with MoS₂/rGO composites had a capacitance of 280F g⁻¹ at a discharge rate of 1 A g⁻¹ at low frequency (due to improved charge transport and less restacking).¹⁰⁴ Also, electrodes based on WS₂ nanotubes were able to demonstrate long-term stability, maintaining 90% of their capacity over 5000 cycles and thus proving that materials with TMD structures can be durable.¹⁰⁵

3. Characterisation techniques for 2D materials

Material characterization plays a crucial role in advancing energy storage technologies, as the performance of batteries and supercapacitors largely depends on their material properties. Examining structural, chemical, and electronic characteristics helps optimise efficiency, stability, and energy density. Without accurate characterization, it becomes difficult to connect material traits with device performance, potentially hindering progress in developing new energy storage solutions.

Analyzing 2D materials such as graphene and TMDs presents particular challenges due to their atomic-scale thickness, surface defects, and structural variability. Their ultra-thin nature makes them susceptible to environmental influences, complicating measurements. While defects can sometimes boost catalytic activity, they may also unpredictably affect electrical and mechanical properties. Variations in layer stacking and chemical composition require high-resolution techniques for detailed analysis, as standard methods might overlook critical nanoscale features.

Different characterization techniques provide insights tailored to specific energy applications. For batteries, methods like X-ray diffraction (XRD) and electron microscopy are used to observe phase changes and degradation across cycles. In supercapacitors, surface area measurements and electrochemical impedance spectroscopy (EIS) assess charge storage mechanisms. For hydrogen evolution reaction (HER) catalysts,

spectroscopy and microscopy help identify active sites and surface characteristics. Selecting the right method is key to addressing material-specific challenges and improving device performance (Fig. 8).

3.1. Spectroscopic techniques

3.1.1. Raman spectroscopy

3.1.1.1. Graphene. Graphene has six normal modes and two atoms per unit cell at the Brillouin zone center (Γ). The E_{2g} phonons are particularly active in Raman spectroscopy. The three most distinctive features of graphene's Raman spectrum are the D peak ($1320\text{--}1350\text{ cm}^{-1}$), G peak ($1580\text{--}1605\text{ cm}^{-1}$), and

2D (or G') peak ($2640\text{--}2680\text{ cm}^{-1}$).^{107,108} The D mode is associated with defects and disorder within the graphite layers, while the G and 2D bands represent the hexagonal lattice structure. The D' peak (around $1602\text{--}1625\text{ cm}^{-1}$) may also be present and is linked to defects and a double-resonance process. These characteristic peaks can be studied in graphene-based catalysts, where some parameters may change due to factors such as interaction with the catalyst, number of graphene layers, heteroatom doping, and strain (Fig. 9).^{109,110}

3.1.1.2. Reduced graphene oxide (rGO). Raman spectroscopy (RS) is an invaluable technique for the analysis of Graphene (G) as it provides crucial information about the number of G layers and the presence of defects within the sheets. Moreover, it holds promise as a tool for characterizing the reduction of Graphene Oxide (GO) to Reduced Graphene Oxide (rGO).

In past studies, distinct characteristic peaks have been observed in G's Raman spectrum at around 1600 and 2700 cm^{-1} , corresponding to the graphitic (G) and 2D bands. The G band arises from the vibration of sp^2 hybridized carbon atoms in the honeycomb lattice structure of G, while the 2D band originates from the Raman scattering of second-order zone boundary phonons in G. The intensity, position, and shape of these bands are pivotal in estimating the number of G layers. Notably, the shape (intensity and width) and position of the 2D band show a trend of increasing with an increasing number of stacked G layers.^{107,112,113}

Additionally, a weak defect band (D) is evident around 1400 cm^{-1} in the Raman spectrum of single-layer G, indicating the presence of disorder, defects, or edge sites. This defect band provides valuable insights into the structural properties of graphene-based materials, revealing information about the quality and integrity of the graphene sheets¹⁰⁹ (Fig. 10).

3.1.1.3. Molybdenum sulfide (MoS_2). The crystal structure of the MoS_2 samples was investigated using Raman spectroscopy Fig. 11. The Raman spectra presented in Fig. 11 display the characteristic vibrational modes of MoS_2 . Two prominent Raman peaks are observed at approximately 382 cm^{-1} and 406 cm^{-1} , which correspond to the E_{2g}^1 (in-plane) and A_{1g} (out-of-plane) vibrational modes of Mo–S bonds in MoS_2 , respectively. The appearance of these two characteristic modes confirms the formation of crystalline MoS_2 . An increase in the Raman intensity of these Mo–S vibrational modes is observed, indicating enhanced crystallinity of the MoS_2 samples. Additionally, a weak and broad band centered around 450 cm^{-1} is detected, which is commonly assigned to a second-order Raman scattering process associated with the longitudinal acoustic phonons at the M point of the Brillouin zone (LA(M) mode $\approx 227\text{ cm}^{-1}$). This second-order Raman mode is typically observed in bulk MoS_2 and is attributed to strong electron–phonon coupling. In contrast, samples lacking distinct E_{2g}^1 and A_{1g} modes indicate the absence of well-developed crystalline MoS_2 .¹¹⁵

3.1.1.4. MXene. MXenes constitute a broad class of two-dimensional transition-metal carbides and nitrides with a general formula $\text{M}_{n+1}\text{X}_n\text{T}_x$, where M denotes an early transition metal, X represents carbon and/or nitrogen, and T_x corresponds to surface terminations such as $-\text{O}$, $-\text{OH}$, and $-\text{F}$. The Raman response of MXenes is highly sensitive to their structural features, including layer thickness, surface chemistry, oxidation state, and defect concentration.

The most prominent Raman features of MXenes are typically observed in the $100\text{--}800\text{ cm}^{-1}$ region, where multiple bands arise from lattice vibrations and interactions involving surface terminations. In particular, low-wavenumber peaks appearing in the range of approximately $100\text{--}240\text{ cm}^{-1}$ are attributed to collective lattice vibrations corresponding to E_g and A_{1g} modes.

Fig. 11 Temperature-dependent Raman spectral analysis of few-layer MoS_2 : (a) supported MoS_2 and (b) suspended MoS_2 with layer numbers from 2L to 6L, showing the evolution of the low-frequency shear (S1/B1) modes and the high-frequency E_{2g}^1 and A_{1g} phonon modes. Reproduced from ref. 115, Z. Lin, W. Liu, S. Tian, K. Zhu, Y. Huang and Y. Yang, *Scientific Reports*, 2021, 11, 7037, © 2021. The authors (CC BY 4.0).

Variations in peak position and relative intensity within this region may indicate structural disorder, oxidation, or partial transformation of MXenes, including the possible formation of titanium dioxide (TiO_2), as evidenced by the characteristic anatase-related feature near 150 cm^{-1} .

Raman bands located in the $550\text{--}650\text{ cm}^{-1}$ range are associated with in-plane C–C vibrational modes of the carbon layers and are particularly sensitive to the nature and distribution of surface terminations such as $-\text{O}$, $-\text{OH}$, and $-\text{F}$. Oxidation processes typically result in a red shift of these bands, whereas an increased proportion of $-\text{O}$ -terminated species can lead to a blue shift. At higher wavenumbers ($1000\text{--}1800\text{ cm}^{-1}$), C–C vibrational modes provide insight into the carbon framework of the MXene films and often show significant variation due to differences in surface heterogeneity and structural disorder (Fig. 12).¹¹⁶

MXene Raman spectra can be difficult to interpret due to variations in peak position, shape and intensity based on the thickness of the MXene sample, the type and amount of surface terminating functional groups ($-\text{F}$, $-\text{O}$, $-\text{OH}$), defects and environmental conditions present. Changes in the chemical properties of the surface of MXene samples, such as oxidation, can cause significant shifts and changes in intensity of vibrational modes related to the lattice of MXene.

3.1.2. Fourier transform infrared spectroscopy (FTIR)

3.1.2.1. Graphene oxide and reduced graphene oxide. Monteserin¹¹⁸ conducted an FTIR spectral analysis of GO, and rGO, as shown in Fig. 13. However, after the oxidation process, characteristic bands appeared in GO attributed to the absorption of oxygenated functional groups (Fig. 13).

In GO, a broad band at 3400 cm^{-1} indicated the O–H bond/stretching vibrations of water molecules and other hydroxyl functional groups. Bands at 2927 and 2849 cm^{-1} corresponded to the symmetric and asymmetric stretching of C–H in GO. Similar bands were observed in Gr, resulting from defects in the SP^2 matrix of the graphitic plane, which could also be seen in the Raman spectrum of G. However, the intensity of these bands in GO was significantly higher than in Gr, indicating a higher number of C–H functionalities.^{119,120}

The bands at 1743 and 1210 cm^{-1} were attributed to the C=O and C–O stretching vibrations of –COOH groups at the edges of GO sheets, respectively. In rGO, the intensity of all the above-mentioned bands reduced significantly due to the removal of oxygenated functionalities. Additionally, a few bands appeared at 1050 cm^{-1} , resulting from the stretching vibrations of C–O–C from the epoxy groups.

Fig. 13 FTIR spectra of GO and rGO reproduced from ref. 117 with permission from John Wiley and Sons, *Macromolecular Symposia*, N. Sharma, V. Sharma and Y. Jain *et al.*, 2017, 376, 1–5, © 2017 John Wiley and Sons.

In the FTIR spectra, rGO exhibited a narrower peak at 3420 cm^{-1} compared to GO, indicating a significant reduction in hydroxyl groups through the reduction process with hydrazine hydrate. Additionally, other peaks at 1739 , 1226 , and 1015 cm^{-1} in the FTIR spectra of rGO became less intense when compared to GO, providing further evidence of partial removal of oxygen functional groups.^{121,122}

Despite the reduction process, low levels of residual functional groups were observed to remain at the edges and basal plane of rGO. These residual functional groups contribute to the stability and dispersion characteristics of rGO and can also serve as sites for potential chemical modifications or functionalization. The narrower peak at 3420 cm^{-1} and the reduced intensity of other peaks in the FTIR spectra of rGO indicate the successful removal of oxygen functional groups during the reduction process. This transformation from GO to rGO results in the restoration of sp^2 hybridized carbon structures, leading to improved electrical conductivity and other desirable properties^{121,122} (Table 2).

3.1.2.2. MXene. The FTIR data are consistent with the expected terminal functional groups present on the surface of MXenes (*i.e.*, typically –OH, =O, –F). The main bands include O–H stretching between 3600 – 3200 cm^{-1} from both –OH terminal groups and bound water; M–O bending (M = Ti, V) between 650 – 550 cm^{-1} ; M–F bending (M = Ti, V) between 750 – 700 cm^{-1} ; and C–F stretching between 1400 – 1000 cm^{-1} . The bands that appear within the “fingerprint” region (1400 – 400 cm^{-1}) are very sensitive probes of the termination chemistry and composition, with many exhibiting peak shifts as a result of the presence of mixed termination chemistries and coordinative effects. Bands corresponding to the O–H bending from the –OH terminal groups will appear between 1500 – 1300 cm^{-1} and thus can be used in conjunction with XPS to analyze the surface chemistry¹²³ (Fig. 14).

3.1.3. X-ray diffraction (XRD)

3.1.3.1. Graphene. XRD commonly shows two peaks at 2θ of $\sim 26^\circ$ for pristine graphite and $\sim 11^\circ$ for graphene oxide in graphene-based catalysts. Nguyen¹²⁵ used XRD to study the crystalline phase of frost-like CuO combined with graphene- TiO_2 as a catalyst for photocatalytic degradation of organic pollutants. The results showed typical diffraction signals for graphene, CuO, and TiO_2 . The peak confirmed the graphene presence at 2θ of 25.9° for (002) reflection in CuO–graphene and CuO–graphene– TiO_2 composites. The peaks attributed to polycrystalline monoclinic CuO phase (110), (111), (202), (020),

(311), (220), and (222) confirmed the loading of catalytic species. The existence of anatase TiO_2 was supported by peaks for (101) and (200).

The purpose of using XRD to analyze graphene-based catalysts is to verify the transformation of GO to graphene.^{126,127} Reduced graphene oxide/g- C_3N_4 composite membranes were developed for catalytic degradation of organic contaminants and oil-in-water emulsion separation. XRD was applied to examine GO, rGO/poly-dopamine (PDA), g- C_3N_4 , and rGO/PDA/g- C_3N_4 composites. The analysis of Raman spectroscopy (Fig. 15(a)) and sulfur K-edge XANES spectra (Fig. 15(b)) for the influence of sulfur functionalization and heat treatment on the structural and chemical characteristics of carbon nanotubes (CNTs) are shown in Fig. 15. The variation in the intensity of the D and G bands in Raman spectra for the three types of samples; CNT, oxidized CNT and sulfur treated CNT show varying defect densities and graphitization levels, while high temperature sulfur treatment ($\text{S-CNT}_{1000^\circ\text{C}}$, $\text{S}'\text{-CNT}_{1000^\circ\text{C}}$) leads to increased defects and changes to the carbon structure. The XANES Spectra support the incorporation of sulfur into different oxidation states (red S, sulfoxide, sulfone, and sulfonate) identified by

unique absorption features. The evidence of multiple sulfur environment post heat treatment demonstrates the successful sulfur doping of CNTs, and illustrates how heat treatment processes affect the chemical state distribution of sulfur incorporated in CNTs. These studies provide an understanding of both the structural transformation and the interactions between sulfur and carbon that determine the electrochemical performance of CNT-based electrodes modified with sulfur.¹¹¹

3.1.3.2. Graphene oxide. The (001) lattice plane of GO is evident in its XRD pattern at a 2θ value of 10° , showing distinct peaks. These peaks indicate the considerable space between the graphene sheets due to electronegative functional groups, which prevent close stacking through π - π interactions. There are also studies on Bruker's D8 advanced X-ray diffractometer with monochromated $\text{Cu K}\alpha$ radiation to analyse Gr flakes and GO.^{128,129}

Upon reduction of GO to rGO, the peak at 2θ value of 10° disappears, replaced by two new peaks at 26.8° and 42.7° , attributed to (002) and (100) planes, respectively. These new peaks indicate the restacking of graphene sheets during the reduction process, resulting from removing oxygenated

electronegative groups. This process allows for π - π interactions to take place.¹³⁰ Neutron diffraction is another effective method for characterising the structure of bulk-scale graphene and its derivatives obtained through thermal or chemical reduction. Researchers have found neutron diffraction particularly valuable in evaluating particle size and the number of graphene layers compared to other characterisation techniques.¹³¹ However, utilising neutron diffraction for industrial-scale characterisation of graphene-based materials poses challenges. Despite this, it offers accurate and reliable information about the size and thickness of lateral graphene sheets, enabling improvements in characterisation techniques.

3.1.3.3. Reduced graphene oxide (rGO). The reduction of oxygen-containing functional groups in GO leads to a significant improvement in its π -conjugated structure and the restoration of the graphene crystal phase, as evident in the XRD patterns of rGO. The XRD pattern of rGO exhibits a broad peak at $2\theta = 24.10^\circ$, indicating a remarkable restoration of the graphene structure. Furthermore, the d -spacing of rGO is reduced from 0.97942 nm to 0.36895 nm, providing clear evidence of the efficient removal of oxygen-containing functional groups during the reduction process.

Although the arrangement of the rGO crystal phase (002) is random compared to the high crystallization structure of graphite, this is attributed to the formation of only a few layers of rGO after reduction. The presence of strong van der Waals forces between layers in rGO also contributes to the formation of thick piles of rGO, resulting in a less ordered stacking arrangement.^{132,133}

Another less intense peak is observed at $2\theta = 42.60^\circ$ with (001) orientation, which can be attributed to the turbostratic band of disordered carbon materials. This indicates the presence of some degree of disorder in the rGO structure. The restoration of the graphene crystal phase and the reduction in d -spacing in rGO are indicative of successful reduction and removal of oxygen-containing functional groups, resulting in a material with enhanced π -conjugation and improved electrical conductivity. The unique structural properties of rGO make it a versatile material with a wide range of potential applications, including electronics, sensors, energy storage devices, and composites^{76,109} (Fig. 16).

3.1.3.4. MXenes. XRD is a valuable and straightforward technique to confirm the production of MXenes. The XRD pattern undergoes changes during the transformation from MAX phases (e.g., Ti_3AlC_2) to multilayer MXenes and then to delaminated MXenes. In the initial XRD pattern of MAX, all

Fig. 17 X-ray diffraction (XRD) patterns obtained for Ti_3AlC_2 , dry multilayer $\text{Ti}_3\text{C}_2\text{T}_x$, wet multilayer $\text{Ti}_3\text{C}_2\text{T}_x$ immediately post-etching, and a vacuum-filtered film delaminated (with LiCl). On the right, a schematic illustrates variations in interlayer spacing (orange), d -spacing (green), and c -lattice parameter (pink), in comparison to a $\text{M}_3\text{X}_2\text{T}_x$ structure featuring two layers of intercalant (e.g., water, TMA^+ , Li^+) reproduced from ref. 138 with permission from Elsevier, *Progress in Materials Science*, M. Shekhirev, C. E. Shuck, A. Sarycheva and Y. Gogotsi, 2021, **120**, 100757, © 2021 Elsevier.

crystallographic peaks are observed, consistent with its $P6_3/mmc$ structure (Fig. 17.) As the MAX phase is processed into multi-layer MXene, the XRD pattern of the dried powder shows broader and shifted (00l) peaks and fewer higher-order peaks compared to standard Ti_3AlC_2 . In the hydrated form of multi-layer powder, the higher-order peaks are reduced or absent compared to the (00l) peaks.^{90,135} During etching of Ti_3AlC_2 , the amount of the Al related peaks that appear is decreased, and the (002) peak will move to a lower 2θ angle. The lower 2θ angle is indicative of an increased d spacing due to the termination of hydroxide/hydrogenfluoride (OH/O/F). When delaminated from the substrate it causes higher order peaks to be lost as the material has lost its long range order. These changes in XRD confirm that the MXene has been successfully created.

For delaminated MXene flakes in film form, only the (00l) peaks are present when the flakes are aligned in-plane. In 2D materials, it is common practice to report the (00l) spacing indices as (001), (002), (003), *etc.* because the films are made of randomly stacked identical 2D flakes with one sheet per unit cell. However, in the MXene community, a different indexing convention, such as (002), (004), (006), *etc.*, is more commonly used. This convention originates from their production from MAX phases, which have two layers (M_3X_2) per unit cell in a $P6_3/mmc$ structure. Although the stacking becomes random in delaminated flakes, the (002), (004), (006), *etc.* indexing is often retained to facilitate comparisons with MAX phases.

It's worth noting that referencing the c -lattice parameter or d -spacing as "interlayer spacing" can be somewhat misleading. The c -lattice parameter of MXene represents two MXene sheets and two interlayer spacings, whereas d -spacing only represents one MXene sheet and one interlayer spacing. To determine the interlayer spacing accurately, a two-step process is necessary: first, measure the d -spacing of the dry sample without intercalants, and then measure the XRD pattern in the active state (*e.g.*, wet multilayer powder or freestanding film). The change in d -spacing or half of the c -lattice parameter will indicate the presence of intercalants between the layers. Removing all intercalants can be challenging and may require annealing at high temperatures in a vacuum due to strong bonding.^{136,137}

3.1.3.5. Molybdenum sulfide (MoS_2). In the (100) and (110) plane at 33.69° and 59.51° the characteristic peaks of MoS_2 nanosheets were noticed. Because of the vacancy of (002) reflections and broadness of peaks in contrast with bulk MoS_2 crystals specify that the outcome is single layer or few layer graphene like MoS_2 (ref. 139) (Fig. 18 and 19).

The XRD patterns of MoS_2 prepared under different hydrothermal temperatures (MoS_2 -180, and MoS_2 -200), are presented, showing that the crystallinity of MoS_2 improves with increasing hydrothermal temperature. For the samples synthesized at approximately $150^\circ C$ and $180^\circ C$, a weak diffraction peak is observed at a 2θ value of 32.91° , which corresponds to the (100) plane of MoS_2 , whereas the characteristic and strongest (002) diffraction peak at 14.39° is absent. This observation indicates poor crystallinity at lower temperatures. Consistently, FESEM images reveal the absence of a well-defined layered structure for these samples.

In contrast, for the samples obtained at $210^\circ C$ and $240^\circ C$, diffraction peaks located at 2θ values of 14.39° , 32.91° , 39.69° , and 58.76° are clearly observed, which can be indexed to the (002), (100), (103), and (110) planes of hexagonal MoS_2 , respectively. These peaks are in good agreement with the standard diffraction data for $2H-MoS_2$ ($a = b = 0.316$ nm, $c = 1.230$ nm;

Fig. 19 XRD patterns of MoS_2 prepared at different temperatures reproduced from ref. 140 H. F. Hasmin, C. Imawan and V. Fauzia, *J. Phys.: Conf. Ser.*, 2021, **1951**, 012014, © 2021. The authors (CC BY).

JCPDS No. 37-1492). The (002) peak exhibits relatively higher intensity, which is attributed to the stacking of MoS₂ layers in the MoS₂-210-37 and MoS₂-240-37 samples. No conspicuous diffraction peaks corresponding to impurity phases are detected. These results indicate that hydrothermal synthesis at temperatures above 210 °C favors the formation of phase-pure hexagonal MoS₂ with improved crystallinity.¹⁴⁰

3.1.4. Ultraviolet spectroscopy. As shown in Fig. 20, the absorption peak of the Graphene Oxide (GO) dispersion was observed at 238 nm. This result closely aligns with the previously reported findings, where a similar absorption peak was detected at 231 nm. Li¹⁴¹ further observed a redshift of the absorption peak towards higher wavelengths (>231 nm) with increasing reaction times. This strong absorption peak around 230 nm is attributed to the π - π^* transitions of graphitic C-C bonds.^{122,142}

Following the reduction process, the rGO exhibited a redshift in its absorption peak from 238 to 279 nm (Fig. 20). This is consistent with the redshift observed in a previous report.^{142,143} This shift is attributed to the π - π^* transition of the graphitic C-C ring, indicating the restoration of the graphitic structure in rGO.

The redshift in the absorption peak towards higher wavelengths in rGO compared to GO confirms the successful reduction of oxygen-containing functional groups, leading to the restoration of the graphitic π -conjugated system. This restoration of the π -conjugated structure is a crucial aspect of rGO's improved electrical conductivity and other desirable properties. The absorption spectroscopy results provide valuable insights into the electronic structure and properties of GO and rGO, and they complement the information obtained from other characterization techniques, such as XRD and FTIR spectroscopy. Continued investigations in this area will deepen our understanding of the reduction process and its impact on the optical and electronic properties of graphene-based

materials, opening new avenues for their application in diverse fields, including optoelectronics, sensors, and photovoltaics.^{75,76}

3.1.5. X-ray absorption spectroscopy. X-ray Absorption Spectroscopy (XAS) is a powerful analytical technique for studying MXenes, offering valuable insights into their structural and electronic properties. Although traditionally requiring synchrotron radiation sources, desktop systems with limited capabilities have made XAS more accessible. XAS encompasses two main methods: X-ray Absorption Near-Edge Structure (XANES) and Extended X-ray Absorption Fine Structure (EXAFS).

XANES provides information about the oxidation state of atoms in MXenes, while EXAFS reveals details about bond length and coordination number. These techniques have been extensively employed to investigate the electronic states of MXenes, elucidating the oxidation states of various transition metals. For instance, XANES spectra have revealed that Mo in Mo₂CT_x exhibits an oxidation state similar to MoO₂ (+4), while Nb₂CT_x and Ti₃C₂T_x display oxidation states akin to NbC and TiC, respectively. Notably, the oxidation state of Ti in MXenes can vary depending on factors such as the number of transition metal layers and the outer layer composition, impacting the properties of ordered double transition metal MXene.^{141,142}

XAS is often combined with *in situ* experiments to gain insights into how fundamental properties change during device operations. For example, XANES spectra were employed to monitor the oxidation state of Ti in Ti₃C₂T_x during cycling in an acidic electrolyte, revealing redox energy storage by Ti₃C₂T_x. Similarly, changes in the oxidation state of V in V₂CT_x during Na-ion battery cycling were investigated using XAS. The technique has also been employed to study the effect of intercalation, such as urea intercalation, on the oxidation state of titanium in Ti₃C₂T_x. Furthermore, XAS spatial resolution has allowed researchers to observe variations in the oxidation state of Ti at the edges compared to the basal plane.

3.2. Microscopy techniques

3.2.1. Atomic force microscopy (AFM)

3.2.1.1. Graphene. AFM is a prevalent method for measuring thickness and counting layer number of graphene-based materials. During a measurement, a sharp tip (5–10 nm) on a cantilever scans across the sample surface, collecting data on changes in vibration amplitude and frequency due to the

sample's surface heterogeneity to create a topographic image.¹⁴⁵ These three-dimensional images are used to determine the thickness of graphene films, and with a perfect graphene having a single atom thickness of 0.35 nm, the number of layers can be determined.³⁰ AFM can also determine surface roughness, providing information on surface area and active area.¹⁴⁶ Studied Pd–Fe/graphene catalysts produced through photocatalytic reduction, examining their performance for electrochemical oxidation–reduction of chlorophenols using AFM. The AFM image of the Pd_{0.5}Fe_{0.5}/graphene catalyst showed an irregular crystal block with an average thickness of 1.2 nm (Fig. 21).

3.2.1.2. MXenes. Atomic Force Microscopy (AFM) is a widely used technique for analysing 2D materials, offering valuable information about their lateral dimensions and thickness. However, when determining the thickness of 2D monolayers using AFM, caution must be exercised due to potential influences from surface adsorbates, trapped interfacial molecules, and the imaging method employed. To achieve accurate measurements, it is often preferable to determine the height of the second layer instead of directly measuring the monolayer on the substrate. This approach has also been applied to MXenes.

For example, in the case of Ti₃C₂T_x MXene, the height of the second layer was measured to be 1.6 nm, while the MXene layer directly on the substrate appeared to have a height of up to 3.0 nm. This discrepancy resulted in an overestimation of the thickness compared to its nominal thickness of approximately 1 nm, as confirmed by high-resolution TEM and computational methods. As a result, cross-sectional TEM is considered a more reliable technique for accurately measuring the thickness of monolayers.^{147,148}

It is worth noting that, to date, no scanning tunnelling microscopy (STM) studies have been conducted on MXenes. As research in this field continues to evolve, the use of advanced imaging techniques will likely contribute to a deeper understanding of MXenes' structural properties and their applications in various fields, including energy storage, catalysis, and electronics. The combination of complementary

characterisation techniques, such as AFM, TEM, and STM, will play a crucial role in providing comprehensive insights into MXene materials and their potential for various technological advancements.

3.2.2. Scanning electron microscopy and transmission electron microscopy

3.2.2.1. Graphene. SEM showed that graphene has a 2D planar structure with well-defined interconnected pores. This structure is believed to enhance adsorption and increase active sites for catalysis. Wrinkles and folds were seen, highlighting graphene's flexibility.¹⁴⁹ TEM and HRTEM¹⁵⁰ showed uniform dispersal of MnO₂ nanoparticles in the shape of nanoneedles on the graphene surface, attributed to the graphene's 2D planar architecture.¹⁵¹ The nanoneedles also prevented aggregation to some extent. HRTEM revealed a *d*-spacing of 0.70 nm assigned to MnO₂ (003), indicating its crystalline nature. The dispersion of MnO₂ was due to graphene's 2D planar structure,¹³⁸ while the nanoneedle-shaped MnO₂ prevented graphene aggregation. HRTEM found a 0.70 nm *d*-spacing assigned to MnO₂ (003), confirming its crystalline structure¹⁵² (Fig. 22).

3.2.2.2. Graphene oxide and reduced graphene oxide. Scanning Electron Microscopy (SEM) was employed to examine the morphologies of graphene, GO, and rGO samples. The SEM micrographs obtained at a magnification of 10000× provided highly magnified images of the material's surface. In Fig. 23 the micrographs for graphene, GO, and rGO samples are displayed.

Fig. 23(a) illustrates the micrograph of graphene, revealing a platelet-like crystalline form of carbon. Moving on to Fig. 23(b), the SEM micrograph of GO shows the presence of wrinkled and layered flakes on the surface, indicating that the graphene layers were fully oxidized to GO. These distinctive flakes are a characteristic feature of GO.

In Fig. 23(c), the micrograph of rGO obtained after chemical reduction using hydrazine hydrate is displayed. The rGO surface exhibits crumpled thin sheets that accumulate to form a disordered structure. This transformation from the wrinkled and layered flakes of GO to the crumpled sheets of rGO signifies the successful reduction process.¹⁵⁴

Remarkably, the morphologies of rGO in Fig. 23(c) closely resemble those reported in the previous work,¹⁴² despite their use of the modified Hummers' method, whereas in this study, the improved Hummers' method was employed. This similarity in morphology confirms the effectiveness of the reduction process in both methods.

The SEM observations provide essential visual evidence of the structural changes that occur during the oxidation and reduction processes, enabling a better understanding of the material's properties and behavior. These morphological insights play a crucial role in tailoring and optimizing the properties of graphene-based materials for various applications in fields such as nanoelectronics, composites, and energy storage devices. Further studies in this direction will undoubtedly contribute to the advancement and utilization of graphene-based materials in cutting-edge technologies.^{155,156}

3.2.2.3. *MXenes*. Scanning electron microscopy (SEM) is a powerful technique widely used to visualize and confirm the

formation of MXene structures. However, it's essential to acknowledge that not all etched MXene samples exhibit the characteristic “accordion” structure, which was initially observed in MXene synthesis using high-concentration HF. SEM images of $\text{Ti}_3\text{C}_2\text{T}_x$ synthesized under different conditions (Fig. 24) demonstrate that as the HF concentration decreases, the accordion structure diminishes, and the multilayer MXene adopts a more typical MAX structure appearance. The presence or absence of the accordion structure is dependent on the kinetics of H_2 production during HF treatment.

In situ HF formation methods, like MILD (mild etching of Al in LiF), prior to delamination, yield MXene structures similar to those produced with low-concentration HF. Additionally, SEM analysis can reveal the presence of oxide nanoparticles on the MXene surface due to severe etching and oxidation, which may not be detected by XRD but can be observed through techniques like Raman spectroscopy or X-ray photoelectron spectroscopy (XPS). Such oxide nanoparticles are more likely to be observed

Fig. 24 The SEM images depict: (a) Ti_3AlC_2 (MAX) powder displaying its compact layered structure; (b)–(d) multilayered $\text{Ti}_3\text{C}_2\text{T}_x$ powders synthesized with 30 wt%, 10 wt%, and 5 wt% HF, respectively, with only the 30 wt% HF etching revealing an accordion-like morphology. (e) Multilayered $\text{NH}_4\text{-Ti}_3\text{C}_2\text{T}_x$ powder synthesized using ammonium hydrogen fluoride, and (f) MILD method (etched with LiF in HCl), both exhibiting minimal opening of MXene lamellas, akin to observations in 5F- $\text{Ti}_3\text{C}_2\text{T}_x$. Additionally, (g) and (h) SEM images illustrate single MXene flakes on a porous alumina substrate, etched using 5 wt% HF and the MILD method, respectively reproduced from ref. 157 with permission from the American Chemical Society, *Chemistry of Materials*, M. when etching Ti_3AlC_2 in high-concentration HF for extended periods.¹²⁴

Post-delamination, it is crucial to examine the MXene flakes using SEM, where they are drop-cast onto substrates like porous anodized alumina membrane (Fig. 24(g and h)). This enables the observation of flake size, dispersion, defects, and edge quality. Rather than merely confirming synthesis through images of MXene flakes, it is more valuable to conduct a comprehensive analysis and compare the flakes with other studies, especially in the development of new synthesis methods or the synthesis of novel MXenes. Different flake sizes and shapes can lead to varying properties and suitability for diverse applications.¹⁵⁸

3.2.2.4. Molybdenum sulfide. FESEM and TEM were performed to study the effect of distinct synthesis condition on the surface morphologies of MoS_2 materials, the molar ratio between S/Mo, the different hydrothermal temperature and time. All the samples were synthesized with in molar ratio of 1 : 1 and at hydrothermal temperature about 240 °C and time about 37 h, these possesses layer like structure with 0.5 to 1 μm diameter. When S/Mo ratios were 1 : 1 and 2 : 1, some MoS_2 with nano-flower structure developed on wrapped monolayer. For 3 : 1 and 4 : 1 Molar ratios a matchless structure of nano sheet could be noticed and the nano-flower structure on monolayer MoS_2 vanished.¹⁰¹

Fig. 25 illustrates the morphological evolution of MoS_2 synthesized at a fixed molar ratio of 3 : 1 under different hydrothermal temperatures (150 °C, 180 °C, 210 °C, and 240 °C) and reaction times (25 h, 37 h, and 47 h). Fig. 25(a–c) show that with increasing hydrothermal time, the MoS_2 fragments become smaller, and the samples MoS_2 -150-25, MoS_2 -150-37, and MoS_2 -150-47 tend to aggregate and form coral-like structures with a porous microstructure.

As shown in Fig. 25(d and e), hierarchical flower-like morphologies with diameters of approximately 0.5–1 μm are observed. These structures are composed of numerous petal-like units, where each petal consists of a large number of

ultrathin nanosheets, indicating the strong tendency of MoS_2 to self-assemble into nanoflower architectures. Furthermore, the size of the MoS_2 nanoflowers increases as the hydrothermal time is extended from 25 h to 47 h.

When the hydrothermal temperature is increased to 210 °C, the MoS_2 nanoflower structures begin to disintegrate and gradually transform into MoS_2 nanosheets, as shown in Fig. 25(g–i). In addition, increasing the hydrothermal time from 25 h to 47 h results in the formation of larger nanosheets. At a hydrothermal temperature of 240 °C, the MoS_2 nanosheets further increase in size, indicating enhanced crystal growth under higher temperature conditions.¹⁵⁹

3.3. Other characterisations

3.3.1. Pair distribution function analysis. PDF analysis is a valuable and powerful tool for investigating MXenes, providing essential insights into their structure at the atomic level. However, its application has been limited due to the requirement for large-scale facilities like synchrotrons or neutron sources. Nevertheless, this technique offers unparalleled benefits by determining the distances between all pairs of atoms in the MXene sample, enabling a comprehensive understanding of their structural details, including surface groups, element arrangement, and intercalants.

The combination of X-ray and neutron scattering data in PDF analysis allows researchers to delve deeply into MXene structures, even revealing the proportions of surface groups like OH and O. Despite the relatively few studies utilizing PDF on MXenes, they have yielded substantial information, such as the characterization of surface groups, the impact of etching on MXene structure, and the identification of M and X element locations in complex MXenes. Moreover, PDF has been instrumental in studying transformations from carbide to nitride MXenes and precisely determining the nature and location of intercalants between MXene layers.

Additionally, PDF analysis serves to validate predictions made by molecular dynamics or density functional theory,

corroborating surface terminations or the presence of intercalated ions with water molecules. While not yet widely employed in MXene research, its potential for directly studying structural features, which are often accessible only through computational methods, is increasingly gaining recognition among research groups. Emphasizing and exploring the capabilities of PDF analysis in the MXene field could lead to groundbreaking discoveries and a deeper understanding of these fascinating 2D materials.^{135,160,161}

3.3.2. Brunauer–Emmett–Teller analysis. Measurements of BET surface area and pore size distributions from nitrogen physisorption isotherm analysis using BET models along with BJH or DFT methods are critical to assess ion access and transport kinetics in 2D electrodes being considered for use in battery or supercapacitor applications. Typically, graphene-derived materials (such as rGO or GNP) have high BET surface areas (typically between 300–800 m² g⁻¹; up to approximately 670 m² g⁻¹ for highly exfoliated forms) due to their atomically-thin sheet structure and large micropore/mesopore network facilitating electric double layer capacitance. Conversely, MXene film samples (for example, Ti₃C₂T_x) generally display low BET surface area values (20–200 m² g⁻¹); Multilayered samples produce BET values of 6–18 m² g⁻¹ while delaminated flake samples produce BET values of 60–100 m² g⁻¹, despite theoretically high surface areas (over 1000 m² g⁻¹ per single layer).^{162,163}

Although MXenes have lower BET areas compared to graphene, they exhibit higher volumetric capacitances due to pseudocapacitive intercalation of ions into the interlayer space instead of being reliant on surface adsorption of ions and thus outperform graphene when constrained to small device dimensions. Thus, optimizing the degree of delamination of MXene films and developing porous structure through engineering can effectively balance gravimetric and voltammetric performance of electrodes with practical electrode designs.

3.4. Summary of electrochemical performance of 2D materials

Tables 3 and 4 summarise the electrochemical performance of representative 2D material-based electrodes in supercapacitor and battery systems. As shown in Table 3, hybrid architectures incorporating rGO, transition metal oxides/sulfides, and

heterostructured composites generally exhibit enhanced specific capacitance (>1000 F g⁻¹ in several cases) and improved cycling stability due to synergistic redox activity and improved electron transport pathways. Similarly, Table 4 highlights that integrating 2D materials with high-capacity active phases such as Si, Li-rich NMC, and composite carbon matrices significantly improves reversible capacity and structural stability compared to conventional electrodes. These comparisons underscore the critical role of interface engineering and conductive network formation in achieving high-performance energy storage devices.

4. Energy storage mechanisms

The field of energy storage has seen remarkable advancements with the emergence of 2D materials. These materials possess unique properties and surface reactivity that make them promising candidates for energy storage applications. Among the various energy storage mechanisms explored in 2D materials, three prominent ones stand out: intercalation, adsorption, and conversion reactions. Each mechanism offers distinct advantages and limitations, providing a diverse range of options for designing advanced energy storage devices.

4.1. Intercalation

Intercalation is a process where guest ions or molecules are inserted between the layers of a 2D material's lattice. This mechanism is commonly observed in TMDs and other layered materials. During charging or discharging, ions or molecules (e.g., Li⁺, Na⁺, K⁺) are inserted or extracted between the atomic layers of the 2D material. The intercalation process allows for efficient ion diffusion and provides high charge storage capacity, making it suitable for rechargeable batteries. For example, GO and its reduced form, rGO, can undergo intercalation of ions or molecules between their layered structures. For example, lithium ions can intercalate into the layers of GO or rGO,¹⁷⁷ enabling their use as anodes in lithium-ion batteries. The large surface area and high electrical conductivity of graphene-based materials make them ideal candidates for intercalation-based energy storage systems.¹⁵¹

Intercalation allows for the insertion of a significant number of guest ions or molecules between the layers of 2D materials, leading to high charge storage capacity and energy density. The

layered structure of 2D materials provides pathways for rapid ion diffusion, enabling fast charge and discharge rates. Intercalation reactions are generally reversible, allowing for repeated charging and discharging cycles without significant capacity loss.⁵²

Some 2D materials may have limited redox activity, leading to lower specific capacities than other energy storage mechanisms. Repeated ion intercalation and deintercalation can cause structural degradation and affect the long-term cycling stability of the material.¹⁷⁸

4.2. Adsorption

Adsorption is a mechanism in which gas molecules, ions, or molecules from an electrolyte are adsorbed onto the surface of 2D materials. This process involves weak interactions between the adsorbates and the material's surface, such as van der Waals forces or physisorption. The high surface area of 2D materials facilitates efficient gas or ion adsorption, leading to enhanced energy storage performance. MXenes, such as Ti₃C₂T_x, show excellent energy storage performance through the adsorption of ions on their 2D surfaces.¹⁷⁹ They possess functional groups on their surfaces that facilitate ion adsorption and desorption. MXenes have been explored as electrode materials in supercapacitors, exhibiting high specific capacitance and rapid charge/discharge rates due to their adsorption-based energy storage mechanism.

2D materials typically possess a large surface area, providing ample sites for gas or ion adsorption and leading to high energy storage capacities. Adsorption processes involve weak interactions, enabling fast charge and discharge rates. Adsorption is a reversible mechanism, allowing for repeated adsorption and desorption cycles.¹⁸⁰ In some cases, the adsorption sites on the surface of the 2D material may become saturated, limiting the amount of ions or gas that can be stored. Adsorption processes can be affected by changes in temperature, humidity, or the composition of the surrounding atmosphere, leading to variations in performance.

4.3. Conversion reactions

Conversion reactions involve chemical transformations of the 2D material during energy storage. In these reactions, the structure of the material changes reversibly during charging and discharging. This mechanism often leads to higher energy densities but can suffer from limited cycling stability. Transition metal oxides, such as MoO₃ and MnO₂,¹⁸¹ are examples of 2D materials that undergo conversion reactions in lithium-ion batteries. During charging, the metal oxide undergoes a conversion reaction with Li⁺ ions, resulting in the formation of new compounds. In subsequent discharging, the new compounds are converted back to the original metal oxide structure.¹⁸²

Conversion reactions can lead to higher energy densities compared to intercalation or adsorption mechanisms due to the formation of new compounds. Conversion reactions often involve multiple redox processes, providing multiple charge storage mechanisms, which can enhance energy storage capabilities.¹⁸³

Some conversion reactions may suffer from incomplete reversibility, leading to capacity fading and reduced cycling stability. Conversion reactions can involve complex chemical transformations, leading to slow reaction kinetics and reduced rate capability. During conversion reactions, 2D materials may undergo significant volume changes, leading to mechanical stress and structural degradation.

4.4. Pseudocapacitance

Pseudocapacitance is a unique energy storage mechanism utilized in 2D materials, characterized by reversible redox reactions occurring at the electrode–electrolyte interface. Unlike the conventional electrical double-layer capacitance observed in supercapacitors, pseudocapacitance involves faradaic reactions, where charge is stored through the reversible transfer of electrons between the electrode and the electrolyte. This redox process leads to the formation of a double layer that contributes significantly to the overall charge storage capacity. For example,

transition metal oxides and hydroxides, such as ruthenium oxide (RuO₂), manganese oxide (MnO₂),¹⁸⁴ and nickel hydroxide (Ni(OH)₂), are commonly used as pseudocapacitive materials in energy storage devices. During charging, these materials undergo redox reactions, where metal cations change their oxidation states, accompanied by the reversible adsorption and desorption of ions from the electrolyte. These redox processes allow for efficient and reversible charge storage, making pseudocapacitors promising candidates for high-performance energy storage systems.¹⁸⁵

Pseudocapacitors can exhibit higher energy density than electrical double-layer capacitors (EDLCs) due to the additional redox reactions, allowing for more efficient charge storage. Pseudocapacitive materials can provide rapid charge and discharge rates, making them suitable for applications requiring quick energy transfer. Many pseudocapacitive materials exhibit excellent cycling stability, resulting in long-lasting energy storage devices with minimal degradation over numerous charge–discharge cycles. Pseudocapacitors can deliver high power output, making them ideal for high-power applications.

The specific capacitance of pseudocapacitive materials may not be as high as some intercalation-based systems, limiting the total amount of charge they can store. Pseudocapacitive materials often have limited voltage windows compared to intercalation-based systems, which can impact their overall energy storage capacity. The performance of pseudocapacitive materials depends on the reversibility of the redox reactions. In some cases, irreversible redox reactions may lead to capacity fading over time.

5. Recent advances in 2D materials for energy storage

Recent years have witnessed remarkable progress in the development of 2D materials for energy storage applications. These atomically thin materials offer unique properties and surface reactivity that make them ideal candidates for various energy storage mechanisms. 5.1.5. Advancements in overall battery performance using 2D materials. Advancements in overall battery performance using 2D materials, with their large surface area and unique electronic properties, enable high-capacity electrode design, leading to higher energy-density batteries. These materials can store a larger amount of charge per unit mass or volume, offering longer-lasting and more energy-efficient batteries. Using 2D materials in electrodes and electrolytes facilitates faster ion diffusion and charge transfer kinetics. This results in batteries that can be charged and discharged at higher rates, enabling rapid charging capabilities and shorter device response times. The stability and mechanical robustness of 2D materials contribute to prolonged cycle life in energy storage devices. Reduced electrode degradation and electrolyte decomposition enhance battery performance and longer service life. 2D materials, particularly graphene and its derivatives, are abundant, lightweight, and environmentally friendly. The utilisation of these materials in energy storage devices promotes sustainable battery technologies with reduced reliance on rare and toxic elements.

5.2. Supercapacitors

5.2.1. Supercapacitors and capacitive energy storage. Supercapacitors, also known as ultracapacitors or electrochemical capacitors, are energy storage devices that can store and release a large amount of electrical energy quickly. They operate based on the principle of “capacitance” and are distinct from batteries and conventional capacitors due to their unique energy storage mechanism. Capacitance is a measure of how much charge a capacitor can store per unit of voltage.

In supercapacitors, the electrodes are typically made of porous materials with high surface areas, such as activated carbon, carbon nanotubes, or various 2D materials like graphene and MXenes.¹⁹⁶ When a voltage is applied across the electrodes immersed in an electrolyte, ions in the electrolyte are adsorbed onto the surface of the electrode, forming a layer of charge known as the “electric double layer.” This double layer comprises two regions: the “Helmholtz layer,” which contains specifically adsorbed ions, and the “diffuse layer,” which

contains ions loosely associated with the electrode surface. The adsorption of ions at the electrode–electrolyte interface leads to a significant increase in the effective capacitance of the supercapacitor, resulting in high charge storage capacity. As a result, supercapacitors can deliver large amounts of charge and discharge rapidly, making them ideal for applications that require high power delivery, such as regenerative braking in electric vehicles and powering electronic devices during peak demand.

Due to their unique properties and large surface areas, 2D materials have emerged as promising candidates for various applications in supercapacitors and capacitive energy storage devices. This breakthrough can potentially revolutionise the hydrogen economy, enabling safer and more efficient hydrogen storage for various applications.²²⁴

5.3.5.3. *Van der Waals heterostructures for energy conversion.* Van der Waals heterostructures for energy conversion: Van der Waals heterostructures, which involve stacking different 2D materials with weak interlayer interactions, have emerged as a powerful platform for energy conversion devices. Researchers have demonstrated improved energy conversion efficiencies in photovoltaics and photocatalysis by combining materials with complementary properties, such as light absorption, charge separation, and transport. These novel heterostructures open up new opportunities for designing high-performance and multifunctional energy conversion devices.

Caroline²²⁵ have demonstrated that 2D van der Waals heterostructure based on mixed chalcogenides such as bi-transition layers, have increased performance in supercapacitors due to lower layer stacking and better access for ions to increase the capacitance of the supercapacitors. Ma²²⁶ has developed a new 2D B₄N₄ monolayer that can store 8.2 wt% hydrogen at room temperature with desorption energy levels of 0.18–0.25 eV and the ability to reversibly release hydrogen at room temperature by optimizing the binding sites and using a light weight structure. Cheng²²⁷ has also fabricated a van der Waals heterostructure composed of BP/GeSe that exhibits a Type II band alignment with a band gap of 1.42 eV and exhibited ultra-fast electron and hole charge transfer times of 147 fs and 839 fs respectively; these heterostructures were also able to achieve 11.40% efficiency in converting photons into electrical current.

5.3.5.4. *MXene-based catalysts for fuel cells.* MXene-based catalysts for fuel cells: fuel cells are promising clean energy technologies, and their commercialisation hinges on finding efficient and cost-effective catalysts. Some improvements achieved using 2D materials:

- **Energy density:** energy density refers to the amount of energy that can be stored in a given volume or mass. 2D materials, such as graphene and MXenes, have high specific surface areas and can accommodate a large number of charge carriers, leading to increased energy storage capacity.¹¹ The use of pseudocapacitive materials, like MXenes, in supercapacitors has significantly improved energy density due to their reversible redox reactions at the electrode–electrolyte interface.²³¹

- **Power density:** power density represents the rate at which energy can be delivered or extracted from an energy storage device. 2D materials, with their high electrical conductivity, low resistance, and efficient charge transport properties, enable rapid charge–discharge rates and enhance power density in supercapacitors. Their fast kinetics and ability to handle high current densities result in quicker energy exchange, making them suitable for applications that require quick bursts of power.²³²

- **Cycling stability:** cycling stability refers to the ability of an energy storage device to maintain its performance over repeated charge–discharge cycles without significant degradation. 2D materials have demonstrated excellent cycling stability due to their strong chemical bonds and mechanical stability. Graphene, for instance, has shown negligible capacity loss over thousands of cycles in supercapacitors. The pseudocapacitive behavior of MXenes also contributes to their excellent cycling stability.

- **Enhanced charge transfer kinetics:** the high electrical conductivity of 2D materials, especially graphene, facilitates efficient charge transfer between the electrode and electrolyte, reducing internal resistance and enhancing energy and power densities.²³³

- **Synergy with other materials:** 2D materials can be integrated with other materials, such as metal oxides or conducting polymers, in hybrid supercapacitors. This combination of materials can result in synergistic effects, improving overall device performance and providing better energy density and cycling stability.

- **Tunability:** 2D materials offer tunable properties, allowing researchers to tailor their electronic structure and surface

chemistry for specific energy storage applications. This tunability enables the optimization of energy and power densities to meet the requirements of various devices.⁸¹

The research of Asrar Alam provided an energy density in MXene-based asymmetric supercapacitor applications at 130.27 Wh kg⁻¹ through pseudocapacitive redox reaction and the high surface area of FeZnS/MnZnS nanoparticle, thus significantly exceeding that of conventional capacitors. The study of Zhao²³⁴ reported a power density of 578 W kg⁻¹ in flexible MXene pouch cells due to the high conductivity and reduced resistance pathways present within the two-dimensional (2-D) layered structure as compared to three-dimensional (3-D) materials. Zhang²²¹ demonstrated a 90.3% retention of capacitance in MXene-rGO hybrid supercapacitor applications after 5000 cycles, primarily due to the mechanical stability of the MXene layer as well as the presence of strong covalent chemical bonds between the layers that prevent degradation. Nazarpour-Fard²³⁵ increased charge transfer through N-doped graphene/MXene electrode interfaces and maintained 90.4% of the capacitance retention up to 25 000 cycles by providing efficient electron pathways. A nanocomposite of WO₃ nanoplates on ZnCo₂O₄ nanopetals combined with Ti₃C₂T_x MXene nanofibers (ZCO-WO₃@MXNF) demonstrated enhanced structural stability, charge-transfer efficiency, and electron mobility, enabling a solid-state asymmetric supercapacitor with high energy density (28 Wh kg⁻¹), power density (578 W kg⁻¹), and 93% capacitance retention after 5000 cycles, proving its practical viability by powering LED lights.²³⁶

5.4. Future materials

5.4.1. Single-atom catalysts on 2D supports. Single-atom catalysts (SACs) anchored on 2D materials like graphene, MXenes, and MoS₂ maximize atom utilization and enable tunable redox sites, enhancing kinetics in batteries and supercapacitors. These are functionalized platforms, not standalone materials, where isolated metal atoms (*e.g.*, Fe, Co, Ni, Sn) create well-defined coordination environments.²³⁷

SACs on N-doped graphene, such as Co SAs/CoNC, facilitate uniform Li nucleation with strong binding energies (*e.g.*, -1.58 eV at H1 sites), suppressing dendrites and enabling 98.4% capacity retention over 340 cycles in Li|LFP cells.²³⁸ Fe/Co SAs on carbon supports deliver high capacities (*e.g.*, 14 777 mAh g⁻¹) in Li-O₂ batteries *via* efficient ORR/OER, outperforming Pt/C.²³⁹

On MXenes, Zn SAs enhance polyselenide anchoring per the Sabatier principle, optimizing Na-Se battery kinetics while avoiding overly strong binding that hinders charge-discharge. Co SAs on MoS₂ basal planes *via* sulfur vacancies boost HER overpotentials to 17 mV, surpassing Pt/C.²⁴⁰

Challenges include atom migration under high currents/potentials. Future designs emphasize stable M-N-C or M-O-C coordination and wide-band-gap supports like h-BN, oxides, or nitrides to decouple sites from degradation, ensuring durability in oxidizing/reducing regimes.²⁴¹

5.4.2. Polyoxometalate-2D material hybrids. Polyoxometalates (POMs), redox-active metal-oxide clusters with tunable potentials, form molecular 2D hybrid electrodes *via*

hydrogen bonding on graphene oxide (GO), MXenes, and RGO, enabling proton-coupled electron transfer (PCET) and dense H-bond networks for fast ion transport.^{242,243}

These hybrids leverage POMs' multi-electron redox ("electron sponge" behavior) and 2D supports' conductivity, boosting pseudocapacitance; *e.g.*, asymmetric Mo/W POMs on GO/MXene deliver 384 F g⁻¹ at 1 A g⁻¹ with 91.7% retention after 2000 cycles, achieving 26 Wh kg⁻¹ in HSCs. H-bonded POM gels and POMOFs enhance capacitance and lifetime *via* self-healing, as in PMo₁₂/RGO with high energy/power density from synergistic ion transport.²⁴⁴

Challenges include oxidative instability and leaching in polar electrolytes. Future strategies: covalently/ionically lock POMs into hosts retaining H-bonds; couple with SACs or conductive 2D carbons for redox-mechanical stability.

5.4.3. Rethinking MOFs, COFs, ternary dichalcogenides. MOFs and COFs offer ultrahigh surface areas (>7000 m² g⁻¹) and tunable porosity for ion accommodation, excelling in pseudocapacitive storage *via* linker/metal redox. However, poor intrinsic conductivity (<10⁻⁸ S cm⁻¹), redox-inactive linkers, and framework collapse under high voltages limit direct electrode use.^{245,246}

In contrast, 2D materials like graphene and MXenes provide superior electronic conductivity (>10³ S cm⁻¹), mechanical flexibility, and electrochemical stability, enabling fast charge transport and cycle life >10 000 without additives.

Transition metal dichalcogenides (TMDs, *e.g.*, MoS₂) and ternary sulfides/oxides (*e.g.*, NiCo₂S₄) deliver rich multi-electron redox and decent conductivity but suffer phase transformations, dissolution, and shuttle effects (*e.g.*, polysulfides in Li-S analogs).²⁴⁷

Scholarly positioning treats MOFs/COFs as sacrificial templates for heteroatom-doped carbons or oxides, yielding composites with retained porosity and band gaps; *e.g.*, ZIF-67-derived Co-N-C achieves 1200 mAh g⁻¹ in Li-S with suppressed shuttling.²⁴⁸

TMDs/ternaries integrate into hierarchical heterostructures (*e.g.*, MoS₂@TiO₂, Cu₂Mo₆S₈@carbon), where stable wide gap phases shield fragile actives, enhancing reversibility. This hybrid paradigm leverages 2D platforms' stability over standalone MOF/COF/TMD limitations.

5.4.4. Large bandgap, oxidation-resistant materials. Ultrawide-bandgap (UWBG) materials like h-BN (5.9 eV), Ga₂O₃ (4.8 eV), AlN (6.2 eV), and diamond resist oxidation and corrosion at high potentials (>4 V), prioritizing stability over capacity in harsh electrolytes.²⁴⁹

h-BN hybrids excel as protective scaffolds; *e.g.*, Fe-BN/PANI electrodes deliver 721 F g⁻¹ at 1 A g⁻¹ with 81% retention after 10 000 cycles, leveraging h-BN's inertness for mechanical/electrochemical durability. BCN (borocarbonitride) variants enhance oxidation resistance beyond graphene in supercapacitors.²⁵⁰

Surface passivated MXenes (*e.g.*, polymer-coated Ti₃C₂T_n) maintain capacitance (85% after 5000 cycles) by blocking nucleophilic attacks, enabling high-voltage operation.²⁵¹

Oxide-protected MoS₂ architectures, such as MoS₂@TiO₂ or GO-wrapped 3D MoS₂, suppress dissolution and shuttling; 3D MoS₂/GO retains 37% capacity (277 mAh g⁻¹) after 3000 cycles at 5 A g⁻¹ in Na-ion batteries.²⁵²

Wide-bandgap oxides (Ga_2O_3 , AlN) integrate with 2D layers as electron/ion-blocking shells around SACs/TMDs, defining sharp potential windows and preventing parasitic reactions.²⁵³

Forward designs feature UWBG phases for stability encasing active sites (SACs, POMs, TMDs), shifting focus from capacity to long-term viability in next-gen devices. Key future design principles for advanced electrode materials emphasize decoupling redox activity from structural stability. This involves spatially separating highly active motifs like single-atom catalysts (SACs), polyoxometalates (POMs), and transition metal dichalcogenides (TMDs) from robust structural backbones composed of wide-band-gap oxides, nitrides, or BN like frameworks. Simultaneously, engineers must create multi-scale porosity with strong interfacial bonding either covalent or coordination-based to ensure H-bonded networks, MOF/COF derived carbons, and POM domains retain intimate contact and conductivity throughout prolonged cycling.

A core metric should target broad electrochemical stability windows, compressing high anodic and cathodic limits. Ultrawideband-gap (UWBG) and oxidation-resistant materials serve here not as primary capacity providers but as vital enablers, facilitating safe, durable operation at elevated voltages.

As these emerging trends unfold, 2D materials are likely to play a significant role in shaping the landscape of next-generation energy storage technologies.

7. Outlook & future challenges

Although 2D materials have made significant strides toward developing new forms of energy storage, many important technical hurdles must be overcome before they may be commercially viable on an enormous scale. Thus, it is not enough for future research to focus solely on increasing the internal material properties of 2D materials; researchers must also develop solutions to the practical problems associated with processing, stability, safety and repeatability.

A major hurdle is the chemical stability and long-term reliability of MXenes due to susceptibility to oxidation upon exposure to air, during storage, processing and cycling. A small amount of oxidation can cause substantial reductions in both conductivity and electrochemical activity. Therefore, it will be essential to develop protective surface coatings using antioxidants, to implement methods of solid-state storage or to identify scalable means of encapsulating MXene materials so that they retain their performance characteristics in actual operating conditions. In addition, graphene-based materials frequently undergo “restacking,” which reduces the available surface area and ion-accessible sites. To prevent this restacking, researchers will need to develop nanostructured architectures for graphene-based materials, introduce spacers between layers or create three-dimensional porous frameworks of graphene in order to maintain the structural openness and facilitate optimal charge-transport pathways through the material.

Semiconductor-phase MoS₂ has a limited rate capability and ability to perform high power applications due to its relatively low intrinsic electrical conductivity. The direction of future research includes controlling the phase composition (*i.e.*, 2H → 1T transition) of semiconductor-phase MoS₂ and modulating defects within the crystal structure of MoS₂. Additionally, researchers should consider forming heterostructures by combining MoS₂ with conductive scaffolding (graphene, MXene, CNTs) to increase conductivity while maintaining structural integrity. Achieving mechanical robustness, high mass loading and scalable fabrication of binder-free electrodes remains a primary challenge for both flexible and thick-film configurations.

In addition to material-related challenges, the field faces broader manufacturing and sustainability-related concerns. Most of the synthesis processes currently used for 2D materials such as HF-based MXene etching and high temperature chemical vapor deposition, for example are either extremely energy intensive or dangerous and not feasible for large-scale manufacturing. It is essential to develop green, inexpensive and scalable synthesis techniques that meet sustainability criteria for use in manufacturing 2D materials. Furthermore, environmental and safety factors, including handling of toxic

chemicals, long-term disposal of nanomaterials, and life cycle assessment, must be included in future research to ensure safe and environmentally friendly implementation of 2D materials.

The field is currently in great need of standardized electrochemical test and reporting protocols to compare studies since there is little standardization regarding how electrodes are prepared, mass loaded, what electrolytes are used, and what test procedures are employed. Standardized performance metrics for capacitance, capacity, rate testing, coulombic efficiency and cycling stability would greatly improve the reproducibility of results across studies and ultimately accelerate the selection of appropriate materials for various applications.

Therefore, the road ahead will require complementary advancements in materials chemistry, device engineering, manufacturing and test standards to realize the potential of 2D materials and create scalable, safe and high-performance energy storage technologies that meet global demand.
