## A perspective on the potential impact of microplastics and nanoplastics on the human central nervous system

Kimia Moiniafshari, <sup>a</sup> Alessandra Zanut, <sup>a</sup> Andrea Tapparo, <sup>a</sup> Paolo Pastore, <sup>a</sup> Sara Bogianni <sup>a</sup> and Fazel Abdolahpur Monikh <sup>a,b</sup>

Humans are constantly exposed to microplastics and nanoplastics (MNPs). Although significant gaps remain in our understanding of their adverse effects on human health, it is increasingly evident that MNPs can penetrate physiological barriers and accumulate in various locations within the human body. Analytical limitations in tracking and measuring nanoplastics in physiological media may persist for several years before we can accurately detect these particles in the human body and establish a clear link between exposure to them and associated hazards. In addition to the few studies that have emerged recently, our knowledge of chemicals with properties similar to those of MNPs, as well as other types of nanomaterials, suggests that MNPs may cross the blood–brain barrier (BBB) and potentially induce damage to the human central nervous system. Here, we provide an overview of the limited number of studies available on this topic and present a perspective on the potential pathways through which MNPs may penetrate the BBB. We also discuss the main mechanisms by which MNPs could potentially impact the central nervous system (CNS), with a focus on neurodegenerative diseases such as Alzheimer's disease (AD), Parkinson's disease (PD), multiple sclerosis (MS), and amyotrophic lateral sclerosis (ALS). This information could contribute to the development of tailored studies exploring the negative effects of MNPs on the CNS.

### Environmental significance

The pervasive presence of microplastics and nanoplastics (MNPs) in the environment poses an emerging threat to both ecosystems and human health. While significant research has been conducted on MNP contamination in aquatic environments, their impact on the central nervous system (CNS) and their role in exacerbating neurodegenerative diseases such as Alzheimer's and Parkinson's remains underexplored. This perspective highlights the potential pathways through which MNPs may cross the blood–brain barrier (BBB), inducing oxidative stress and neuroinflammation, that can lead to neurodegenerative disease. By addressing these previously overlooked environmental pollutants, this work aims to inspire targeted studies that can inform better regulation of plastic waste, ultimately protecting human neurological health in an increasingly plastic-laden world. Understanding the mechanistic links between environmental exposure and CNS disorders could lead to transformative policy changes and preventive measures to safeguard future generations.

## 1. Introduction

The increase in plastic products has led to a global environmental challenge with far-reaching consequences. Plastic degradation (by physical, chemical, or biological processes) in the environment releases a staggering amount of micro- and nanoplastics (MNPs).<sup>1</sup> Microplastics are plastic particles and fragments with a size smaller than 5 mm,<sup>2</sup> while nanoplastics are generally defined as particles with a

size smaller than 1  $\mu\text{m}$ .<sup>3</sup> Note that some definitions consider nanoplastics to be particles smaller than 100 nm. This broad definition itself may contribute to the challenges associated with investigating and handling nanoplastics.<sup>4</sup> The most common plastic debris in the environment is reported to be polyethylene, propylene, polystyrene, and polyvinyl chloride,<sup>5,6</sup> although that differs from location to location, which are found mainly accumulating in aquatic ecosystems. In recent decades, the exposure of humans and other organisms to MNPs has increased significantly due to industrial production, application, and mismanagement of plastic waste.<sup>7</sup>

Organisms are exposed to MNPs mainly through inhalation<sup>8</sup> and ingestion<sup>9</sup> (Fig. 1). Air-borne exposure of

Fig. 1 Exposure to MNPs through the common routes. According to the WHO and EFSA report, human can be exposed to different amounts of MNPs in their daily life through various routes, particularly by ingestion and inhalation.<sup>16-18</sup>

humans can occur in both indoor and outdoor environments, although the concentration of MNPs and the flow are different.<sup>10</sup> The outdoor air typically has more flow and circulation, resulting in a lower MNP concentration. In contrast, indoor environments, where infants and children spend more time, have a higher risk of exposure due to the expected higher concentrations of MNP.<sup>8,9</sup> Water-born exposure is another significant pathway for MNPs. Humans can be exposed to MNPs by drinking tap water, consuming beverages from single-use plastic bottles, or even by drinking tea<sup>10,11</sup> soft drinks<sup>12</sup> or beer. Furthermore, several food sources including seafood,<sup>13</sup> sugar,<sup>14</sup> honey, and salt,<sup>10</sup> are reported to be sources for intake of MNPs. The increase in exposure routes for MNPs is particularly concerning for children, as their developing bodies are more vulnerable to the potential health impacts of MNPs.<sup>15</sup>

The effects of MNPs on humans are not well understood due to limitations in human tissue sampling and analytical techniques for *in situ* characterization of these particles.<sup>19</sup> In the human body, the nervous system is a complex network containing a large number of neurons that regulate physiological activities.<sup>20</sup> Although studies on the effect of exposure to MNPs on the nervous system are limited, MNPs are potentially able to cross physiological barriers, *e.g.* the blood-brain barrier (BBB).<sup>21</sup> Translocation and accumulation of MNPs in the brain are expected to cause various forms of damage, mainly through induction of oxidative stress<sup>22</sup> leading to an increase in vulnerability to neurodegenerative disease. Although not yet reported, there appears to be a potential link between increased exposure to MNPs and the rising number of reports on neurodegenerative disorders. This may be important as the data reported by the World Health Organisation (WHO) indicated an increase of up to

18% in the prevalence of neurodegenerative disorders which are known as the seventh cause of death<sup>23,24</sup> (Fig. 2).

From the available body of evidence on the toxicity of MNPs, it is apparent that, like other nanomaterials, the effects of MNPs are largely driven by their oxidative stress-inducing properties. The increase in oxidative stress can affect the structure and function of neural cells, potentially contributing to the development of neurodegenerative diseases<sup>25,26</sup> and the disruption of neurotransmitters.<sup>27</sup> This disruption is particularly concerning regarding acetylcholine (ACh) and dopamine<sup>28</sup> which are the leading causes of neurodegenerative diseases such as Alzheimer's disease (AD) and Parkinson's disease (PD).<sup>29</sup> For example, Gou *et al.*<sup>30</sup> demonstrated that exposure to MNPs can increase the aggregation of amyloid- $\beta$  leading to Alzheimer's. Liang *et al.*<sup>31</sup> reported that MNPs can increase PD by increasing inflammation and neural cell dysfunction. Moreover, Cao *et al.*<sup>32</sup> demonstrated that MNPs can affect neurodevelopment, behavioral abnormalities, and motor neuron function by increasing oxidative stress.

Linking exposure to hazards from MNPs remains a challenge at this stage of scientific progress.

After internalisation, the biological fate of MNPs in the human body, and consequently, their effects are dictated by the physicochemical characteristics of the particle such as particle size, charge, shape, and chemical composition.<sup>33</sup> However, to date, there has been no straightforward and systematic investigation showing that the presence of MNPs can drive the hazard in the brain, depending on their characteristics.

This perspective aims to provide an overview of the potential entry of MNPs into the brain and link the exposure and the particle physicochemical properties to

**Fig. 2** Schematic describing the incidence of neurodegenerative diseases in the population. According to WHO, the prevalence of neurological disorders has risen within the past years. Among the diagnosed neurodegenerative disorders, Alzheimer's disease is known as the most prevalent disease, Parkinson's disease, multiple sclerosis and amyotrophic lateral sclerosis are the other prevalent diseases.<sup>23,24</sup>

neurodegenerative diseases such as AD, PD, and other neurodegenerative diseases. Additionally, it offers insights into the mechanisms of MNPs' effects on the aforementioned diseases. Finally, the perspective highlights the research needed to understand the connection between MNP exposure and the development of these diseases. This perspective excludes biodegradable polymeric materials such as polyvinyl alcohol, polyethene glycol, polyvinylpyrrolidone, and polyphenylene sulfide, and focuses primarily on the most common polymer types (Table 1).

## 2. Mechanisms of MNP entry into the brain

The mechanism through which MNPs enter the brain primarily involves their penetration through the BBB<sup>46</sup> (Fig. 3). More research is still needed to fully understand these pathways for MNPs.<sup>47,48</sup> In general, internalization of

MNPs can occur *via* two main mechanisms: passive penetration and active endocytosis,<sup>49</sup> which includes both pinocytosis and phagocytosis.<sup>49</sup> Endocytosis can occur through clathrin-mediated pathways (typically for small nanoplastics) and caveolin-mediated pathways (usually for larger particles).<sup>50</sup> The mechanisms of MNP penetration are influenced by their physicochemical properties, such as particle size, shape, chemical composition, and surface charge.<sup>51,52</sup>

To date, very few studies have investigated how the size of MNPs influences their penetration through the BBB. This is due to the complexity of conducting such experiments, which require MNPs of different sizes that are detectable in the complex matrices of biological media.<sup>56</sup> Zhou *et al.*,<sup>53</sup> showed that a higher number of smaller-size PS (100 nm) could enter the brain of zebrafish embryos compared to their larger counterparts (500 and 1000 nm), consequently, causing more neurotoxicity. This study used fluorescent-labelled PS

**Table 1** The linkage between MNPs' physicochemical properties and the observed central nervous system diseases

Polymer type	Particle size	Mechanism of toxicity	Neurodegenerative diseases	Ref.
Polystyrene	30–50 nm	Microglia activation, neural suppression, and decrease in neural development	Memory loss, cognitive decline	34, 35
	25, 50 nm	Dopaminergic neuron degeneration, $\alpha$ -synuclein aggregation	PD	36
	30 nm	Oxidative stress, TDP-43 aggregation	ALS	37
	25, 50 nm	Decrease in myeline protein, decrease myeline thickness, increase cell apoptosis	MS	38
Polyethylene	80, 100 nm	Increase in amyloid- $\beta$ aggregation	AD	39, 40
	<20–50 $\mu$ m	Oxidative stress, amyloid plaque aggregation	Cognitive decline, AD	41, 42
Polypropylene	10–30 nm	Oxidative stress, AChE activity reduction, $\alpha$ -synuclein aggregation	Cognitive decline, memory deficit, AD, PD	43, 44
	100 nm	Increase in $\alpha$ -synuclein aggregation	PD	45

**Fig. 3** Consequence of MNP penetration through BBB. Particles with smaller size, can pass the BBB more likely through passive penetration. As the particle size increases, particles are more likely to penetrate through active endocytosis. Particle charge can also affect their penetration through tight junction impairment and damage to cells due to their ability have electrostatic interaction with BBB membrane along with impairment in tight junctions.<sup>53–55</sup>

particles, utilizing fluorescence as a tracer to facilitate the detection of their penetration into the brain. However, it is worth mentioning that the use of fluorescent-labelled particles to represent nanoplastics has fallen out of favour due to the potential release of dyes from the particles,<sup>56</sup> which can lead to inaccurate results and conclusions regarding particle uptake. Thus, strong evidence for the penetration of MNPs through the BBB based on particle size remains questionable. Yin *et al.*<sup>57</sup> used adverse effect assessments to confirm that smaller nanoplastics can penetrate the brain more readily than microplastics. Their findings suggested that the smaller particles appeared to be more toxic.

Nevertheless, medical and environmental studies have already used different types of metallic nanomaterials to demonstrate that particle size plays a crucial role in the ability of nanomaterials to cross the BBB.<sup>52</sup> For example, the study by Liu *et al.*<sup>58</sup> compared different particle sizes of silica nanomaterials for their ability to pass through cerebral endothelial cells in mice. The results indicated that smaller particles (25 nm) were taken up by the brain more efficiently than the 50 nm and 100 nm particles. It has been suggested that large-size nanomaterials are more likely to penetrate through active routes, including pinocytosis (micropinocytosis) and phagocytosis.<sup>50,59</sup> Although the transferability of this knowledge to MNPs is questionable due to differences in chemistry and particle density, factors that significantly influence cellular penetration, these studies provide a basic understanding and a starting point for conducting similar experiments with MNPs.

The shape of MNPs can also influence their penetration through the BBB into the brain as it can modulate their binding to the cell. Da Silva-Candal *et al.*<sup>60</sup> investigated the toxicity of spherical and rod-shaped PS nanoplastics in mice. They demonstrated that rod-shaped nanoplastics can have greater binding capacity compared to the spherical shape PS MNPs. This finding is further supported by Kolhar *et al.*,<sup>61</sup> who compared nano-rods and nano-spheres and showed a higher accumulation of rod-shaped particles. Much more evidence on the influence of particle shape on their penetration in BBB is available for other nanomaterials. For example, Salatin *et al.*<sup>62</sup> reported that rod-shaped gold (Au) nanomaterials have higher affinity and efficacy for endothelial cells, resulting in greater uptake. Sharp-shaped Au nanomaterials instead, can penetrate the membrane more easily compared to the other shapes, resulting in particle localization. The study by Niaz *et al.*<sup>63</sup> on Au nanomaterials demonstrated that the sharp edges of particles enable them to penetrate and cause damage to the membrane more easily than other shapes, which is also reported for the nano-stars and nano-spike-shaped particles.

An important factor that can influence the penetration of MNPs through the BBB, and that also distinguishes different nanomaterials from one another, is the chemical composition of the particles. A recent study by Abdolahpur Monikh *et al.*<sup>21</sup> showed that nanoplastics composed of PS and PVC can cross the BBB, albeit at low concentrations. The study further highlighted that the presence of a biological corona (proteins and metabolites) significantly modulates the penetration efficiency of nanoplastics across the BBB.<sup>21</sup> The formation of the corona on the nanoplastics was dictated by

the chemical composition of the particles. It was also reported that PS, PE, PP, and PVC were able to enter the CNS, and PP and PE caused more inflammation.<sup>33</sup> The study by Abdolahpur Monikh *et al.*<sup>64</sup> demonstrated that different chemical compositions can have different effects on the behaviour of zebrafish embryos, even at the same particle size. It is worth mentioning that, so far, PS MNPs have been more extensively investigated than other plastic particles. This creates a challenge in understanding how chemical composition may contribute to the biological fate and toxicity of the particles.<sup>65</sup>

The particle surface charge is another key indicator of the ability of MNPs to penetrate the BBB.<sup>27</sup> Negatively charged particles are unlikely to pass easily through the membrane due to electrostatic interaction. Although Ikeda *et al.*<sup>66</sup> showed that ionic imbalance in the cell membrane can lead to direct penetration of negative particles. The study by Chen *et al.*<sup>67</sup> demonstrated that 20 nm negatively charged silica nanomaterials can penetrate the BBB in the zebrafish model. However, the increase in the particle size led to a decrease in penetration. On the other hand, Chirio *et al.*<sup>54</sup> showed that positively charged nanoplastics have a greater ability to penetrate the BBB and localize in cells. Shan *et al.*<sup>55</sup> reported that negatively charged PS (50 nm) could penetrate through BBB due to their ability to affect the tight junctions. It is also confirmed by Grodzicki *et al.*<sup>68</sup> that negatively charged PS nanoplastics are more likely to accumulate in rodent brains compared to positively charged PS nanoplastics with the same particle size of 50 nm. Another mechanism through which positively charged MNPs can penetrate the BBB is by inducing damage to the cell membrane as a result of impairment of the membrane structure.<sup>69</sup> The study by Zhang *et al.*<sup>70</sup> demonstrated that positively charged PS nanoplastics (20–100 nm size) can increase the permeability of the BBB. Although there is some evidence that nanoplastics can pass through the BBB and cause neurodegeneration, there remains a lack of definitive data.<sup>71</sup>

### 3. Consequence of MNPs passage into the brain

The consequences of MNPs' presence in the brain are not yet fully understood, as these non-biodegradable materials can undergo biotransformation—such as biological corona formation, polymer swelling, and surface functionalization<sup>56</sup> which alters their characteristics and potentially influences their effects. Subsequently, MNPs might damage the structure and function of the brain.<sup>72</sup> Studies on brain cells in mice revealed that exposure to MNPs can induce neuron and astrocyte apoptosis while reducing cell viability.<sup>73</sup> Moreover, a study on zebrafish embryos showed that MNPs can penetrate and accumulate mainly in lipid-rich regions such as the brain in a dose-dependent manner.<sup>74</sup> It is reported that MNP decrease the number of Purkinje cells and mitochondria function in the brain, mainly through an increase in oxidative stress.<sup>75–77</sup> This can irreducibly damage

neurons and accelerate neurodegenerative processes due to neuron loss and disruption in the balance of neurotransmitters, especially acetylcholine and dopamine, leading to neurodegenerative disease.<sup>78</sup> The question to raise is what consequences the presence of MNPs and the associated brain damage might have on the nervous system and what brain diseases could be linked to MNPs. Although it may be challenging to answer or draw definitive conclusions, in this perspective, we review the published results to identify whether any patterns might emerge.

#### 3.1. Alzheimer's disease

Alzheimer's disease is a progressive neurodegenerative disease accompanied by memory loss, known as the most common type of dementia.<sup>79</sup> AD is characterized by the accumulation of amyloid-beta (A $\beta$ ) plaques in the brain and misfolded protein inside neurons<sup>80</sup> MNPs have recently been studied for their potential role in exacerbating neurodegenerative conditions such as AD.<sup>34</sup> Exposure to nanomaterials has been linked to AD by increasing oxidative stress, inflammation, protein aggregation, and synaptic dysfunction.<sup>41,42,81</sup> It has been reported that MNPs accelerate A $\beta$  aggregation<sup>52</sup> by changing the secondary structure of the protein<sup>30</sup> mainly through oxidative stress, inflammation, and alterations in cellular metabolism.<sup>80</sup> Gou *et al.*<sup>30</sup> demonstrated that exposure to PS nanoplastics size 70–150 nm could cause trigger the progression of AD, specifically by inducing A $\beta$  nucleation and aggregation, along with cell membrane damage, increased ROS and Ca<sup>2+</sup>. Sun *et al.*<sup>39</sup> evaluated the effect of 80 nm PS nanoplastics on mice brains and found that exposure to PS could increase their accumulation in the brain and lead to A $\beta$  aggregation and AD. The study by Paing *et al.*<sup>35</sup> indicated that PS nanoplastics (30–50 nm), can internalize into the microglial cells over astrocytes *in vitro* and the mice brains, resulting in increased inflammation and cognitive decline. Moreover, Bai *et al.*,<sup>40</sup> confirmed that exposure to 100 nm-sized amino-modified PS nanoplastics in mice can cause brain damage and show AD-like characteristics.

Despite the emerging evidence, significant gaps remain in understanding the specific molecular mechanisms through which MNPs contribute to AD.<sup>50,80</sup> Given the similarities between MNPs and other nanomaterials, it is reasonable to hypothesize that MNPs may follow pathological pathways similar to those of other metallic nanomaterials which are reported to destabilize protein secondary structures, leading to protein misfolding and amyloid aggregation. One may argue that most of the observed adverse effects associated with metallic nanomaterials are linked to their dissolution and the release of ions, whereas MNPs do not undergo such dissolution. However, this may not be entirely accurate, as there remains a significant gap in knowledge and analytical methods to clearly distinguish between the effects of ionic and particulate forms of metallic nanomaterials. Furthermore, most protocols used to detect the effects of

nanomaterials, in general, are based on those developed for chemicals and metallic ions rather than particles. These protocols are predominantly focused on oxidative stress mechanisms, creating the impression that toxicological studies are designed with an “I see what I expect to see” approach, rather than aiming to identify new endpoints specifically associated with the particulate form of nanomaterials. Finally, exposure to MNPs has been linked to increased protein denaturation, fibrillation, and amyloid aggregation, all of which are key contributors to AD progression.

### 3.2. Parkinson's disease

Parkinson's disease (PD), is another progressive neurodegenerative disorder. This is primarily characterized by the loss of dopaminergic neurons in the “*Substantia nigra*”, leading to motor impairment and cognitive loss.<sup>82</sup> The pathological pathway of PD, includes the accumulation of  $\alpha$ -synuclein,<sup>43–45,83,84</sup> protein misfolding, and formation of Lewy bodies within neurons, contributing to the degeneration of dopaminergic neurons.<sup>85</sup> Similar to AD, nanomaterials can contribute to PD by inducing increased oxidative stress, neuroinflammation, and the aggregation of  $\alpha$ -synuclein protein.<sup>86</sup> As indicated in the study of Huang *et al.*<sup>87</sup> the exposure of SH-SY5Y cells to 50–100 nm sized PS nanoplastics, resulted in mitochondrial dysfunction and dopaminergic neuron damage. Liang *et al.*<sup>88</sup> showed that exposure of mice to PS and PE microplastics with a particle size of 5  $\mu\text{m}$  caused dysfunction of mitochondrial energy, leading to restriction of the energy reservoir, especially in excitatory neurons, and PD-like disorder. Another way MNPs can cause PD is by increasing dopaminergic neuron degradation and  $\alpha$ -synuclein protein aggregation.<sup>83</sup> For example, *C. elegans* was exposed to PS (25 nm) and showed degradation of dopaminergic neurons and  $\alpha$ -synuclein protein aggregation.<sup>36</sup>

Despite some studies reporting the neurotoxicity of MNPs, primarily due to oxidative stress, the underlying mechanisms remain unclear. We believe that to better understand the toxicity of MNPs, it is essential to develop new toxicology guidelines, such as those by the OECD. These guidelines should incorporate endpoints beyond those used for conventional chemicals, enabling not only the linkage of exposure to hazard but also a deeper understanding of the mechanisms by which MNPs induce PD and other neurological disorders. It also remains to be investigated whether alterations in gene expression and apoptosis contribute to increased neural cell death, or if changes in neurotransmission pathways play a more significant role in the development of PD.

### 3.3. Other neurodegenerative diseases

Amyotrophic lateral sclerosis (ALS) is characterized by progressive neuronal degeneration that causes motor dysfunction and cognitive loss.<sup>89</sup> The mechanism recognized

so far for the development of ALS following exposure to MNPs is an increase in oxidative stress, which may activate inflammatory responses.<sup>90</sup> Exposure to MNP can increase the possibility of ALS from the level of DNA and gene expression<sup>91</sup> and increased oxidative stress.<sup>92</sup> Sun *et al.*<sup>37</sup> exposed TDP-43 cells to PS (20 nm) and reported damage in motor neurons. A similar result was shown by Chen *et al.*,<sup>93</sup> where rodent exposure to PS with a particle size of 50 nm could increase neural injury and cognitive decline that could be linked to ALS.

Multiple sclerosis is an autoimmune and inflammatory disease characterized by neural demyelination and sensory, motor, and cognitive decline.<sup>94</sup> Exposure to MNPs can increase the risk of MS, in a similar way to other neurodegenerative diseases.<sup>95</sup> The results from de Oliveira *et al.*<sup>96</sup> demonstrated that patients diagnosed with MS, had higher serum metallic nanomaterials in their blood serum, suggesting that the increase in nanomaterials can increase the risk of developing MS. Zhang *et al.*<sup>38</sup> evaluated the effect of exposure to PS (25 and 50 nm) in rats and the results indicated that the exposure reduced myelin basic proteins, myelin thickness, and myelin formation in the fetal brain which are the leading cause for MS. Similarly, the study on zebrafish conducted by Aliakbarzadeh *et al.*<sup>97</sup> indicated that exposure to PS with a particle size of 57.7 nm caused neural cell damage in the brain and a decrease in the number of myelinated axons.

Research on other types of nanomaterials has also revealed similar neurotoxic effects that might be transferable to MNPs. For example, studies involving silver nanomaterials have shown that they can induce inflammation in neuronal cells, contributing to neurodegeneration.<sup>98,99</sup> Similarly, titanium dioxide nanomaterials have demonstrated the ability to penetrate the BBB and trigger neuroinflammatory responses, leading to neuronal damage.<sup>100,101</sup> These findings from different nanomaterials studies suggest commonalities in the mechanisms by which various particles can lead to different neurodegenerative diseases. This reinforces the idea that there are potential risks posed by MNPs, given their similar physicochemical properties and biological interactions.

One important factor in inducing neurodegenerative diseases as a result of exposure to MNPs, as well as other nanomaterials is the duration of exposure. This factor must be carefully reviewed and incorporated into the new guidelines being developed for MNP toxicity testing. Table 2 summarizes the key findings from recent animal studies investigating the effects of MNPs on neural tissues and neurodegenerative diseases, highlighting that the duration of exposure plays a critical role in the neurotoxic effects of MNPs. Studies with longer exposure periods, such as those by Bai *et al.*<sup>40</sup> (15 weeks), Liang *et al.*<sup>31</sup> (28 days), and Aliakbarzadeh *et al.*<sup>97</sup> (45 days), revealed more pronounced neurotoxic outcomes, including brain damage, mitochondrial dysfunction, and neurodegeneration. Shorter exposure periods, such as the 7-day exposure in Sun *et al.*<sup>39</sup> and the

**Table 2** An overview of the MNPs toxicity in neural tissue and neurodegenerative diseases

MNP type and size	Exposure duration and pathways	Mechanisms of toxicity	Ref.
PS nanoplastic (100 nm, 500 nm, 1000 nm)	120 h (5 days) exposure to $10 \text{ mg L}^{-1}$ PS nanoplastic	The smaller sized PS nanoplastic could penetrate the BBB in zebrafish larvae easier and cause more neurotoxicity	53
PS nanoplastics (200 nm)	100 $\mu\text{g}$ per animal weight, administered through the jugular vein	Rod-shaped nanoplastics demonstrated greater binding capacity in the mice brain compared to spherical-shaped PS nanoplastics	60
PS nanoplastic (50 nm)	28 days oral exposure to PS $0.25\text{--}250 \text{ mg kg}^{-1}$ body weight (BW) PS nanoplastics	The exposure outcome was mitochondrial dysfunction, energy restriction in excitatory neurons, and PD like disorders in mice	31
PS microplastics (5 $\mu\text{m}$ )	6 weeks exposure to 1, 10 and $100 \text{ mg L}^{-1}$	The chicken exposure to PS microplastics impaired tight junction proteins expression and reduced number of Purkinje cells, resulting in neurotoxicity	76
PS nanoplastics (80 nm)	7 days 50 mg per bodyweight intranasal administration (INA), gastric feeding (GF) and intratracheal instillation (ITI) exposure to PS nanoplastics	Exposure increased particle accumulation in the mice brain and led to $\text{A}\beta$ aggregation, a cause for AD	39
Amino-modified PS nanoplastics (100 nm)	15 weeks exposure to oral $40 \text{ mg kg}^{-1}$ body weight of PS nanoplastics	Mice exposure caused brain damage and characteristics of AD	40
PS nanoplastics (20–80 nm)	45 days of PS nanoplastics $0.1, 1, 10$ , and $100 \mu\text{g L}^{-1}$	The exposure caused neural cell damage and a decrease in myelinated axons in zebrafish	97

5-day exposure in Zhou *et al.*<sup>53</sup> still demonstrated significant neurotoxic effects, but with varying degrees of impact depending on the particle size and administration route. Overall, these findings suggest that extended exposure to MNPs increases the likelihood and severity of neurodegenerative effects, highlighting the importance of considering exposure duration in the development of new toxicology guidelines for MNPs.

## Perspective and future directions

The threat MNPs pose to neurodegenerative diseases highlights the deep interconnectedness between human health and environmental well-being. The consequences of persistent plastic pollution extend far beyond its visible impacts on the environment; they may be quietly undermining brain health, with long-lasting and devastating repercussions. Most of the investigated effects of MNPs are based on oxidative stress, which is attributed to two main factors: 1) the research protocols commonly used to study the adverse effects of MNPs are primarily centred around oxidative stress, even though the aims and mechanisms of the studies may differ; and 2) it is well-established that the effects of MNPs, like other nanomaterials, are largely driven by their oxidative stress-inducing properties. Exposure to MNPs can affect the CNS both structurally and functionally, which may serve as a predictor of neurodegenerative diseases and neurodevelopmental disorders at all stages of life. Available evidence confirms that MNPs impact development, growth, and behaviour.

There are several mechanisms by which MNPs can adversely affect neural health, mainly dependent on the dose and duration of exposure. By crossing biological barriers and accumulating in tissue, MNPs increase oxidative stress and trigger immune response. This leads to higher levels of inflammatory mediators and increased gene expression of

inhibitory proteins, while the expression and function of regulatory proteins decrease. These effects are associated with increased lipid peroxidation resulting in DNA damage, the accumulation of misfolded proteins, activation of apoptosis pathways and neuroinflammation. Furthermore, MNPs may reduce the expression of neurotransmitter-related genes and decrease the activity of antioxidant enzymes, even if the expression of proteins involved in oxidative stress increases in different regions of the brain and neural cells. This can lead to significant disruption in the expression of proteins crucial for neural development, which can regulate the structure and plasticity of the CNS. Considering the function and potential effects on neurodegenerative disease and neurodevelopmental disorders, MNPs can decrease important genes involved in cognition, which is the leading cause of cognitive decline.

The mechanisms by which MNPs induce oxidative stress and inflammatory responses, and impair myelin formation align closely with those observed for other nanomaterials like Ag and  $\text{TiO}_2$ . This convergence of evidence underscores the urgent need for comprehensive investigations into the neurotoxic effects of MNPs. Establishing causative links between exposure and disease progression will be vital for developing effective preventive strategies and interventions to mitigate the health risks posed by MNPs in our increasingly plastic-laden environment. More studies are needed to clarify dose-response relationships, the long-term consequences of chronic exposure, and the differential effects of various plastic types and additives. Understanding precisely how MNPs harm the brain will be crucial in developing effective interventions.

While MNPs have been hypothesized to affect the structure and function of the neurons, there is a lack of extensive studies confirming this effect. Understanding how MNPs may disrupt this complex brain network is crucial, as it could have far-reaching health implications.

Evidence for the uptake of spherical MNPs by cells currently relies on indirect assumptions rather than definitive visual or experimental proof. Developing methods to directly track and visualize the uptake of spherical MNPs is necessary to fully understand their cellular interactions and potential toxicity. Research is needed to determine if specific antioxidants can protect against MNP-induced neurotoxicity and the optimal antioxidant strategies for mitigating these risks. Additionally, exploring how different plastic compositions and particle shapes affect their ability to cross the BBB will provide a more comprehensive understanding of the potential health risks associated with MNPs.
