Effect of redox reactions on the thermoluminescence characteristics of Cu-doped NaLi₂PO₄ phosphors

Bhuli Bai and P. D. Sahare *

A Cu-doped NaLi₂PO₄ phosphor material was successfully synthesized through the high-temperature solid state diffusion method. It was mainly doped with Cu₂Cl₂ and CuCl₂ salts for impurities in the form of Cu⁺ and Cu²⁺, respectively. Formation of the material in the single phase of the phosphor material was confirmed by powder XRD. Morphological and compositional characterization was done using XPS, SEM and EDS techniques. The materials were annealed in reducing, (10% H₂ in Ar) and CO/CO₂ (by burning charcoal in a closed system), as well as in oxidizing (air) atmospheres at different temperatures. ESR and PL studies were conducted for studying redox reactions due to annealing and its effect on TL characteristics. It is known that the impurity Cu could exist in Cu²⁺, Cu⁺ and Cu⁰ forms. The material was doped with two different salts (Cu₂Cl₂ and CuCl₂) as sources of the impurities in two different forms *i.e.*, Cu⁺ and Cu²⁺, however, it was found that it gets incorporated in both the forms inside the material. Also, annealing in different atmospheres not only changed their ionic states but also affected the sensitivity of these phosphors. It was observed that at ~10 Gy, NaLi₂PO₄:Cu(II) is around 3.3 times, 3.0 times and almost equally sensitive than commercially available TLD-900 phosphor on annealing in air, 10% H₂ in Ar and CO/CO₂ at 400, 400 and 800 °C, respectively. However, NaLi₂PO₄:Cu(I) becomes 1.8 times sensitive after annealing in CO/CO₂ at 800 °C as compared to TLD-900. With high sensitivity, both the materials NaLi₂PO₄:Cu(II) and NaLi₂PO₄:Cu(I) are good candidates for radiation dosimetry with a wide dose response (mGy–5.0 kGy).

1. Introduction

Thermoluminescence (TL) is one of the popular dosimetric techniques used for measuring doses of high energy-radiations. In this technique, electron traps and holes (luminescence centers) are generated during irradiation which could be stimulated by providing heat energy. The energy of recombinations emitted as TL on stimulation in the form of visible light makes it possible to estimate the doses of high-energy radiations as the intensity of the emitted light is proportional to the absorbed doses.^{1–4} In search of an “ideal dosimeter”, many TLD phosphors have been investigated. But most of them still possess one or more drawback(s).^{5,6} A good TLD material should consist of the following ‘good’ characteristics, such as, simple synthesis process, low-Z (tissue equivalence), high sensitivity, non-toxicity, negligible fading, linearity over a wide dose range and excellent reusability. NaLi₂PO₄ doped with rare earth impurities, is a well-known highly sensitive TLD/OSLD phosphor material.

Initially, Shinde and Dhoble in 2011 reported reddish-orange emission for Eu³⁺ and Tb³⁺-doped NaLi₂PO₄ materials for white-

LED applications.^{7,8} Later, in 2014 Sahare and Singh observed intense red emission with 99.9% colour purity due to peak wavelength centered at around 702 nm in the former phosphor.⁹ Further, PL emission due to Eu²⁺ ion in blue region, because of induced reduction of Eu³⁺ on irradiation with γ-rays, was also observed.¹⁰ Sahare and co-workers further explored rare earth impurity(ies) (Eu³⁺, Ce³⁺, Tb³⁺) doped NaLi₂PO₄ materials for their applications as TLD and OSLD phosphors.^{11–15} However, rare-earth materials are quite expensive and some of them may consist of radioactive isotopes that may give self-dose introducing errors in dose estimations, especially, at low dose levels. Other transition metals can also act as luminescence activators, such as Mn⁴⁺,¹⁶ Ti,¹⁷ Cr³⁺¹⁸ or Cu^{19–30} for such hosts. For example, LiF:Mg,Cu,P^{21–23} and Li₂B₄O₇:Cu,²⁴ *etc.* are well-known dosimetry phosphors. PL, TL and OSL in some Cu-doped lithium based-orthophosphates have also been reported.^{25–29} This prompted us to study Cu-doped NaLi₂PO₄. We were more encouraged when we saw that the phosphor material is many fold sensitive than the commercially available popular material CaSO₄:Dy (TLD-900) procured from Nucleonics Systems Pvt. Ltd Hyderabad, India.

Recently, Sahare *et al.*³⁰ studied Cu-doped LiF nanophosphor. Their interests seem to be investigating the role of Cu impurity in well-known LiF:Mg,Cu,P phosphor on heating/annealing on TL readouts beyond 250 °C. It was important as

Department of Physics and Astrophysics, University of Delhi, Delhi-110007, India.
 E-mail: pdsahare@yahoo.co.in; pdsahare@physics.du.ac.in

the phosphor loses its reusability on heating beyond 250 °C and if not heated some remaining traps could add errors during its reuse. They could reveal that this is because of the incorporation of the impurity in both Cu²⁺ and Cu⁺ ionic forms though doping is done with either of the starting materials (*i.e.*, CuCl₂ or Cu₂Cl₂). They also further showed using different experimental techniques, such as, TL, ESR, PL that redox reactions taking place during irradiation/readouts/annealing, *etc.* And all the traps might not either be emptied as the material is not heated beyond 250 °C or all the impurity ions in different states after irradiation might not be coming back to their initial states on readouts/annealing. According to them, if this is occurring in Cu-doped LiF and reusability is not maintained, it must be occurring in LiF:Mg,Cu,P also. This was another reason to take up this study to see whether such reactions are also taking place in Cu-doped NaLi₂PO₄ material as well. It has lot of significance from application point of view, if it is found occurring in many Cu-doped phosphors, then their applications as TLD/OSLD/white LED/lamp phosphors would be questionable.

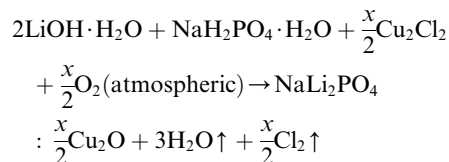

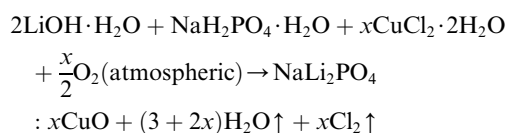

In the present work, Cu-impurity was tried as an activator in NaLi₂PO₄ for its application as TLD phosphor. The material was doped with Cu₂Cl₂ and CuCl₂ salts as starting impurities in Cu⁺ and Cu²⁺ ionic forms, respectively. However, it was found that it gets incorporated in both the forms inside the material. It may be noted here that though the doped impurity gets incorporated in to two ionic forms, *i.e.*, Cu⁺ and Cu²⁺, there is no evidence that they act as activators and sensitizers. For optimizing the luminescence characteristics, the materials were annealed in reducing (10% H₂ in Ar and CO/CO₂ atmosphere by burning charcoal in a closed system) and oxidizing (air) atmospheres at different temperatures. The redox reactions were studied and found useful for optimizing the dosimetry properties. High sensitivity (around 2.2 times at low doses and 6.8 times at high doses compared to that of TLD-900) in the wide dose range of mGy–kGy, excellent reusability, *etc.* makes the phosphor a good candidature for dosimetry of high energy radiations. Effective atomic number (Z_{eff}) of the material was

determined by using the formula $Z_{\text{eff}} = \sqrt[3]{\frac{\sum n_i X_i^4}{\sum n_i X_i}}$, where, n_i is the fractional part by weight of whole compound occupied by an element i , X_i is the atomic numbers of that element.³¹ It was found to be 10.8 for NaLi₂PO₄.

2. Experimental

2.1. Synthesis

Microcrystalline form of Cu²⁺ doped NaLi₂PO₄ phosphor prepared by high temperature solid state method. Details could be found in our earlier papers.^{11–15} It has also been described here for beginners. The initial materials LiOH·H₂O and NaH₂PO₄·H₂O (99.0% Central Drug House, India). The materials were prepared taking into the consideration the following chemical reactions:

where, x is the dopant concentration.

Initially, suitable amount of CuCl₂·H₂O (CDH, India) and Cu₂Cl₂ (CDH, India) were taken as sources of Cu²⁺ and Cu⁺ impurity ions, respectively. It is to be noted here that one needs to be little cautious while calculating the impurity concentrations as the former consists of one Cu²⁺ ion while the later consists of two Cu⁺ ions. The material doped with the salt having Cu⁺ initial ionic state has been named as NaLi₂PO₄:Cu(I) and the other one doped with the salt having Cu²⁺ initial ionic state was named as NaLi₂PO₄:Cu(II). LiOH·H₂O and NaH₂PO₄·H₂O taking into molar ratio of 2 : 1 along with the required amount of impurity salt were thoroughly mixed using an agate mortar and pestle continuously for few hours in the presence of ethanol for better mixing. The mixture in powder forms was initially heated for 12 h at 400 °C in quartz container in a resistive furnace controlled by a temperature-controller and programmer (West 6400 with stability around ±1.0 K) and cooled slowly to room temperature (RT). The material (ingot), thus formed was crushed to fine particles and given heat treatment at 600 °C and repeated the same at 800 °C for the same interval of time and again cooled down slowly to RT. The sample thus prepared was finally crushed in motor pestle and sieved (by using standard test sieves) to obtaine different particle size ranges. The best results were obtained for the particle size in the range of 63–150 μm of NaLi₂PO₄:Cu(II). All the prepared samples were annealed in oxidizing atmosphere (air) at different elevated temperatures ranging from 100 °C to 1000 °C for 1.0 h and quenched to RT by placing quartz container on a metal block to improve sensitivity. These materials were used for further studies.

2.2. Annealing in reducing atmospheres

The annealing of the samples in reducing atmospheres (10% H₂ in Ar and also in CO/CO₂ by burning charcoal in a closed system) was also done. For annealing in 10% H₂ in Ar gas the following procedure was adopted. Initially, the samples were put in alumina boat inside a cylindrical alumina tube inserted in a tubular furnace. As mentioned earlier, the temperature of the furnace was controlled by a temperature controller and programmer. One end of the alumina tube was connected to gas cylinder (filled with 10% H₂ in Ar for generating reducing atmosphere) through a digital mass flow controller (DMFC) and the other end was attached to a gas bubbler through which gas could flash out into the atmosphere. The samples were put inside at the centre of the tubular furnace and the desired temperatures were reached with the help of temperature controller at the rate of 100 °C h⁻¹. The annealing was carried out at different temperatures, such as, 400, 600 °C and so on for 1.0 h. After annealing the samples were cooled to room temperature naturally under the same atmosphere by switching

of the furnace. The same treatment was given to a set of all the samples for further studies.

Another set of samples was also annealed in CO/CO₂ (reducing) atmosphere by burning charcoal in a closed system. For this, samples were placed in alumina crucibles and covered using ceramic wool under a steel net and another alumina crucible one above the other and upside down (in order to avoid contamination of the sample with the fine charcoal powder while heating).^{32,33} These crucibles were then placed inside a closed charcoal box. Burning of the charcoal under scarcity of oxygen produces CO/CO₂ gas as reducing atmosphere. Annealing of samples under this atmosphere at different temperatures, *i.e.*, 400 °C, 600 °C and 800 °C, *etc.* for 1.0 h was done by controlling and maintaining the furnace temperature as mentioned earlier.

2.3. Characterization and measurements

The powder X-ray diffraction (PXRD) patterns were recorded at room temperature using a high-resolution Bruker D8 X-ray diffractometer and utilizing its monochromatic Cu_{Kα} line ($\lambda = 1.54060 \text{ \AA}$) radiation ($E = 8.04 \text{ keV}$) with scan rate 2° min^{-1} , step dimension of 0.02 s and 2θ ranging from 20° to 80° . The PXRD diffractometer was operated at a voltage of 40 kV and current 25 mA. TL were taken under nitrogen atmosphere after irradiating the material with γ -rays for different doses from ⁶⁰Co radioactive source (gamma chamber) using the 3500 Harshaw TLD Reader attached with PMT as detector and temperature programmer for linear heating by taking $\sim 5 \text{ mg}$ of sample each time. The chemical composition and elemental analysis were done using XPS technique (Thermo Fisher Scientific, UK, Model: K-Alpha XPS) with energy resolution of 0.1 eV at a base vacuum of 10^{-9} Torr. XPS peaks were deconvoluted using the Peak-41 Software. Free radicals and transition metal ions can be identified using ESR technique. ESR was done ESR instrument (Bruker Biospin, Germany, Model: EMXmicro A200-9.5/12/S/W) with microwave X band source. The morphology of the materials annealed in different atmospheres was studied by high resolution images using SEM instrument (JEOL, Japan, Model: JSM 6610LV). PL emission and excitation spectra was taken with the help of Horiba Scientific fluorescence spectrophotometer, PTI QM-8450-11-C system # 3560.

3. Result and discussion

3.1. PXRD analysis

The PXRD patterns of the microcrystalline NaLi₂PO₄:Cu(I) and that of NaLi₂PO₄:Cu(II) phosphor materials were matched with that of the reported data in the literature PCPDF file # 80-2110 with lattice parameter $a = 6.884$, $b = 9.976$, $c = 4.927$ and $\alpha = \beta = \gamma = 90^\circ$. It was also confirmed that both the materials have single phase having space group $Pmn2_1(62)$ and orthorhombic structure. The experimental data was also analysed using Rietveld refinement. It could be seen from Fig. 1(a) and (b) that the experimental and theoretically fitted data matches well with each other and also with the standard JCPDS file # 80-2110. No additional peak(s) related to impurity or any other phase was present. It could be seen that the lattice parameters also match.

The 3D-crystal structure has been shown in Fig. 1(c). As seen in the figure, Na⁺ is bonded to six O²⁻ ions in a 6-coordinated geometry and the Na–O bond distances range from 2.30–2.82 Å, while Li⁺ forms LiO₄ tetrahedra and is bonded to four O²⁻ ions to share corners with four equivalent LiO₄ tetrahedra. The Li–O bond distances range from 1.98–2.02 Å. P⁵⁺ ion is bonded to four O²⁻ ions to form PO₄ tetrahedra that share corners with eight equivalent LiO₄ tetrahedra. All P–O bond lengths are 1.56 Å. Thus, there are three inequivalent O²⁻ sites as shown in the figure. In the first O²⁻ site, O²⁻ is bonded in a 5-coordinate geometry to two equivalent Na⁺ ions, two equivalent Li⁺ ions and one P⁵⁺ ion. In the second O²⁻ site, O²⁻ is bonded to one Na⁺ ion, two equivalent Li⁺ ions and one P⁵⁺ ion to form distorted corner-sharing ONaLi₂P trigonal pyramids. In the third O²⁻ ion site, O²⁻ ion is bonded in a 5-coordinated geometry to two equivalent Na⁺, two equivalent Li⁺ and one P⁵⁺ ion.³⁴

The ionic radii of Li⁺, Na⁺, P⁵⁺, O²⁻, Cu²⁺, Cu⁺ and Cu⁰ are 0.76, 1.02, 0.38, 1.40, 0.73, 1.40, and 1.45 Å, respectively. From this data, it could be seen that the ionic radii of Li⁺ and that of Cu²⁺ are 0.76 and 0.73 Å, respectively, therefore, two Cu²⁺ ions could go to the two Li⁺ substitutional sites and the oxygen (O²⁻) ion (diffused from the atmosphere) at the interstitial site do the charge compensation by forming bonds with Cu²⁺ ions. But, when it comes to Cu-impurity in its Cu⁺ ionic form, the ionic radii neither match that of Li⁺ nor that of Na⁺. Thus, it does not seem to be possible to substitute any of these two ions, moreover, it could neither go to P⁵⁺ site as the radius is too small. Therefore, it could get incorporated at the oxygen vacancies (revealed in XPS analysis) as the ionic radius of (O²⁻) ion/its vacancy being the same as that of Cu⁺ ion (1.40 nm) or go to interstitial site. The oxygen vacancy(ies) could exist in (O_v²⁺), (O_v⁺) and (O_v⁰) forms³⁵ by sharing electron pairs of other oxygen ions attached to the PO₄³⁻. Thus, two Cu⁺ ions (both may be oxygen vacancy occupied ions at nearby PO₄³⁻ tetrahedra or at interstitial sites) could form bonds with the oxygen (O²⁻) ion at the interstitial site (diffused from the atmosphere) and compensate charges. On annealing in reducing/oxidising atmospheres the ratio of Cu²⁺, Cu⁺ and/or that of oxygen vacancies could change keeping the material neutral. This is confirmed by XPS and ESR analysis discussed below (Sections 3.7 and 3.8).

3.2. SEM/EDS analysis

SEM and EDS analysis of the materials were done to study the morphology and composition of the materials. A typical EDS spectrum of NaLi₂PO₄:Cu(II) (0.1 mol%) is shown in Fig. 2. SEM image and a table of the composition of the constituent elements are also shown in the insets. It could be seen in the figure that well-defined granular particles are seen in the SEM image. The Cu impurity concentration (0.17%) is of the same order of the doping.

3.3. Effect of impurity concentration on TL properties of Cu-doped NaLi₂PO₄

Variation of impurity concentration (0.05–2.0 mol%) with TL intensity of NaLi₂PO₄:Cu(II) is shown in Fig. 3(a). The materials were annealed at 400 °C in air. It was observed that on increasing the doping concentration, TL intensity increases up

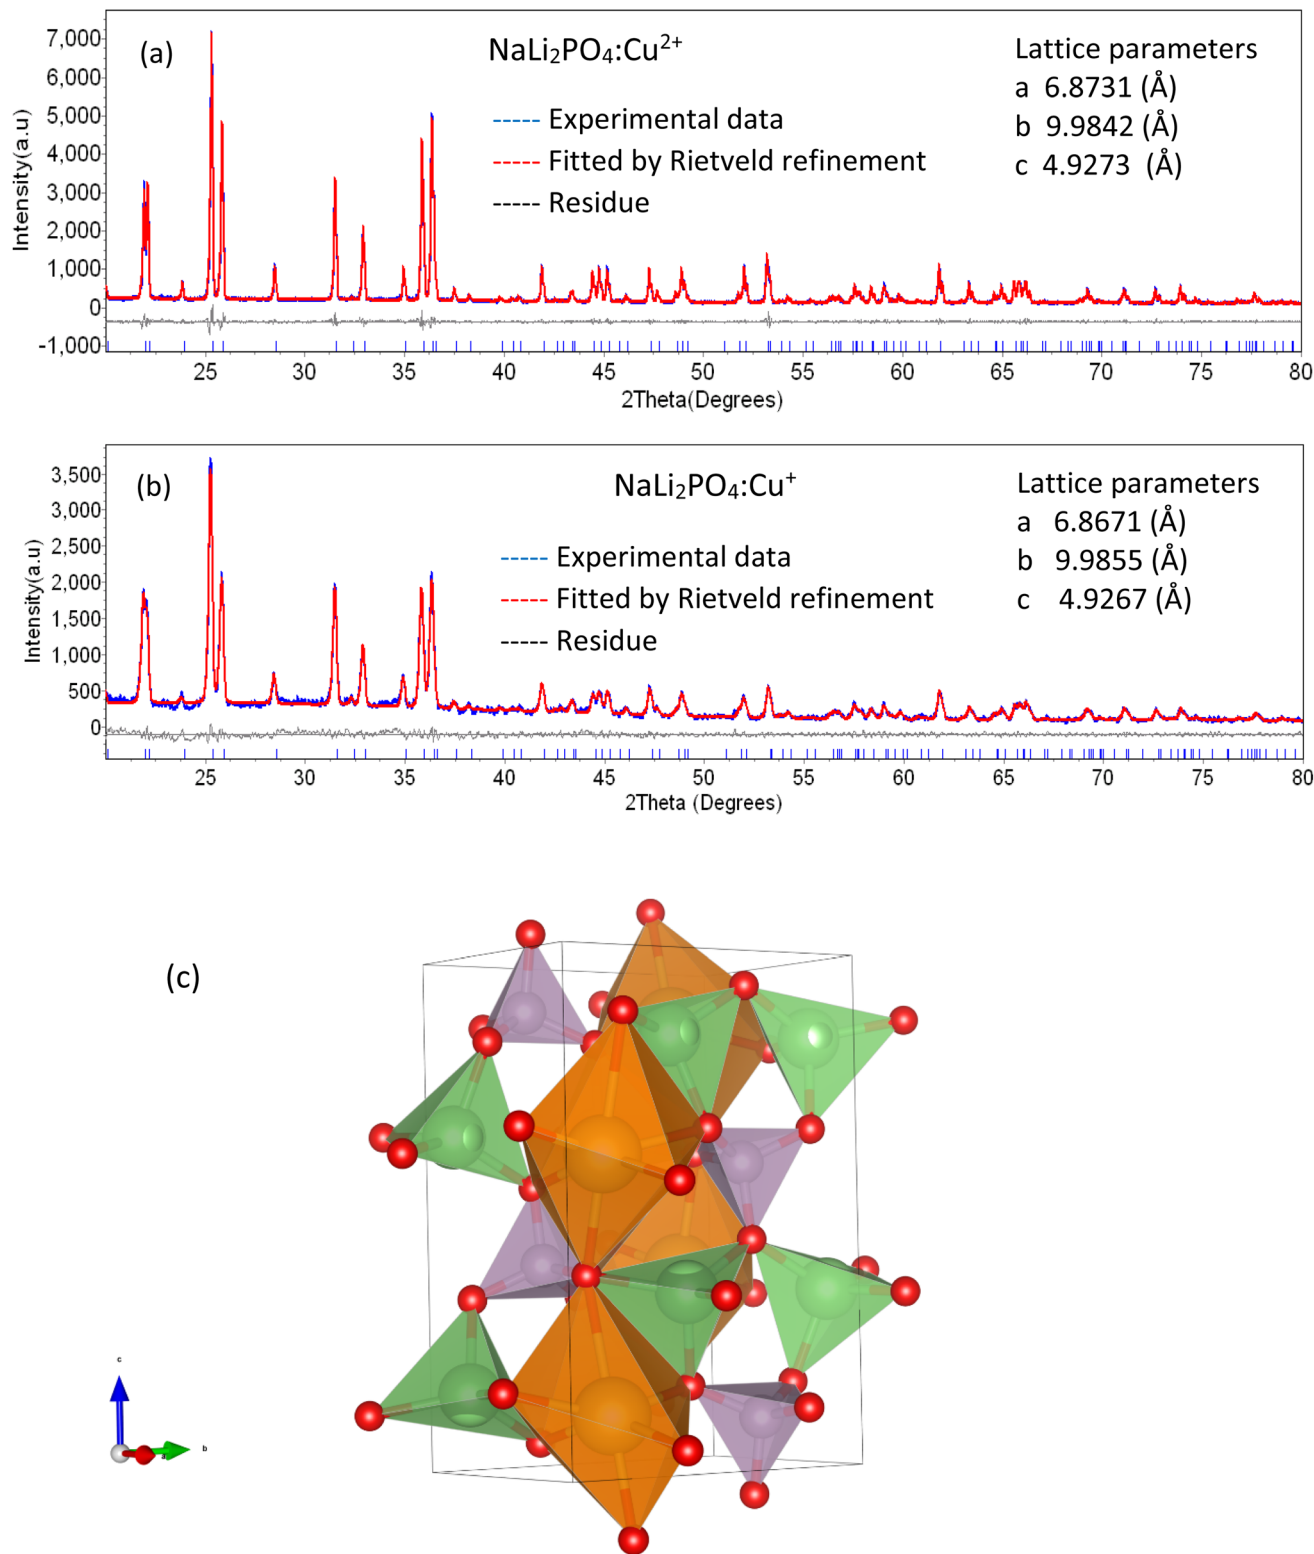

Fig. 1 PXRD patterns of the NaLi_2PO_4 phosphors: (a) PXRD pattern of the $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ phosphor material, (b) PXRD pattern of the $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ phosphor material, (c) crystal structure. Theoretically fitted by Rietveld refinement patterns along with JCPDS data (file # 80-2110) are shown for comparison. The lattice parameters used for the fittings are also shown in the inset.

to 0.1 mol% after that it starts decreasing due to concentration quenching effect. However, there are some small changes in the glow curve structures at high concentrations which may be

attributed to the rearrangement of trapping levels originated due to incorporation of the impurity in different ionic states, *i.e.*, Cu^+ and Cu^{2+} . The impurity could be incorporated in the

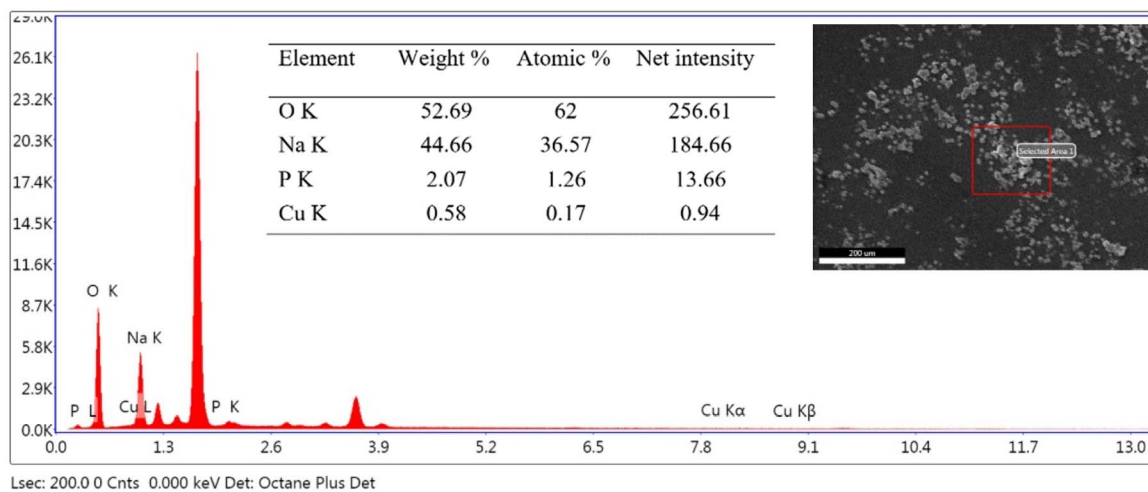

Fig. 2 A typical EDS spectrum of $\text{NaLi}_2\text{PO}_4:\text{Cu(II)}$ (0.1 mol%) material. The SEM image and the elemental composition are also shown in the inset.

form of Cu^+ and Cu^{2+} ionic states, though the starting ionic state was in Cu^{2+} form.^{30,36} But the ratio of $\text{Cu}^+/\text{Cu}^{2+}$ ions may vary with the impurity concentration. As discussed earlier, Cu^{2+}

ions may go to substitutional sites of Li^+ ions and the charge compensation is done the oxygen ions diffused from the air atmosphere. This may, however, change the TL sensitivity of the material. The maximum TL intensity at doping concentration (Cu^{2+} ions) is 0.1 mol% observed at 10.0 Gy Co^{60} source.

For $\text{NaLi}_2\text{PO}_4:\text{Cu(I)}$ material doped with Cu^+ impurity, the maximum TL intensity was found at 0.1 mol% shown in Fig. 3(b). The materials were annealed at 400 °C in air. But, as mentioned earlier, it is not necessary that the impurity would be incorporated as Cu^+ only even if it is in this form initially in the salt used for doping, it may be incorporated in both Cu^+ as well as in Cu^{2+} forms.^{30,36} It is also known that the TL intensity of Cu^+ (using Cu_2Cl_2 salt) initially doped material is more than that of Cu^{2+} (using CuCl_2 salt), for example, Cu-doped LiF .³⁰ However, it seems here that it is otherwise, *i.e.*, the TL intensity of the Cu^{2+} initially doped material is more than that of the Cu^+ doped. This may be because of difference in their ionic radii (0.73 Å for Cu^{2+} and 1.40 Å Cu^+ , respectively). As the ionic radius of Cu^{2+} is much comparable with that of Li^+ (0.76 Å) while that of Cu^+ is almost the same that of O^{2-} (1.40 Å). Also, it is easier for charge compensation of the additional charges of the Cu^{2+} ions by forming bonds with the nearby O^{2-} ions diffused from air atmosphere. More studies on redox reactions after giving annealing treatments at different temperatures and in different oxidizing and reducing atmospheres has been done and discussed in next sections (Sections 3.3–3.5). In both the cases, however, as the impurity concentration increases, it results in concentration quenching.

A number of processes may be involved in concentration quenching, such as, interaction between the quencher and the activator (both could be same kinds of ions/radicals or may also be different), energy transfer, charge transfer reaction or complex formation. Quenching could be a static or dynamic phenomena. The dynamic quenching could be attributed to the energy transfer between activators, which come closer to each other with increase in concentration and agglomeration. This results in increase of probability of the non-radiative interaction due to tunnelling.³⁷ However, in the present case, it would be more complex as it is not just the energy transfer between the

Fig. 3 (a) Optimization of concentration of the impurity in the host matrix NaLi_2PO_4 . TL glow curve of the material doped with different impurity (Cu^{2+}) concentrations (0.05–2.0 mol%) and exposed at 10 Gy of γ -rays from Co^{60} source. The materials were annealed at 400 °C in air. Inset shows TL intensity of $\text{NaLi}_2\text{PO}_4:\text{Cu(II)}$ vs. Cu^{2+} impurity concentration, (b) TL glow curve of the material doped with different impurity (Cu^+) concentrations (0.05–1.0 mol%) and exposed at 10 Gy of gamma-rays from Co^{60} source. Inset shows TL intensity of $\text{NaLi}_2\text{PO}_4:\text{Cu(I)}$ vs. Cu^+ impurity concentration.

quencher and the activator but it is due to electron traps (trapped at the local energy levels of the activators) and holes/luminescence centres (LCs) generated on irradiation.

On stimulation by heat energy in TL, the traps make several attempts for detrapping (frequency factor) as the stimulation energy is very less ($k_B T$ in meV) than the trap depth (energy difference the trap level and the lowest level of the conduction band which is of the order of a few eV). They could get re-trapped also. As there are three kinds of activators (Cu^{2+} , Cu^+ and Cu^0) and redox reactions could occur on irradiation and annealing, it is difficult to say which mechanism would be responsible for concentration quenching. However, mostly nonradiative recombinations of the shallow traps, crossover energy level transitions, retrapping and more complex defect formations at higher concentrations would be responsible for quenching.

3.4. Effect of annealing temperatures on TL glow curves and intensity after annealing in oxidizing atmosphere (air)

$\text{NaLi}_2\text{PO}_4:\text{Cu(II)}$ material (0.1 mol%) was annealed in air at different elevated temperatures (ranging from 100–800 °C). Effect of annealing temperature is shown in Fig. 4(a) where it could be observed that 400 °C is optimized temperature for highest intensity. Similarly, $\text{NaLi}_2\text{PO}_4:\text{Cu(I)}$ material (0.1 mol%) was annealed at different elevated temperatures (ranging from 100–800 °C), as the annealing temperature is increased, the TL intensity of the dosimetric peak increases up to 400 °C but it starts gradually decreasing on annealing beyond this temperature. Annealing temperature effect for $\text{NaLi}_2\text{PO}_4:\text{Cu(I)}$ is shown in Fig. 4(b) and it could be seen that optimized temperature to achieve the highest TL sensitivity for $\text{NaLi}_2\text{PO}_4:\text{Cu(I)}$ is around 600 °C. There are reports that atmospheric oxygen could get diffused inside the material on annealing at higher temperatures in air and may help propagating redox reactions of the impurity of Cu-ions.^{38,39} The TL sensitivity goes on increasing with the annealing temperature increasing till 600 °C (at which TL intensity was maximum) but starts decreasing thereafter. The possible reason for this could be the more uniform dispersion of impurity ions in the crystal but further decrease in intensity (*i.e.*, beyond 600 °C) could be attributed to diffusion of atmospheric oxygen leading to more complex defects at the impurity ion sites as well as redox reactions.^{32,40}

It is known that after heat treatments above 250 °C, the ratios of TL emissions 380 and 350 nm corresponding to Cu^{2+} and Cu^+ in Cu-doped LiF, respectively, in the samples annealed at different temperatures decrease; this has been attributed to the $\text{Cu}^+ \rightarrow \text{Cu}^{2+} + e^-$ conversions during heating treatments.^{32,40} Similar results are also observed by Yang *et al.* in Cu-doped LiF^{41} on irradiation to different γ -ray doses and it has been shown that the relative intensity of the two peaks (appearing at around 187 and 292 °C) in Cu-doped LiF change again due to $\text{Cu}^+ \rightarrow \text{Cu}^{2+}$ conversions. Apparently, there are two TL glow peaks, one at around 127 °C and another at around 202 °C were observed in $\text{NaLi}_2\text{PO}_4:\text{Cu(II)}$ and 177 and 327 °C in $\text{NaLi}_2\text{PO}_4:\text{Cu(I)}$ materials. We also have observed the change in peak ratios of $\text{NaLi}_2\text{PO}_4:\text{Cu(I)}$ and $\text{NaLi}_2\text{PO}_4:\text{Cu(II)}$ materials annealed in air. This may be attributed to the redox reactions taking place in these materials. At high-temperatures,

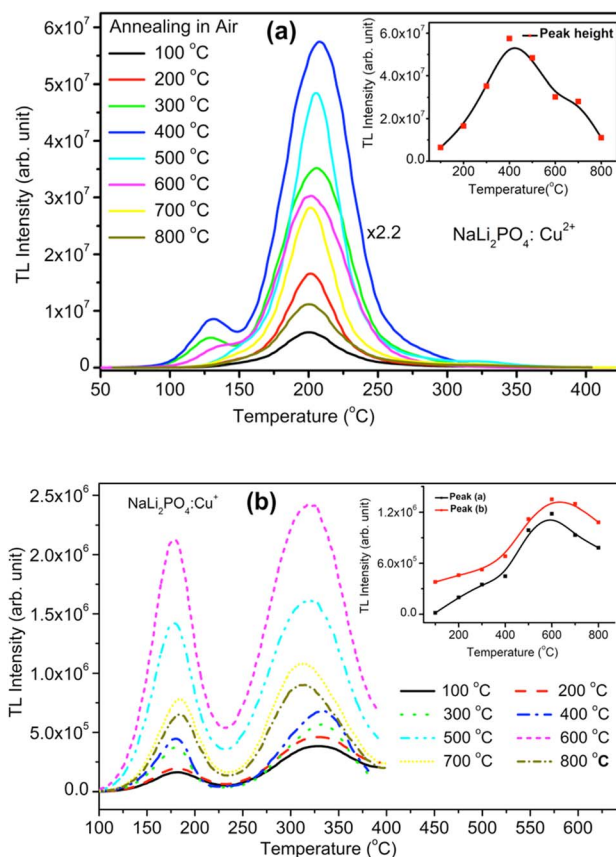

Fig. 4 (a) Optimization of the annealing temperature effect on $\text{NaLi}_2\text{PO}_4:\text{Cu(II)}$. TL glow curve of the material with doped Cu^{2+} impurity (0.1 mol%) concentration and exposed at 10 Gy of gamma-rays from the Co^{60} source. The plot of TL intensity (peak height) vs. annealing temperature is also shown in the inset, (b) optimization of the annealing temperature effect on $\text{NaLi}_2\text{PO}_4:\text{Cu(I)}$. TL glow curve of the material doped with Cu^+ impurity (0.1 mol%) concentration and exposed at 10 Gy of gamma-rays from the Co^{60} source. The plot of TL intensity (peak height) vs. annealing temperature is also shown inside.

such redox reactions could also occur in reverse order, *i.e.*, $\text{Cu}^{2+} + e^- \rightarrow \text{Cu}^+$.³⁰ We strongly believe that such conversions must be taking place in our Cu-doped NaLi_2PO_4 materials also. However, it is difficult to assign a particular TL glow peak(s) to one or the other kind(s) of impurity(ies) in a phosphor material as the TL emissions could take place from different kinds of traps competitively at the same time and even if it is not occurring at the same time a number of traps could move from deeper traps to shallow traps at their positions after their thermal stimulation and recombinations.

3.5. Effect of annealing temperatures on TL glow curves and intensity after annealing in different reducing atmospheres (H_2 in Ar and CO/CO_2)

Samples were annealed in H_2 atmosphere (10% H_2 in Ar) at different temperatures (*i.e.*, 400, 600 and 800 °C) using the procedure described earlier (Section 2.2). $\text{NaLi}_2\text{PO}_4:\text{Cu(II)}$ was annealed in hydrogen atmosphere at 400, 600 and 800 °C for 1.0 h. After annealing TL of these materials was taken. The

results are as shown in Fig. 5(a). The TL glow curves apparently consist of two peaks, one at around 137 and another at around 177 °C. There is a significant change in the peak temperatures (~ 25 °C) and change in their intensity ratios on annealing at different temperatures and in different atmospheres show that some redox reactions due to heating, such as, $\text{Cu}^{2+} + \text{e}^- \rightarrow \text{Cu}^+ + \text{e}^- \rightarrow \text{Cu}^0$ might be occurring inside the material.^{30,36} However, the number of such different species may also change due to redox reactions on irradiation.⁴¹ The TL intensity was found to be maximum for annealing at 400 °C due to reduction of $\text{Cu}^{2+} + \text{e}^- \rightarrow \text{Cu}^+$. However, further increase in temperature may result in further reduction of the impurity in metallic copper, *i.e.*, $\text{Cu}^+ + \text{e}^- \rightarrow \text{Cu}^0$ leading to quenching of the TL intensity.

Similar, type of behavior was observed on annealing in CO/CO₂ atmosphere (Fig. 5a) NaLi₂PO₄:Cu(II) samples were annealed at 400 °C, 600 °C, 800 °C in charcoal atmosphere for 1.0 h then TL was taken. The intensity of the TL glow peaks annealed in this (CO/CO₂) atmosphere is very less than the same annealed in hydrogen atmosphere at the same temperatures, *i.e.*, 8, 6.0 and 2.2 times at 400 °C, 600 °C, 800 °C, respectively. There is also a reverse trend than observed in case of the material annealed in 10% H₂ in Ar gas atmosphere, *i.e.*, the intensity is lowest for the sample annealed in CO/CO₂

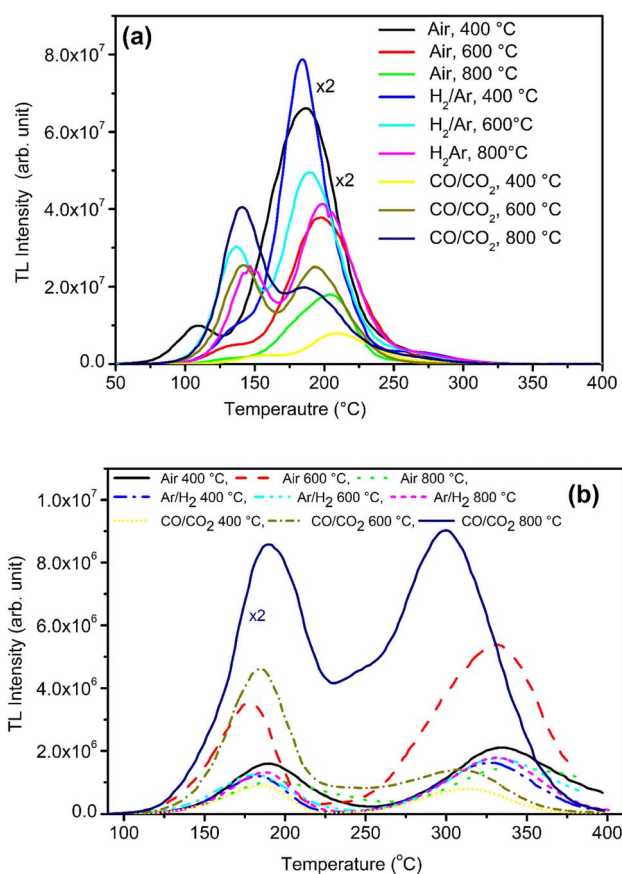

Fig. 5 (a) NaLi₂PO₄:Cu(II) phosphor material annealed in various atmosphere at different temperatures 400, 600 and 800 °C for 1.0 h, (b) NaLi₂PO₄:Cu(I) phosphor material annealed in various atmosphere at different temperatures 400, 600 and 800 °C for 1.0 h.

atmosphere at 400 °C and increases subsequently on annealing at 600 °C and saturates thereafter. This may be occurring because of two reasons. Firstly, as the CO/CO₂ is stronger reducing reagent than that of H₂, most of the Cu²⁺ ions might have been reduced to metallic copper, *i.e.*, $\text{Cu}^{2+} + \text{e}^- \rightarrow \text{Cu}^+ + \text{e}^- \rightarrow \text{Cu}^0$. As mentioned earlier, it could be observed that the TL due to the impurity in Cu²⁺ ionic state is more than that of Cu⁺ state and may be least due to Cu⁰. This may be occurring due to changes in the relative ratios of these ionic species on irradiation.³⁰

Study on effect of annealing was also done on NaLi₂PO₄:Cu(I) as well in order to understand its behavior in different atmospheres at high temperatures. Fig. 5(b) shows the variation in the TL glow curves of NaLi₂PO₄:Cu(I) with increase in temperature range 400 to 800 °C in different atmospheres for 1.0 h. Here also the TL glow curves apparently consist of two peaks one at around 177 and another at 327 °C. However, the change in peak temperatures on annealing at different temperatures in different atmosphere shows that there must be some redox reactions taking place in the material. It could be seen in the figure that the overall TL intensity of the material annealed in 10% H₂ in Ar atmosphere is less than that of the material annealed in air and moreover, there is not much change on annealing at different temperatures. It seems that as H₂ is a weak reducing agent than CO/CO₂, it might not have reduced the Cu⁺ ions further to metallic Cu⁰ ions. But when this material was annealed in CO/CO₂ atmosphere, most of the Cu⁺ ions might have been converted Cu⁰ ions which on irradiation could generate more Cu⁺ and electron traps. There are reports that diffusion of CO/CO₂ in the material could generate more complex defects as in case of Al₂O₃:C and make the material more sensitive.^{42,43} The shift in the main dosimetry peak from ~ 327 to ~ 302 °C (~ 25 °C) indicates generation of different kinds of traps related to such defects.

However, it needs to be seen that what kind traps are generated corresponding to different ions/radicals as well as holes (luminescence centers, LCs) formed during irradiation and whether their recombinations during TL readout is radiative or nonradiative. However, to understand the phenomenon in more details, we have taken ESR, XPS and PL measurements and are discussed in the following sections (Sections 3.7–3.9).

3.6. Change in colours of the images of powder samples on annealing in different atmospheres and temperatures

The changes taking place in the material (due to redox reactions) could also be visualized by change in the colour of the powder samples. The powder samples annealed at different temperatures in different reducing (*i.e.*, 10% H₂ in Ar gas and CO/CO₂ by burning charcoal in a closed system) atmospheres were spread on Petri dishes and their images were taken under room light. The images are as shown in Fig. 6(a) and (b). It could be seen in the figure that the changes in colors of these samples from bluish to grey and grey to brown, *etc.* in NaLi₂PO₄:Cu(II) materials on annealing. Similar changes were also observed in NaLi₂PO₄:Cu(I) also except none of the samples were bluish. The

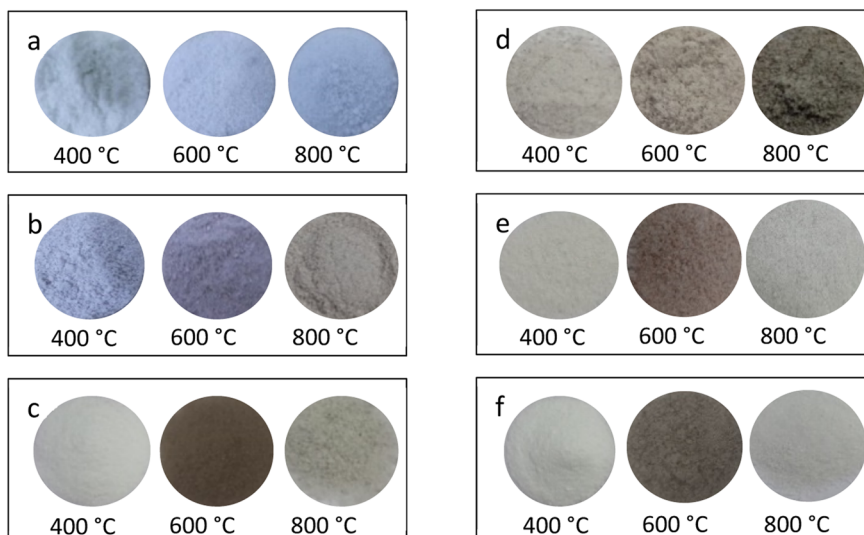

Fig. 6 Change in colour of the powder samples after annealing: (a) $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ annealed in air atmosphere at various temperatures, (b) $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ annealed in 10% H_2 in Ar atmosphere at various temperatures, (c) $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ annealed in CO/CO_2 atmosphere at various temperatures, (d) $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ annealed in air atmosphere at various temperatures, (e) $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ annealed in 10% H_2 in Ar atmosphere at various temperatures, (f) $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ annealed in CO/CO_2 atmosphere at various temperatures. All the images were taken in room light with high-resolution Canon DSLR camera EOS 1500D.

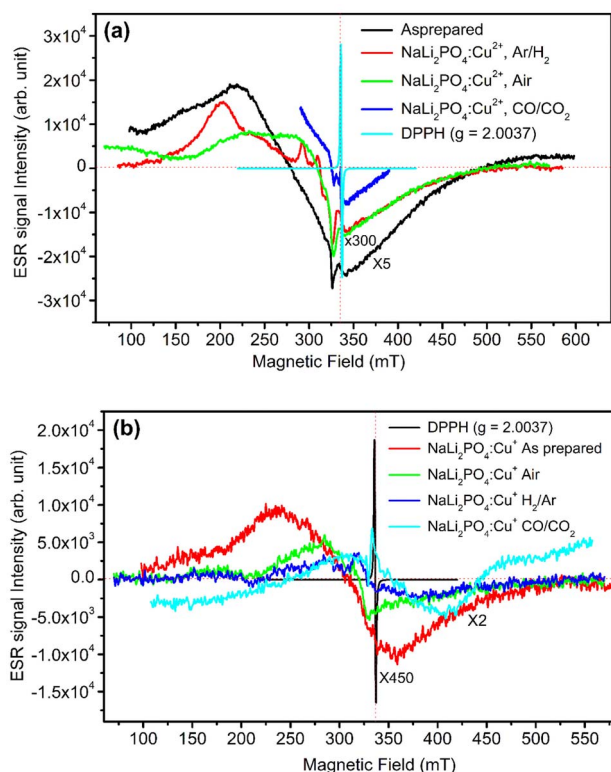

Fig. 7 (a) ESR spectra of the microcrystalline $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ phosphor materials annealed in air, 10% H_2 in Ar and CO/CO_2 atmospheres, (b) ESR spectra of the microcrystalline $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ phosphor materials annealed in air, 10% H_2 in Ar and CO/CO_2 atmospheres. The ESR spectrum for the DPPH ($g = 2.0037$) has also been given for calibration.

change in colour of these materials clearly shows that some redox reactions were occurring in these materials.

3.7. ESR measurements

In order to understand more about the redox reactions in the materials under investigation, ESR measurements were taken at room temperature. As mentioned earlier, the materials were annealed in oxidizing atmosphere (air) and reducing atmosphere (10% H_2 in Ar and CO/CO_2) at different temperatures. However, the ESR spectra of the $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ samples annealed at 400, 400 and 800 °C and that of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ samples annealed at 600, 400 and 800 °C in air, H_2 in Ar and CO/CO_2 atmospheres, respectively, are given for better clarity. The spectra of as prepared (pristine) samples and that of 2,2-diphenyl-1-picrylhydrazyl (DPPH) are also given for comparison. The results are shown in Fig. 7(a) and (b) (Table 1). Lande g -factor was also determined using the following formula: $h\nu = \mu_B H$, where, $h = 4.135 \times 10^{-15}$ eV s, $\nu = 9.40$ GHz, $\mu_B = 5.788 \times 10^{-5}$ eV T^{-1} , $H =$ applied magnetic field (mT). The results are given in Table 2 and 3. The assignment of these values to different probable ions/radicals having unpaired electrons are also done. It may be seen in these tables that the values of g_{\parallel} and g_{\perp} vary on annealing in oxidising as well as reducing atmospheres showing that Cu^{2+} ions are in a very much stressed environments. Not only that but it is difficult to believe that in case of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ material just on annealing in reducing, *i.e.*, CO/CO_2 atmosphere at 800 °C, the TL intensity would increase many fold (Fig. 5(b)) as compared to that of annealed in air at 400 °C (optimized temperature for air atmosphere). The ESR spectrum in this case shows an ESR peak 324.5 mT indicating increase in the Cu^{2+} ions population as well as a new peak at around 340.4 mT, which could be assigned to CO_2^- radicals.⁴⁴

Table 1 Lande g -factors for $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{i})$ materials annealed in different atmospheres

^a Indicates annealing temperatures.

Table 3 Percentage of Cu^+ and Cu^{2+} impurity ions in the materials annealed at optimised temperatures. The areas under the curves of the deconvoluted peaks (932.1 and 933.4 eV) were used to determine the relative concentrations of copper species

Material annealing atmosphere	% of Cu^+ ($2p_{3/2}$), peak position at 932.1 eV	% of Cu^{2+} ($2p_{3/2}$), peak position at 933.4 eV	% of O^- (1s), peak position at 530 eV	% of $\text{O}_{\text{vac.}}^-$ (1s) peak position at 531.18 eV
$\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{i})$, (annealed at 600 °C)	55.40%	44.59%	72.40%	27.59%
$\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{i})$, (annealed in 10% H_2 in Ar gas at 400 °C)	38.68%	61.31%	73.50%	26.49%
$\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{i})$, (annealed in CO produced by burning charcoal at 1073 K 800 °C)	100%	0.0%	66.25%	33.37%
$\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{ii})$, (annealed at 400 °C)	79.53%	20.46%	38.62%	61.37%
$\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{ii})$, (annealed in 10% H_2 in Ar gas at 400 °C)	50.12%	49.87%	57.04%	42.95%
$\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{ii})$, (annealed in CO produced by burning charcoal 800 °C)	100%	0.0%	60.99%	39.00%

So, the carbon impurity thus incorporated may act as codoping and form new defects as in case of $\text{Al}_2\text{O}_3:\text{C}$ and increase the sensitivity.^{41,42} In case of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{i})$ also we have observed

such peak, however, as the ionic state of the impurity (Cu^{2+}) is different it might not have helped in enhancement of TL due to formation of different kinds of defects.

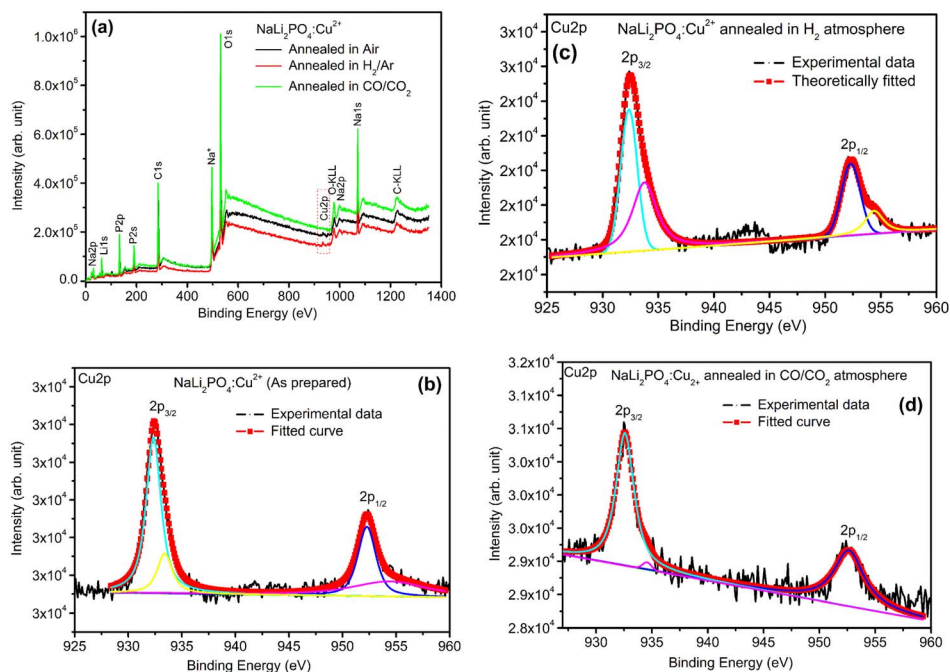

Fig. 8 (a) XPS survey of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ annealed in various atmospheres for Cu ions, (b) XPS deconvoluted spectrum of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ as prepared sample for Cu $2p_{3/2}$ and Cu $2p_{1/2}$, (c) XPS spectrum of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ annealed in 10% H_2 in Ar atmosphere at 400 °C for Cu $2p_{3/2}$ and Cu $2p_{1/2}$, (d) XPS spectrum of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ annealed in CO/CO_2 atmosphere at 800 °C for Cu $2p_{3/2}$ and Cu $2p_{1/2}$.

3.8. XPS spectra of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ and $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ materials annealed in various atmospheres and temperatures

XPS was done to know more about the composition of the material under investigation, especially, about the ionic states of the impurity ions doped in the materials and the changes taking place due to redox reactions occurring on their annealing at different oxidising and reducing atmospheres, (*i.e.*, in air, 10% H_2 in Ar and CO/CO_2). Though the experiments were conducted on all the materials, the results of only the materials annealed at optimized temperatures (400, 400 and 800 °C in air, 10% H_2 in Ar and CO/CO_2 atmospheres for $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ and 600, 400 and 800 °C temperatures in these atmospheres, respectively) are presented here (Fig. 8 and 9). Fig. 8(a) and 9(a) show the complete XPS spectra of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ and $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ samples annealed in different atmosphere, respectively, over the whole energy range of 0–1200 eV. The enlarged views of the spectra in different ranges corresponding to (O 1s and Cu 2p) are also shown in Fig. 8(b–d), 9(b–d), 10(a–c) and 11(a–c) for better clarity. Different peaks are also deconvoluted using the software XPS PEAK-41 to know about the relative concentration of different species and are shown in these figures. The results are summarized in Table 3.

The ratios of areas under these curves to the total area of a particular peak after deconvolution was used to determine the relative concentration of different ionic compositions.⁴⁵ For example, the deconvoluted spectra in the range of 925–960 eV show that the relative concentration of Cu^{2+} and Cu^+ on annealing in different atmospheres. XPS spectra for Cu^+ after deconvolution show peaks at around 932.1 and 952.4 eV for $2p_{3/2}$ and $2p_{1/2}$ energy levels, respectively and similarly at 933.4 eV

and 954.4 eV for Cu^{2+} ions corresponding to $2p_{3/2}$ and $2p_{1/2}$ levels.^{46–49} However, although the ionic states of the impurity before doping was in Cu^{2+} (CuCl_2) and Cu^+ (Cu_2Cl_2) forms, respectively, for the materials $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ and $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$, the relative concentrations after synthesis were found to be in both Cu^+ and Cu^{2+} (55.40 and 44.59% in pristine $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ and 79.53 and 20.46% in pristine $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$) states. After annealing in H_2 atmosphere at 400 °C they changed to 38.68% and 61.31% for Cu^+ and Cu^{2+} in $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ and 50.12% and 49.87% for the same in $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$, respectively, and in CO/CO_2 atmosphere at 800 °C changed to 100% Cu^+ ionic state in both the cases. It shows that redox reactions are occurring on annealing in oxidizing atmospheres and during synthesis also. These kind of reactions not only change the ionic states of the doped impurity but also change the concentrations of oxygen and its vacancies probably due to diffusion of atmospheric oxygen at high temperatures as shown in the table (Table 3). The diffusion of CO at such temperatures might be affecting the concentration(s) of oxygen species/vacancies. It might not only be affecting their concentrations but might also act as impurity, generate different kinds of other complex defects responsible for enhancement of TL in $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ phosphor material. The XPS results are supporting the ESR results discussed earlier (Section 3.7).

3.9. Photoluminescence (PL) spectra

Photoluminescence (PL) emission and excitation spectra of all the samples annealed at different temperatures in different oxidizing and reducing atmospheres was recorded at room temperature. The results are given in Fig. 12 (a–d). The

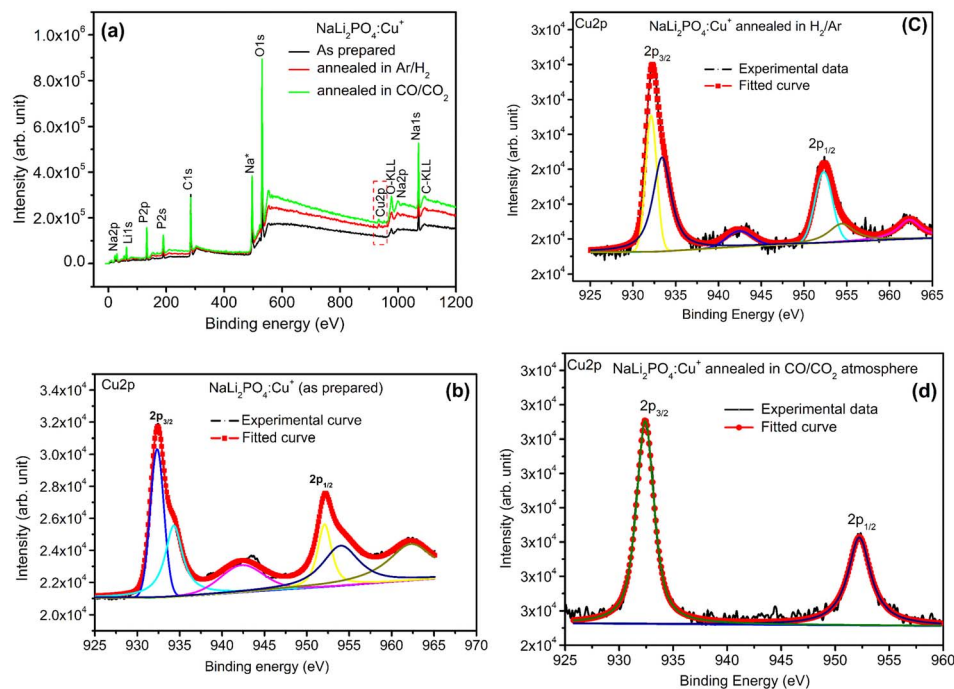

Fig. 9 (a) XPS survey of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ annealed in various atmospheres for Cu ions, (b) XPS deconvoluted spectrum of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ as prepared sample for Cu $2p_{3/2}$ and Cu $2p_{1/2}$, (c) XPS spectrum of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ annealed in 10% H_2 in Ar atmosphere at 400 °C for Cu $2p_{3/2}$ and Cu $2p_{1/2}$, (d) XPS spectrum of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ annealed in CO/CO_2 atmosphere at 800 °C for Cu $2p_{3/2}$ and Cu $2p_{1/2}$.

excitation/emission spectra shown in this figure are that of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ annealed at different temperatures (400, 600 and 800 °C) in air, CO/CO_2 and H_2 in Ar, respectively. The excitation spectra (by keeping emission wavelength at around 469 nm) consists of a sharp peak at around 254 nm. This wavelength, therefore, was chosen as excitation wavelength for all the $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ samples. Emission spectrum consists of a broad band at around 350 nm and many other sharp emission at around 404, 430, 450, 469, 484, 495, 523, 534, 552, 620 and 661 nm. The 350 nm band may be attributed to $3d^9 \rightarrow 4s^1 3d^{10}$ transitions, while the other sharp transitions could be from different sublevels of ${}^2T_{2g} \rightarrow {}^2E_g$ bands of Cu^{2+} . The Cu^{2+} ions belong to the $3d^9$ configuration. Depending upon its octahedral, tetragonal, and square planar (2D) configurations, the levels may split into different configurations. For example, within the octahedron crystal field, the 2D states split into 2E_g and ${}^2T_{2g}$ energy levels. The 2E_g levels split into ${}^2B_{1g}$ and ${}^2A_{1g}$, and the ${}^2T_{2g}$ levels are split into ${}^2B_{2g}$ and 2E_g . Of these levels, ${}^2B_{1g}$ becomes the ground state. Therefore, in the case of copper ions, there are at least three bands corresponding to the transition of ${}^2B_{1g} \rightarrow {}^2A_{1g}$, ${}^2B_{1g} \rightarrow {}^2B_{2g}$ and ${}^2B_{1g} \rightarrow {}^2E_g$ are expected.^{48–52} However, in the present case as the redox reactions occur and as the impurity ions could occupy different positions, *i.e.*, substituting for Li^+ or Na^+ and getting the charge balanced the PO_4^- octahedra may get very much distorted giving rise to more energy levels. Therefore, many more emissions are thus seen as expected. It could also be seen in these figures (Fig. 12(a–d)) the redox reactions occurring. For example, for the materials annealed in air (Fig. 12(a)), the overall intensity of the emission spectrum is low and the ratios of the 350 nm band of Cu^+ some of the prominent bands of Cu^{2+} are

little less than one, however, as the annealing temperature is increased to 600 °C, these bands corresponding to Cu^{2+} become more prominent, indicating that $\text{Cu}^+ \rightarrow \text{Cu}^{2+} + e^-$ type of reactions are occurring. However, at still higher temperature (800 °C) more complex defects must be generated decreasing the overall intensity but the 350 nm band is still prominent. In case of the materials annealed in CO/CO_2 atmosphere, the overall intensity goes on increasing as the temperature is increased from 400 to 800 °C, while in case of the materials annealed in H_2 (10% H_2 in Ar), the 350 nm band is weak initially but the temperature is increased from 400 to 800, this band becomes more prominent indicating that $\text{Cu}^{2+} + e^- \rightarrow \text{Cu}^+$ kind of redox reactions are occurring. In case of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ materials annealed in H_2 , the excitation and emission spectra are very much different, the excitation and emission bands were observed at around 262 and 360 nm, respectively and the intensity increased with the temperature increasing up to 600 °C. However, in cases of the as prepared as well as annealed in CO/CO_2 materials, they are the same as in earlier cases, though the intensity of these spectra is very low as compared to the earlier ones. This is in confirmation with the XPS results that though before doping the impurity was in Cu^{2+} state it was incorporated prominently as Cu^+ in the host matrix (Fig. 8).

3.10. Comparison of sensitivity of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ and $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ materials with that $\text{CaSO}_4:\text{Dy}$ (TLD-900) commercial phosphor

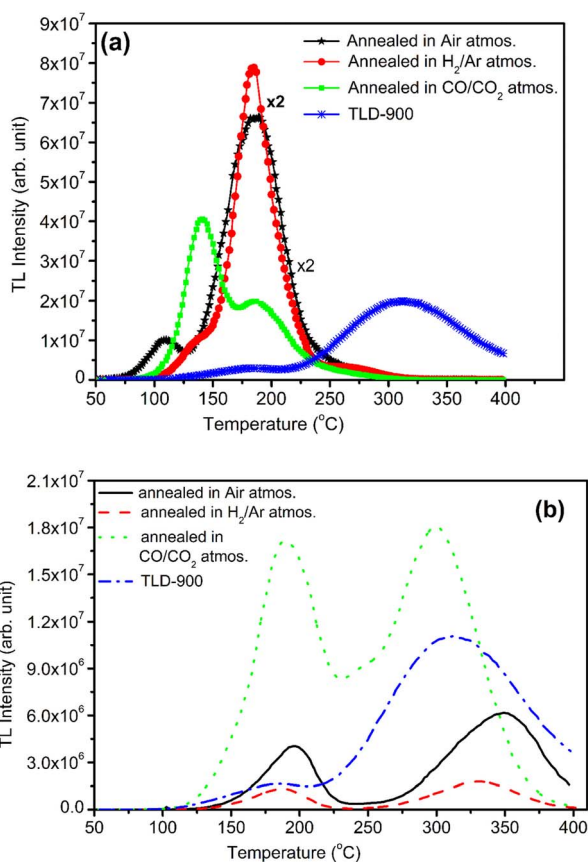

Fig. 13 (a) Comparison of TL sensitivity of the $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ materials annealed in air, in 10% H_2 in Ar and in CO/CO_2 atmospheres annealed at 400, 400 and 800 °C, respectively, with that of $\text{CaSO}_4:\text{Dy}$ (TLD-900) phosphor, (b) similar comparison of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ phosphors annealed under same conditions.

times less but at least 1.8 times enhancement could be seen on annealing in CO/CO_2 atmosphere (annealed at 800 °C) than that of $\text{CaSO}_4:\text{Dy}$ commercially available phosphor at 10 Gy, respectively, as shown in Fig. 13(b).

3.11. Dose response of the materials annealed in air atmosphere

Fig. 14(a) shows the dose responses (areas under the curves) of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ (0.1 mol%) and that of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ (0.1 mol%) the former annealed at 400 °C and the later one annealed at 600 °C (temperatures optimized for TL) in air. It could be seen that $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ (0.1 mol%) was found to be the most sensitive than $\text{CaSO}_4:\text{Dy}$ (TLD-900) and also $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ (0.1 mol%). All the responses were found to be almost linear up to 5.0 Gy thereafter becomes supralinear at low doses. The material was also irradiated at high doses of γ -rays from ^{60}Co radioactive source and TL was taken. The high-dose response curves are as shown in Fig. 14(b). It could be seen that if we consider individual peaks of the glow curve of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ material it seems getting saturated around 100 Gy, however, if we consider the area under both the peaks together the dose response gets widened up to 1.0 kGy though it is little supralinear. In case of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ material, it is sublinear up to 500 Gy and then becomes supralinear till it saturates at around 5.0 kGy.

As mentioned earlier, $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ phosphor material with 0.1 mol% concentration and annealed in H_2 in Ar atmosphere at 400 °C and 600 °C. The phosphor material was found to be most sensitive at 400 °C and it can be used for dose measurements. $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ (0.1 mol%) samples were irradiated with gamma radiation by using ^{60}Co source for different dose range of 10 Gy–10 kGy. The dose response of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ is linear up to 5.0 kGy after that it gets saturated so that it

Fig. 14 (a) Dose response (curve a) of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ (0.1 mol%) material annealed at $400\text{ }^\circ\text{C}$ in air in the dose range of 1.0 to 10 Gy. The dose response (curve b) of $\text{CaSO}_4:\text{Dy}$ (TLD-900) is also given for comparison. Dose response (curve c) of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ (0.1 mol%) material annealed at $400\text{ }^\circ\text{C}$ in air in the dose range of 1.0 to 10 Gy. Dose response (curve d and e) of individual peaks (peak a and peak b) are also given for clarity, (b) dose response (curve a) of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ (0.1 mol%) material annealed at $400\text{ }^\circ\text{C}$ in air in the dose range of 10.0 Gy to 10 kGy. Dose response (curve b) of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ (0.1 mol%) material annealed at $400\text{ }^\circ\text{C}$ in air in the dose range of 10.0 Gy to 10 kGy. Dose response (curve c and d) of individual peaks (peak a and peak b) are also given for clarity.

can be used for high radiation dosimetry. Similarly, $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ (0.1 mol%) annealed in CO/CO_2 atmosphere at $800\text{ }^\circ\text{C}$ are irradiated with dose range 10.0 Gy–10 kGy by using gamma source. The dose response of it is linear up to 5.0 kGy after that it starts saturating. The dose responses of the $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ (0.1 mol%) samples annealed in 10% H_2 in Ar and that in CO/CO_2 atmospheres at optimized temperatures were also studied but all the dose responses are not given here due to paucity of space and similarity with the dose responses described here for annealing in air except enhanced intensities.

3.12. Fading

To study the fading effect (how much TL signal fades with respect to time) of the material, irradiation of 10.0 Gy of gamma ray Co^{60} source was given to the samples. The samples were stored at 300 K in the black paper to protect from the direct sunlight to

Fig. 15 (a) TL fading of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$, TL fading was taken immediately after the irradiation, *i.e.*, day 1 to 60 days, (b) TL fading $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ from day 1 to 60 days.

stop the fast fading. In case of $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ fading will be observed 29% shown in Fig. 15(a) and $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{I})$ fades 30% shown in Fig. 15(b) in 2 months, respectively.

3.13. Reusability

Reusability is one of the most important properties to satisfy for a good TLD phosphor. A material is not considered to be a good TL dosimeter, if its sensitivity/glow curve structure change after its use, *i.e.*, these characteristics should remain unaltered even after its irradiation and TL readouts for several number of cycles. Therefore, the newly developed $\text{NaLi}_2\text{PO}_4:\text{Cu}(\text{II})$ TLD phosphor was tested for its reusability. Pallets of the samples were exposed to 10 Gy of γ -rays and TL glow curves were recorded up to $400\text{ }^\circ\text{C}$, followed by quickly cooling it to the room temperature. The same sample was annealed at $400\text{ }^\circ\text{C}$ for 10 min to ensure that all traps from earlier irradiation were emptied. The sample was again irradiated second time with the same amount of dose and readout was taken using the same heating and cooling procedure. Several such cycles of irradiations and readouts were performed on the same sample by keeping all other parameters constant. No significant changes have been observed in the TL sensitivity of the phosphor material. A very good reusability is thus seen in the newly developed TLD phosphor.

4. Conclusions

NaLi₂PO₄ material was doped with two different compounds Cu₂Cl₂ and CuCl₂ as sources of the Cu-impurity in order to see the effect of Cu⁺ and Cu²⁺ on the luminescence and other characteristics of the material under investigation. However, it was observed that though the initial ionic states of the impurity were Cu⁺ or Cu²⁺ they were incorporated in both the forms in the material. The impurity concentrations in both the cases were optimized and found that it gives the maximum TL intensity at around 0.1 mol%. From our earlier studies,³⁰ it was known that redox reactions could occur in Cu-doped materials. Therefore, the materials were annealed in oxidizing (air) and reducing (10% H₂ in Ar and CO/CO₂) atmospheres. Redox reactions of Cu⁰ ↔ Cu⁺ ↔ Cu²⁺ kinds take place on annealing the materials at different temperatures and on irradiation. The redox reactions were studied using different experimental techniques, such as ESR, XPS and PL. The effect of such redox reactions on TL was also studied from dosimetry applications point of view and found that there was many fold enhancement in both Cu⁺ and Cu²⁺ doped materials. It was also found from ESR measurements that there could be incorporation of carbon due to annealing in CO/CO₂ atmosphere at high temperatures and may act as co-dopant, form some more complex defects enhancing the TL intensity. Thus, higher sensitivity (3.3 and 1.0 times more) than the commercially available CaSO₄:Dy (TLD-900) phosphor at optimized annealing temperatures (400 °C for annealed in 10% H₂ in Ar and 800 °C for annealed CO/CO₂ atmospheres) at 10.0 Gy dose, wide dose response up to 5.0 kGy, (though for NaLi₂PO₄:Cu(II) materials it is sublinear up to 3.0 kGy and becomes supralinear till it gets saturated), low fading (30% in 2 months) and very good reusability make this material a good candidate for the dosimetry of high-energy radiations.

Abbreviations

TL	Thermoluminescence
TLD	Thermoluminescence dosimetry/dosimeter
OSL	Optically stimulated luminescence
OSLD	Optically stimulated luminescence dosimetry/dosimeter
PXRD	Powder X-ray diffraction
XPS	X-ray photoluminescence spectroscopy
ESR	Electron spin resonance
PL	Photoluminescence
LC	Luminescence centre
RT	Room temperature
LED	Light emitting diode
DMFC	Digital mass flow controller
NaLi ₂ PO ₄ :Cu(I)	Sodium lithium phosphate doped with Cu ₂ Cl ₂
NaLi ₂ PO ₄ :Cu(II)	Sodium lithium phosphate doped with CuCl ₂

Author contributions

Both the authors have equal contribution.

Conflicts of interest

There is no conflict of interest to declare.

Acknowledgements

We are thankful to the USIC, Delhi university to provide their facilities. We also grateful to Inter University Accelerator Center (IUAC), New Delhi, for providing irradiation facility of Co⁶⁰ source. One of the authors (BB) is thankful to Council of Scientific and Industrial Research, New Delhi, India for a research fellowship (CSIR award letter No. 09/045(1681)/2019-EMR-I). We are also thankful to Institute of Eminence (IoE), University of Delhi for partial funding through FRP (IoE Ref. No./IoE/2021/12/FRP).
