Engineering Pt nanoclusters on CeO₂ surface with abundant point defects by *in situ* confined-domain encapsulation strategy for the catalytic elimination of VOCs†

Siyi Ma,^{ab} Fang Dong,^{ac} Weiliang Han,^a Weigao Han^a and Zhicheng Tang^{id}*^a

Pt nanoclusters are a promising catalyst for VOC catalytic combustion, but they have been rarely studied so far. Herein, Pt nanoclusters (Pt NCs) and Pt nanoparticles (Pt NPs) were constructed by an *in situ* confined-domain encapsulation strategy, and then the reaction mechanism of Pt species on the catalytic combustion of VOCs was studied systematically. Interestingly, the addition process of Pt and Ce components greatly affected the dispersion and surface states of Pt species. The catalytic performance over Pt_{NC}@CeO₂ (0.01 wt% Pt loadings) was proved to be of outstanding activity and stability, and the reason was related to the contribution of Pt nanoclusters and more lattice oxygen and Ce³⁺ species, whose formation was inextricably linked to the strong interfacial effect between Pt and CeO₂. Notably, the *in situ* introduction approach of Pt species can effectively build up the point defects on the surface of CeO₂ to promote the dispersion and anchoring of Pt species. *In situ* DRIFT spectroscopy verified that the role of lattice oxygen was significant in accelerating the catalytic oxidation of VOCs, and the oxidation process of toluene followed the reaction path: toluene → benzyl alcohol → benzaldehyde → benzoic acid → phenol → maleic anhydride → carbon dioxide and water. Meanwhile, the rate-determining step in the oxidation of toluene may be the further decomposition of alcohol or carboxylic acid intermediates.

1. Introduction

Volatile organic compounds (VOCs) have a significant effect on the atmosphere. As one of the contaminants in the atmosphere, VOCs can also cause relatively serious damage to human health.^{1,2} In fact, VOCs are essential precursors to pollutants like ozone, photochemical smog, and PM_{2.5} and are mostly produced by the production activities of industrial and human sources. Therefore, it is of great importance to convert VOCs into environmentally friendly substances to minimize the impact on human health and the environment. Toluene, as one of the typical indoor VOCs, is mainly used in various common materials, including paints, furniture, adhesives, upholstery materials and chemical solvents.^{3,4} The

most important point is that nowadays, people are exposed most of the time to toluene, so highly attentive efforts are required to eliminate toluene.⁵ Currently, catalytic oxidation is a more significant and effective method for VOC elimination.^{6,7} Moreover, as a key factor in the reaction process, the catalytic performance of catalysts has a positive relationship with the efficiency of VOC elimination.⁸ Obviously, designing a class of excellent and efficient catalysts can help promote the prevention and control of VOC pollutants.

Compared with non-precious metal catalysts, precious metal catalysts^{9–12} are selected to promote the catalytic oxidation efficiency of VOCs by virtue of their high catalytic activity, strong anti-inactivation ability, and low reaction temperature. Among the noble metal catalysts, platinum-based catalysts have better catalytic effects for hydrocarbon and aromatic hydrocarbon VOCs.^{13–15} Naturally, the key to preparing highly active platinum-based catalysts is to improve the active centers, which requires the assistance of a carrier. The typical active carrier cerium dioxide (CeO₂), with its unique characteristic of defect-prone structure and interconversion between different valence states of cerium,¹⁶ can act extensively in VOC catalytic combustion especially after the addition of the noble metal platinum (Pt).^{17,18} More

importantly, this type of carrier has strong interactions with precious metal nanoparticles.^{19,20} Moreover, strong metal-support interactions (SMSIs), generally formed by chemical bonding and associated charge transfer in the active interface region, can significantly improve the catalytic performance of Pt/CeO₂ catalysts. Undoubtedly, Pt/CeO₂ catalysts stand out among the many catalysts used for VOC catalytic combustion.

However, in typical supported Pt/CeO₂ catalysts, noble metal nanoparticles have an uneven size distribution that is not uniform enough to maximize the utilization of their active sites, and the catalysts are prone to agglomeration after a long reaction time and even high-temperature reactions, resulting in catalyst deactivation. These deficiencies have hindered the wide application of Pt/CeO₂ catalysts to some extent.²¹ Therefore, in recent years, there has been a surge of research to improve the dispersion of Pt species (construction of nanoclusters or even atomic-level Pt)^{22,23} and study the connection between the distribution of the Pt species and catalytic activity.²⁴ Nevertheless, the impact of Pt nanoclusters (Pt NCs) on the efficiency of VOC catalysis has not received much attention. Compared to ordinary metal nanoparticles (M NPs), metal nanoclusters (M NCs) are particularly suited for the field of catalysis because they have a distinct coordination environment, a smaller size, a greater specific surface area and a well-defined atomic structure.^{25,26} For example, Mostafa *et al.*²⁷ studied the oxidation of 2-propanol by different shapes of Pt NCs with different

reaction efficiencies. Xue *et al.*²⁸ explored the combustion mechanism of methane with the help of Pt NCs. Likewise, M NCs, as transitions between nanoparticles and atoms, exhibit a more stable electronic energy band structure than single atoms²⁹ and have more abundant catalytically active exposure sites than nanoparticles (NPs), which can significantly increase catalytic efficiency.^{30,31} Therefore, it is important to expose additional active sites by shrinking Pt species to nanoclusters, thus effectively boosting the catalytic performance. Commonly, the methods of catalyst synthesis also significantly affect their catalytic performance.^{32,33} For instance, Lai *et al.*³⁴ enhanced hydrogen precipitation catalysis by modulating the electronic structure of Pt nanoclusters. In addition, SMSI is also a factor that cannot be neglected in the catalyst preparation process. To our knowledge, nonetheless, there have not been any studies on surface defect engineering on CeO₂ to control the particle size of Pt species and their use in catalytic oxidation of VOCs.

Herein, Pt NCs and Pt NPs were constructed by an *in situ* confined-domain encapsulation strategy, and the reaction mechanism of the action of Pt species was systematically investigated. In order to carefully optimize Pt–CeO₂ catalysts, the effects of Pt and Ce species on the catalytic performance of Pt–CeO₂ catalysts were examined in this article. Scheme 1 shows the preparation process of each catalyst. Among them, adding sodium borohydride (NaBH₄) *in situ* to generate more Ce³⁺ species was beneficial to promote the catalytic performance.³⁵ With the aid of many characterization

Scheme 1 Schematic illustration of the synthetic process of Pt–CeO₂ catalysts.

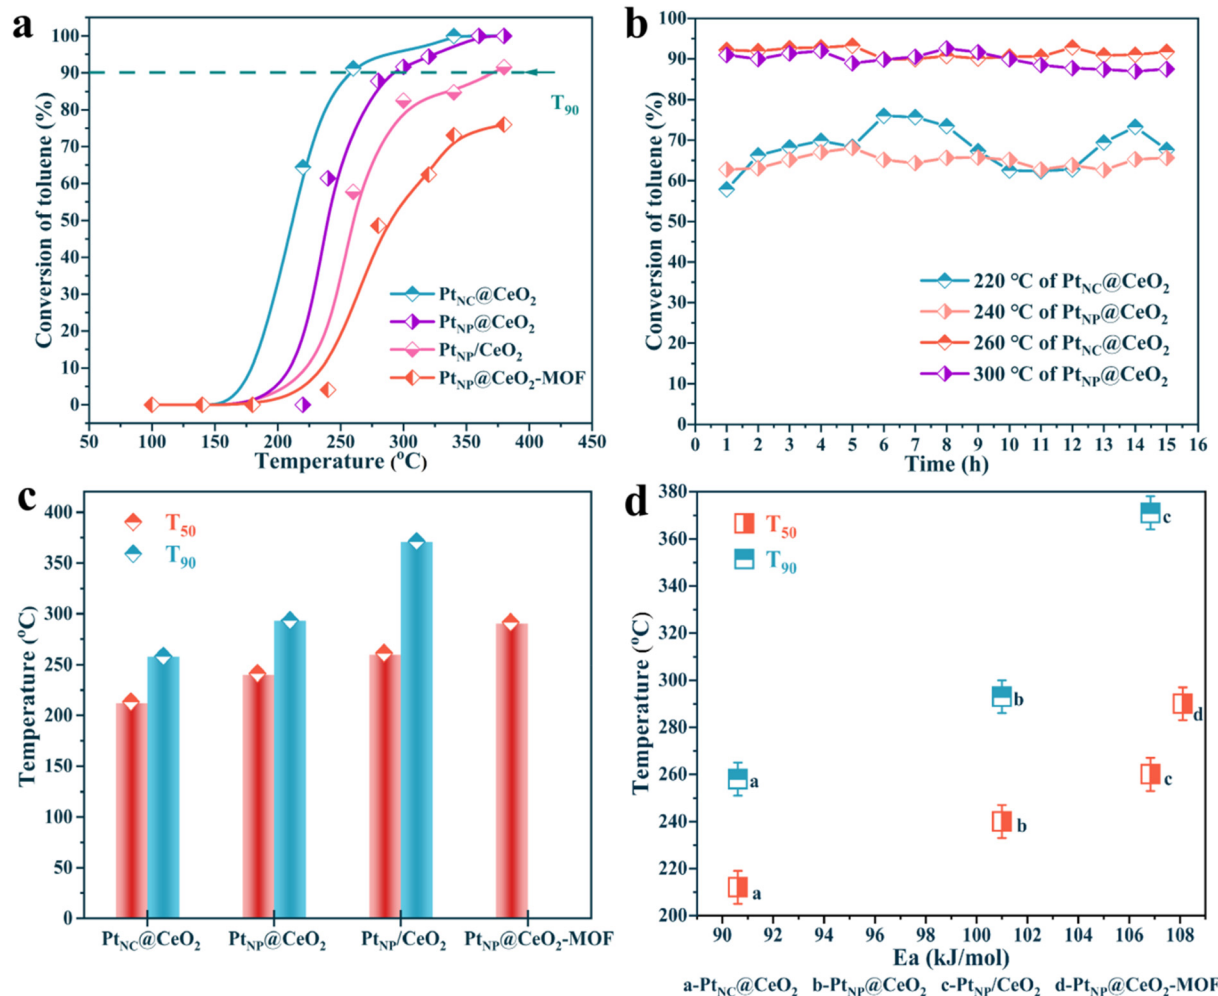

Fig. 1 The activity plot of Pt_{NC}@CeO₂, Pt_{NP}@CeO₂, Pt_{NP}/CeO₂ and Pt_{NP}@CeO₂-MOF catalysts (a), the stability tests of Pt_{NC}@CeO₂ and Pt_{NP}@CeO₂ under dry conditions (b), the comparison of T₅₀ and T₉₀ of each catalyst (c) and the catalytic activity versus E_a over the catalysts (d).

activity of the Pt–Ce catalysts showed a wide variation, highlighting the prominent influence of Pt and Ce introduction methods on the catalytic reactivity. First, the activity of the Pt_{NC}@CeO₂ sample (T₉₀ = 260 °C) was significantly better than that of the Pt_{NP}@CeO₂ sample (T₉₀ = 292 °C), demonstrating that the Pt species introduction method was preferable to the Ce species introduction approach for improving the catalytic activity. Second, the use of different substrates may have a significant impact on the catalytic activity. As an example, the activity of Pt_{NP}@CeO₂-MOF did not exceed 90% conversion when compared to that of Pt_{NC}@CeO₂ and Pt_{NP}@CeO₂-MOF. Furthermore, compared to Pt_{NP}/CeO₂ (T₉₀ = 373 °C) synthesized by the impregnation method, the Pt_{NC}@CeO₂ catalyst produced by the *in situ* confined-domain encapsulation approach was more practical for the catalytic combustion of VOCs. Moreover, the catalyst that had not been subjected to NaBH₄ treatment was measured and the result is displayed in Fig. S1a.† The catalytic performance was significantly impacted by the addition of NaBH₄. The activity of the Pt_{NC}@CeO₂ catalyst was also relatively good as shown in Table S1.†

Subsequently, the thermal stability of Pt_{NC}@CeO₂ and Pt_{NP}@CeO₂ samples was tested under dry conditions at high and low conversions (Fig. 1b), respectively. For the Pt_{NC}@CeO₂ catalyst, the toluene conversion remained at 60–70% for 15 h at 220 °C, while that was maintained essentially above 90% at 260 °C. As for the Pt_{NP}@CeO₂ catalyst, the toluene conversion was kept between 60% and 65% for 15 h at 240 °C, while at 300 °C the toluene conversion was around 90% for 15 h, and slightly decreased after 10 h. Besides, we also performed stability tests (T₉₀) on Pt_{NC}@CeO₂ and Pt_{NP}@CeO₂ catalysts for up to 40 h (Fig. S1b†). The Pt_{NC}@CeO₂ sample still maintained 90% conversion, while the conversion of the Pt_{NP}@CeO₂ sample was maintained above 85%. It was clear that the Pt_{NC}@CeO₂ catalyst exhibited better durability at a high temperature than the Pt_{NP}@CeO₂ catalyst. The strategy of *in situ* introduction of Pt species could effectively promote the catalytic activity as shown in Fig. 1a. In Fig. 1c, a comparison of T₅₀ and T₉₀ for each catalyst was drawn. The temperature order of the low conversions for each catalyst was similarly consistent with the order of the high conversions, and the Pt_{NC}@CeO₂

catalyst demonstrated the best activity. In addition, the carbon balance based on the import and export concentration was calculated and the carbon balance of each catalyst was significantly better than 96%.

As shown in Fig. S2,† there was a certain linear relationship about the four samples of $\ln r$ and $1000/T$, which was named as the Arrhenius curve, and the E_a value of each catalyst can be calculated. The results showed that the main order of the E_a value of each catalyst was $\text{Pt}_{\text{NC}}@\text{CeO}_2$ ($90.61 \text{ kJ mol}^{-1}$) < $\text{Pt}_{\text{NP}}@\text{CeO}_2$ ($101.00 \text{ kJ mol}^{-1}$) < $\text{Pt}_{\text{NP}}/\text{CeO}_2$ ($106.84 \text{ kJ mol}^{-1}$) < $\text{Pt}_{\text{NP}}@\text{CeO}_2\text{-MOF}$ ($108.11 \text{ kJ mol}^{-1}$). It was also established that the $\text{Pt}_{\text{NC}}@\text{CeO}_2$ catalyst had the highest activity, when the activity analysis was combined with the E_a value of each catalyst, which had an inverse pattern with regard to the activity. More importantly, the oxidation of toluene mainly depends on kinetics at low conversion (<20%), leading to the construction of the Arrhenius plot. Therefore, the credibility of the E_a value of this work was relatively high. In addition, both T_{50} and T_{90} of the catalysts were positively correlated with E_a (Fig. 1d), confirming that the $\text{Pt}_{\text{NC}}@\text{CeO}_2$ catalyst had the most excellent catalytic performance.

3.2 Microstructure of the catalysts

Fig. 2 displays the micromorphology of each catalyst and the dispersion conditions of the Pt species by TEM. $\text{Pt}_{\text{NC}}@\text{CeO}_2$ and $\text{Pt}_{\text{NP}}@\text{CeO}_2$ exhibited short rod-shaped structures which

have a length of 50–100 nm with a width of about 10 nm. The $\text{Pt}_{\text{NP}}@\text{CeO}_2\text{-MOF}$ sample displayed an elongated rod-like structure with a length of 50–100 nm, and the $\text{Pt}_{\text{NP}}/\text{CeO}_2$ sample showed polyhedral structures of about 10 nm in diameter, demonstrating that the preparation methods had a massive effect on the morphology of catalysts. For $\text{Pt}_{\text{NC}}@\text{CeO}_2$ and $\text{Pt}_{\text{NP}}@\text{CeO}_2$, the differed introduction methods of Pt and Ce species did not affect the catalyst morphology but altered the size of Pt species over the Pt/CeO₂ catalyst (Fig. 2e and f). Generally speaking, when the particle size is reduced to a nanocluster, the lattice is not easily identified and eventually disappears.³⁶ Therefore, it is clear that $\text{Pt}_{\text{NC}}@\text{CeO}_2$ had more Pt nanoclusters (Pt NCs) and the diameter of the nanoclusters was mainly less than 1 nm as seen by HRTEM.³⁷ The $\text{Pt}_{\text{NP}}@\text{CeO}_2$ sample exhibited the presence of nanoparticles (>1 nm) as shown in Fig. 2f, which could also be confirmed by Fig. S3.† In addition, the presence of Pt nanoparticles (Pt NPs) on $\text{Pt}_{\text{NP}}@\text{CeO}_2\text{-MOF}$ and $\text{Pt}_{\text{NP}}/\text{CeO}_2$ samples is revealed in Fig. 2g and h. Combined with the catalytic performance, the production of Pt NCs was one of the crucial elements to enhance the catalytic activity. It may be because the metal atoms in nanoclusters were mainly located at the corners and edges with a large contact surface,³⁸ which increased the active sites' exposure and thus promoted the catalytic activity. Moreover, the irregularity of the microstructure may be the reason for the poor activity of the $\text{Pt}_{\text{NP}}/\text{CeO}_2$ catalyst.^{39,40}

Fig. 2 The TEM images of $\text{Pt}_{\text{NC}}@\text{CeO}_2$ (a and e), $\text{Pt}_{\text{NP}}@\text{CeO}_2$ (b and f), $\text{Pt}_{\text{NP}}@\text{CeO}_2\text{-MOF}$ (c and g) and $\text{Pt}_{\text{NP}}/\text{CeO}_2$ (d and h) and the schematic structure of each catalyst (i–l). The inset shows the lattice diffraction rings of each catalyst.

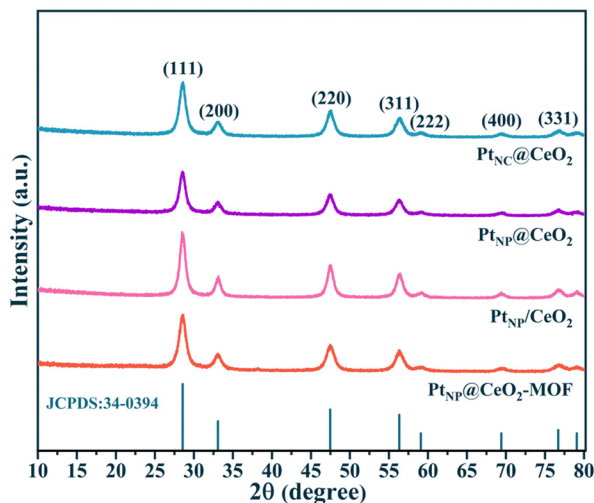

Fig. 3 The XRD patterns of the four catalysts.

The XRD patterns are shown in Fig. 3. The derived peaks of 28.6° , 33.1° , 47.5° , 56.3° , 59.1° , 69.4° , and 76.7° (2θ) were attributed to the (111), (200), (220), (311), (222) and (331) crystal planes of CeO_2 with face-centered cubic structure, respectively. The results could be compared with the XRD peaks of CeO_2 (JCPDS 34-0394), indicating that the four catalysts contained primarily the crystal structure of CeO_2 . At the same time, the XRD patterns showed no Pt-related diffraction peak, which may be related with the low Pt content or the existence of highly dispersed Pt nanoparticles. In common, the presence of wider peaks in the XRD diffraction peaks indicated that the active metal components exhibited high dispersion,⁴¹ which facilitated the emergence of more active sites and thus promoted the catalytic oxidation process. In contrast to the $\text{Pt}_{\text{NP}}@\text{CeO}_2$ sample, $\text{Pt}_{\text{NC}}@\text{CeO}_2$ showed a border peak width, which implied that it had a smaller grain size contributing to the generation of lattice defects.^{42,43} The XRD results demonstrated that the different

methods of Pt and Ce introduction had an impact on the crystal sizes of the catalysts.

To gain insight into the molecular structure, Raman measurement was performed on the catalysts (Fig. 4). There were two main peaks for each catalyst in the Raman spectrum. The peak at around $458\text{--}464\text{ cm}^{-1}$ could be attributed to the Ce–O–Ce mode of the fluorite-type CeO_2 structure (F_{2g}).³¹ The peak of 579 cm^{-1} was attributed to the defect-induced (D) mode, which was associated with Ce^{3+} -induced oxygen vacancies. Metal–support interactions, in general, influenced the energy produced by the band in the D mode, implying that various amounts of oxygen vacancies were formed. It can be seen in Fig. 4a that more oxygen vacancies were exhibited in the $\text{Pt}_{\text{NC}}@\text{CeO}_2$ catalyst, which may be related to the presence of Ce^{3+} or may be due to the vibrations generated when the highly dispersed PtO interacts with the cerium oxide carrier to form Pt–O–Ce bonds, thus creating defects in the cerium oxide lattice, which was also consistent with the XRD result. Apparently, the D-mode peak of the $\text{Pt}_{\text{NP}}@\text{CeO}_2\text{-MOF}$ sample was relatively weak compared to that of the other three catalysts, which may also be caused by the insignificant interaction between the precious metal (Pt) and the carrier (CeO_2). More importantly, through the magnified schematic of Raman (Fig. 4b), compared with the $\text{Pt}_{\text{NP}}@\text{CeO}_2\text{-MOF}$ sample, we found that the F_{2g} mode bands of $\text{Pt}_{\text{NC}}@\text{CeO}_2$, $\text{Pt}_{\text{NP}}@\text{CeO}_2$ and $\text{Pt}_{\text{NP}}/\text{CeO}_2$ catalysts showed a certain degree of red shift and the peak intensity also decreased to a certain degree. This suggested that the structure of fluorite might have changed, which was confirmed to be due to the emergence of Pt–O–Ce bonds. It is possible that the introduction of the reducing agent promoted the construction of point defects in the carrier, thus contributing to the SMSI effect.⁴⁴ The Raman result elucidated that the formation of the SMSI effect in the $\text{Pt}_{\text{NC}}@\text{CeO}_2$ catalyst caused the production of additional Pt–O–Ce bonds. At the same time, the $\text{Pt}_{\text{NC}}@\text{CeO}_2$ catalyst generated more oxygen vacancies, which provided the active

Fig. 4 Raman diagrams of the catalysts.

Fig. 5 The N₂ physisorption isotherms of catalysts (a) and the BJH pore size distributions of catalysts (b).

centers and promoted the catalytic reaction of VOCs. It was also verified that the Pt_{NC}@CeO₂ catalyst had the best activity, which was in agreement with the activity result.

Furthermore, the molecular structure and chemical bonds in the catalysts can be identified in the range of 500–4000 cm⁻¹ by Fourier transform infrared spectroscopy (FTIR). The FTIR results of Pt_{NC}@CeO₂, Pt_{NP}@CeO₂, Pt_{NP}/CeO₂ and Pt_{NP}@CeO₂-MOF are displayed in Fig. S4.† The broad peak at 3420 cm⁻¹ was mainly attributable to the physically adsorbed water (H₂O), while the band at 1578 cm⁻¹ corresponded to the δ(OH) vibration of H₂O molecules. The narrow band in the 2825–2990 cm⁻¹ range was mainly associated with the incorporation of PVA. The presence of two broad bands within 990–1420 cm⁻¹ was mainly related to the formation of “carbonate-like” materials on the surface of CeO₂, possibly caused by residues in the catalysts,⁴⁵ and the peak at 848 cm⁻¹ corresponded to the metal–oxygen bond. Notably, the Pt_{NP}@CeO₂, Pt_{NP}/CeO₂ and Pt_{NP}@CeO₂-MOF catalysts showed an asymmetric stretching vibration band of CO₂ at 2352 cm⁻¹, but the Pt_{NC}@CeO₂ catalyst did not exhibit the corresponding peak. This indicated that CO₂ from the calcination process was not easily adsorbed on the surface of the Pt_{NC}@CeO₂ catalyst,⁴⁶ suggesting that CO₂ could be quickly desorbed. This may imply that the CO₂ products during the catalytic reaction are easily desorbed, thus facilitating the catalytic reaction of VOCs.

Naturally, the data on the pore structure and specific surface of each catalyst are also important parts of the analysis of catalytic microstructure. Thus, the BET data of each sample were calculated and the outcomes are presented in Fig. 5 and S5† and Table 1. According to the IUPAC classification, the N₂ adsorption–desorption isotherms of each catalyst exhibited distinct type IV isotherms with H3-type hysteresis loops of elongated crack-like structures.^{47,48} Table 1 shows the detailed BET data for Pt_{NC}@CeO₂, Pt_{NP}@CeO₂, Pt_{NP}/CeO₂ and Pt_{NP}@CeO₂-MOF catalysts. The BET surface area of Pt_{NC}@CeO₂ with Pt nanoclusters was 112.22 m² g⁻¹, the pore volume was 0.37 cm³ g⁻¹, and the average pore diameter was 13.04 nm. Most importantly, Pt_{NC}@CeO₂ had a larger specific surface, pore volume and average pore size than Pt_{NP}@CeO₂, Pt_{NP}/CeO₂ and Pt_{NP}@CeO₂-MOF samples. Moreover, the order of the specific surface area was Pt_{NC}@CeO₂ (112.22 m² g⁻¹) > Pt_{NP}@CeO₂ (104.69 m² g⁻¹) > Pt_{NP}/CeO₂ (98.44 m² g⁻¹) > Pt_{NP}@CeO₂-MOF (97.13 m² g⁻¹). It is worth noting that there was a direct relationship with the activity of the catalysts. In Fig. 5b and the enlarged schematic, it can be seen that there are two distinct peaks in the pore size between 0 and 50 nm and the Pt_{NC}@CeO₂ catalyst has the largest average pore size (13.04 nm) according to the data in Table 1. The Pt_{NC}@CeO₂ sample prepared by an *in situ* confined-domain encapsulation method with the larger pore size was more

Table 1 The data of specific surface, pore structure, and Pt content of catalysts

Catalysts	BET surface area (m ² g ⁻¹)	Pore size (nm)	Pore volume (cm ³ g ⁻¹)	Pt content (wt%)
Pt _{NC} @CeO ₂	112.22	13.04	0.37	0.0075
Pt _{NP} @CeO ₂	104.69	12.19	0.32	0.0113
Pt _{NP} /CeO ₂	98.44	9.60	0.24	0.0073
Pt _{NP} @CeO ₂ -MOF	97.13	7.49	0.18	0.0097
CeO ₂ -OH	107.42	7.96	0.26	—
CeO ₂ -MOF	87.03	8.33	0.23	—

suitable for anchoring Pt, thus facilitating the active sites' exposure, and the larger pore size facilitated the diffusion of reactants, thus accelerating the catalytic oxidation of toluene. Obviously, the Pt_{NC}@CeO₂ catalyst with larger pore size did well for molecular retention and diffusion. In conclusion, the methods of the introduction of Pt and Ce were crucial to the microscopic properties. In Table 1, the individual BET data of the catalysts well confirmed the relationship between the microstructure and the catalytic performance of the catalysts. Compared with those of the Pt_{NP}@CeO₂-MOF and CeO₂-MOF samples, the pore structure data of the Pt_{NP}@CeO₂-MOF sample were decreased by the introduction of Pt species, which may be one of the causes of the poor activity of the Pt_{NP}@CeO₂-MOF sample. However, the comparison between the Pt_{NC}@CeO₂ and CeO₂-OH samples showed that the method of *in situ* introduction of Pt species had a positive impact on the BET surface area, pore size, and pore volume of the Pt_{NC}@CeO₂ sample. In short, the Pt_{NC}@CeO₂ catalyst with large specific surface area would provide more active sites to promote the adsorption, which may be one of the factors for the superior catalytic performance. Furthermore, with the help of ICP-OES, we observed that the Pt contents of each catalyst were close to the theoretical value (Table 1).

3.3 Analysis of surface chemical properties and redox behaviors of catalysts

Importantly, the catalytic performance for VOC combustion is related to the elemental valence, redox ability, and adsorption capacity of the catalysts.^{49,50} Therefore, we need to detect the physicochemical properties of the catalysts. For XPS characterization, it can evaluate the chemical environment of each element on the surface of catalysts, and the results are shown in Fig. 6, S6–S9,† and Table 2. Fig. S6† shows that the Pt 4f spectrum and the Pt 4f curves for each catalyst did not have obvious peaks, which may be due to the low Pt content. The fine spectra of Ce 3d were deconvoluted into eight major peaks (Fig. 6a). The peaks at *u'* (884.8–885.4 eV) and *v'* (904.1 eV) were assigned to Ce³⁺ species, and other fitted peaks were mainly attributed to Ce⁴⁺ species.^{42,51} As shown in Table 2, the order of the Ce³⁺ content was Pt_{NC}@CeO₂ (19.90%) > Pt_{NP}@CeO₂ (18.23%) > Pt_{NP}/CeO₂ (16.57%) > CeO₂-OH (16.38%) > Pt_{NP}@CeO₂-MOF (14.08%) > CeO₂-MOF (14.03%). The Ce 3d spectra of fresh and used Pt_{NC}@CeO₂ and Pt_{NP}@CeO₂ catalysts are also shown in Fig. S7† and Table 2. It is obvious that the content of Ce³⁺ species of the catalysts decreased significantly after use, indicating that the Ce³⁺ species promoted the catalytic combustion of VOCs as active species, and the addition of Pt

Fig. 6 The XPS spectra about Ce 3d (a) and O 1s (b), the oxygen species ratios (c) and the active species ratios (d) of catalysts.

Table 2 The XPS data of catalysts

Catalysts	Ce ³⁺ /Ce _{total}	Ce ⁴⁺ /Ce _{total}	O _{latt} /O _{total}	O _{ads} /O _{total}	O _{OH} /O _{total}
Pt _{NC} @CeO ₂	19.90	80.10	74.12	25.88	—
u-Pt _{NC} @CeO ₂	14.64	85.36	66.23	30.19	3.58
Pt _{NP} @CeO ₂	18.23	81.77	70.91	24.07	5.02
u-Pt _{NP} @CeO ₂	15.16	84.84	66.80	26.27	6.93
Pt _{NP} /CeO ₂	16.57	83.43	69.17	30.83	—
Pt _{NP} @CeO ₂ -MOF	14.08	85.92	66.40	33.60	—
CeO ₂ -OH	16.38	83.62	68.99	24.87	6.14
CeO ₂ -MOF	14.03	85.97	65.57	34.43	—

species effectively promoted the generation of Ce³⁺ species, which contributed to the production of more oxygen vacancies, as seen in Table 2. It is worth mentioning that the introduction of reducing agents promoted the creation of Ce³⁺. Therefore, the presence of more reactive Ce³⁺ species in the catalyst implied the formation of more oxygen vacancies. Moreover, combined with the Raman results, it is clearly pointed out that oxygen vacancies were essential for toluene molecules. It meant that the Pt_{NC}@CeO₂ sample contained more active Ce³⁺ species, which promoted the production of more oxygen vacancies and unsaturated chemical bonds. The Pt_{NC}@CeO₂ catalyst had more outstanding activity than the other three catalysts. Thus, having more active Ce³⁺ species could effectively propel the activity at a lower temperature, and it was also confirmed that the presence of Ce³⁺ species was one of the beneficial factors to boost the catalytic reaction.

Moreover, the O 1s spectra of each catalyst are displayed in Fig. 6. The fine peaks at 529.2–529.4 eV, 531.3–531.5 eV and 532.9 eV corresponded to lattice oxygen (O_{latt}), surface adsorbed oxygen (O_{ads}) and surface hydroxyl (O_{OH}), respectively.^{52,53} The four catalysts contained mainly O_{latt} and O_{ads} with a small amount of O_{OH} (Fig. 6b). We also performed XPS on the oxygen species content of fresh and used Pt_{NC}@CeO₂ and Pt_{NP}@CeO₂ catalysts, and the results are illustrated in Fig. S8;† there was a significant reduction of O_{latt} content in the used catalysts. Subsequently, the percentages of oxygen species for each

catalyst were summarized and recorded in Table 2 and Fig. 6c for more visual analysis of the O_{latt}, O_{ads} and O_{OH}. Therefore, it is evident that the content of O_{latt} presented the following order: Pt_{NC}@CeO₂ (74.12%) > Pt_{NP}@CeO₂ (70.91%) > Pt_{NP}/CeO₂ (69.17%) > CeO₂-OH (68.99%) > Pt_{NP}@CeO₂-MOF (66.40%) > CeO₂-MOF (65.57%). Similarly, the introduction of Pt species favored the generation of lattice oxygen. According to previous studies,^{54,55} O_{latt} plays a key role in many thermocatalytic reactions. O_{latt} can oxidize the reducing molecules and then create oxygen vacancies, which are subsequently filled with the activation of molecular oxygen. The ratio of O_{latt} could explain that Pt_{NC}@CeO₂ had the best catalytic performance. It has been proven that more O_{latt} generated sufficient oxygen vacancies, thus promoting toluene adsorption and activation. As shown in Fig. 6d, it can be concluded from the percentage of active species of each catalyst that Ce³⁺ and O_{latt} were the main active components to improve the activity of the Pt_{NC}@CeO₂ catalyst. Also, the addition of Pt species effectively promoted the generation of Ce³⁺ species and lattice oxygen, which contributed to the production of more oxygen vacancies. Moreover, Ce³⁺ also facilitated the generation of unsaturated bonds and more Ce species would interact with Pt species, thus building Pt–Ce interfaces to promote the catalytic oxidation of VOCs.

To determine the types of oxygen species for each catalyst, O₂-TPD curves are recorded in Fig. 7a. The peak at 100–325 °C was considered to be O_α, which was mainly present at the

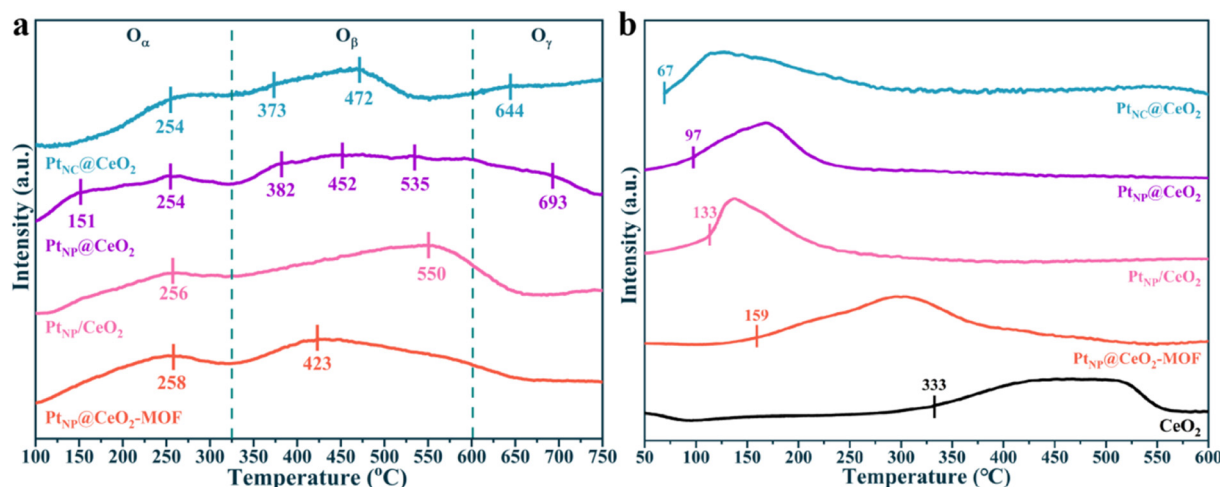

Fig. 7 O₂-TPD curves (a) and H₂-TPR curves (b) of samples.

Fig. 8 NH₃-TPD profiles (a) and percentages of surface acid sites (b) of catalysts.

surface oxygen vacancies. The peak between 325 and 600 °C was caused by the desorption of O_β, and this oxygen species was distributed at the surface lattice. The peak above 600 °C corresponded to O_γ, which was mainly found in the lattice bulk phase.⁵⁶ For Pt_{NC}@CeO₂ and Pt_{NP}@CeO₂, the types of oxygen species were essentially the same. However, the O₂-TPD curve of the Pt_{NC}@CeO₂ sample exhibited higher mobility of O_β and O_γ. Combined with the results of activity, it was revealed that O_β and O_γ transfer from the body to the catalyst surface was accelerated during the reaction process,⁵⁷ thus promoting the activation of VOCs. It has been shown that the methods of *in situ* introduction of Pt and Ce could alter the mobility of oxygen species. It was discovered that the Pt_{NC}@CeO₂ catalyst contained different types of oxygen species. This indicated that the method of Pt and Ce introduction also had a great influence on the type of oxygen species produced by Pt–Ce-based catalysts. In short, the lattice oxygen was significant for the catalytic performance of the Pt_{NC}@CeO₂ catalyst and might be probably due to the interaction between Pt nanoclusters and the carrier. According to the results of the above work, we suggested that the presence of more Ce³⁺ species and a substantial amount of lattice oxygen species on the Pt_{NC}@CeO₂ catalyst may be one of the key factors to enhance the catalytic performance.

The reducibility of each species in the catalysts was tested by H₂-TPR, and the results are presented in Fig. 7b and S10.† Each catalyst showed a wide reduction temperature interval (Fig. 7b), and the H₂ consumption of the catalysts is shown in Table S2.† The finely fitted peaks of each catalyst are displayed in Fig. S10.† In general, the first reduction peak was classified as the reduction of adsorbed oxygen on the surface of CeO₂. The second peak belonged to the reduction of adsorbed oxygen on the subsurface of CeO₂.^{58–60} It is obvious from Fig. 7b that the reduction peaks of CeO₂ shifted toward lower temperatures after the addition of Pt, and the onset reduction temperatures of each catalyst were in the order Pt_{NC}@CeO₂ (67 °C) < Pt_{NP}@CeO₂ (97 °C) < Pt_{NP}/CeO₂ (133 °C) < Pt_{NP}@CeO₂-MOF (159 °C) < CeO₂ (333 °C). In

addition, the lower onset reduction temperature indicated that the Pt species in the catalysts were more likely to produce active hydrogen and transfer it to the CeO₂ carrier, thus greatly decreasing the reduction temperature of CeO₂.⁶¹ Obviously, the H₂-TPR of each catalyst confirmed the existence of a hydrogen overflow phenomenon. It should be noted that the onset reduction temperature of each catalyst remained positively correlated with the activity of each catalyst, indicating that the Pt_{NC}@CeO₂ catalyst established a strong Pt–O–Ce interaction and more Pt active sites, which facilitated the production of more active hydrogen, thus significantly reducing the reduction temperature of CeO₂ and promoting the activation of VOCs.⁶² However, the difficulty in reaching 90% toluene conversion of the Pt_{NP}@CeO₂-MOF sample may also be due to extremely poor redox ability, which did not establish a solid interfacial effect between Pt NPs and CeO₂, thus resulting in a decrease in activity.⁶³ In conclusion, H₂-TPR confirmed that the Pt_{NC}@CeO₂ catalysts had a strong interaction between Pt and CeO₂, so the main reasons for the best activity of the Pt_{NC}@CeO₂ sample could be the formation of the SMSI effect and the highly dispersed Pt nanoclusters. Combined with Fig. 1a and 7b, it can be visualized that the low-temperature reduction peaks had a significant impact on the activity of the catalysts.

The results of NH₃-TPD are exhibited in Fig. 8, S11,† and Table 3. The acid sites could be roughly divided into three types from Fig. 8a. The peaks below 200 °C belonged to weak

Table 3 The proportion of surface acid sites of each catalyst

Catalyst	Weak acid (%)	Medium strong acid (%)	Strong acid (%)
Pt _{NC} @CeO ₂	63.14	24.90	11.96
Pt _{NP} @CeO ₂	41.25	16.04	42.71
Pt _{NP} /CeO ₂	38.89	10.36	50.75
Pt _{NP} @CeO ₂ -MOF	—	27.44	72.56
CeO ₂ -OH	67.34	24.30	8.36
CeO ₂ -MOF	46.47	6.38	47.15

acid sites, the peaks within 200–400 °C were assumed to be medium strong acid sites, and the peaks above 400 °C could be strong acid sites.^{64,65} Obviously, the Pt_{NP}@CeO₂-MOF catalyst showed no significant peak in the range of 0–200 °C, while obvious weak acid sites were present in the other three catalysts. The NH₃-TPD curves of Pt_{NC}@CeO₂, Pt_{NP}@CeO₂, and Pt_{NP}/CeO₂ catalysts showed similar peak shapes within 400 °C. In addition, weak acid sites were useful for the adsorption of toluene molecules,⁴² which can effectively promote the oxidation of VOCs. As shown in Fig. 8b and Table 3, the content of each acid site could be clearly seen and the percentage of weak acid sites on the catalyst surface mainly followed the order Pt_{NC}@CeO₂ (63.14%) > Pt_{NP}@CeO₂ (41.25%) > Pt_{NP}/CeO₂ (38.89%) > Pt_{NP}@CeO₂-MOF. In addition, the Pt_{NC}@CeO₂ catalyst with the largest amount of weak acid sites had the best activity, indicating that the weak acid sites were the main active sites, and the weak acid sites could strengthen and accelerate the adsorption of the reacting molecules, thus making it have excellent activity. Interestingly, the addition of Pt species decreased the number and intensity of weak acid sites on the CeO₂ surface, but the method of *in situ* introduction of Pt species could effectively suppress the reduction of weak acid sites (Table 3). Therefore, it was revealed that the Pt and Ce introduction methods had different effects on the number and intensity of acid sites. Overall, the good activity of the Pt_{NC}@CeO₂ catalyst may be due to the joint action of Pt nanoclusters and weak acid sites to promote the catalytic combustion reaction of VOCs.

3.4 Investigation of reaction mechanism

To clarify the oxidation process of toluene, the formation of intermediates, and the reaction mechanism over the Pt_{NC}@CeO₂ catalyst, *in situ* DRIFTS tests were carried out. The toluene adsorption of the Pt_{NC}@CeO₂ catalyst was conducted at 100 °C (Fig. 9). In Fig. 9a and b, *in situ* DRIFTS results are presented by toluene adsorption of Pt_{NC}@CeO₂ at pure N₂ conditions. The peak at 1030 cm⁻¹ corresponded to the ν (C–H) in-plane bending vibration of the aromatic ring.⁶⁶ The bands at 1105 cm⁻¹ and 1153 cm⁻¹ were attributable to the ν (C–O) stretching vibration of alkoxy species and the ν (C–O) stretching vibration of benzyl alcohol, respectively. It may be speculated that the breakage of the C–H bond of methyl (–CH₃) in adsorbed toluene generated benzyl alcohol (C₆H₅–CH₂O–) species or even short-chain alkoxy species.⁶⁷ The strong bands at 1255 cm⁻¹ and 1646 cm⁻¹ were classified as C–H in-plane bending vibrations and classical aldehyde bands (stretching vibrations of the C=O bond), respectively. This affirmed that benzaldehyde species could accumulate rapidly and be converted to important intermediates in the adsorption process.^{68,69} In addition, peaks at 1302 cm⁻¹, 1800 cm⁻¹, 1867 cm⁻¹ and 1960 cm⁻¹ were correlated with maleic anhydride species.^{69,70} The details of each adsorption band are listed in Table S3.† The most important point is that the Pt_{NC}@CeO₂ catalyst was

capable of adsorbing and activating toluene at 100 °C and allowed toluene to interact with oxygen species at low temperatures to form various intermediates (benzoic acid, benzyl alcohol, maleic anhydride, *etc.*). It is worth mentioning that various intermediates were generated under a toluene/N₂ atmosphere, indicating that lattice oxygen was present on the surface of the catalyst.

Besides, to investigate the mechanism of action of oxygen species, the toluene oxidation process on the Pt_{NC}@CeO₂ catalyst was exposed to toluene/N₂ and O₂/N₂ atmosphere at different temperatures (Fig. 9c and d), respectively. Fig. 9c and d presented similar spectra and also confirmed that lattice oxygen could be involved in the catalytic process of toluene without the need for gaseous oxygen. Additionally, a detailed control of the *in situ* DRIFTS spectra for different atmospheres at various temperatures (100 °C, 200 °C, 300 °C) was performed and the results are shown in Fig. 10a–f. Interestingly, the peak intensity in toluene/air was higher than that in toluene/N₂ gas. It is possible that toluene molecules may not only be adsorbed by the metal active sites but also interacted with already adsorbed oxygen species to yield other substances. Moreover, sufficient gaseous oxygen can supplement the lattice oxygen to rebuild the reactive oxygen species.⁶⁶ The features corresponding to each spectral band are also summarized in Table S3.† The original adsorption bands at 1030 cm⁻¹, 1255 cm⁻¹ and 1646 cm⁻¹ gradually disappeared with increasing temperature, but the characteristic bands of benzoate species and alcohol salt species were significantly enhanced, revealing that these species were the essential intermediates in the catalytic process of toluene.⁷¹ Moreover, the carbonate species could be preferentially converted to CO₂ and H₂O on the surface. It is reasonably concluded that in the reaction of toluene over Pt_{NC}@CeO₂ catalyst, the rate-determining step may be the further decomposition of the alcohol or carboxylic acid intermediate. Based on the analysis of results and Table S3,† it is clearly illustrated that the reaction process of toluene followed the following pathway: toluene → benzyl alcohol → benzaldehyde → benzoic acid → phenol → maleic anhydride → carbon dioxide and water.

In summary, we discovered that lattice oxygen was thought to serve the leading role in the removal of toluene compared to adsorbed oxygen. Therefore, the Mars–van Krevelen (MvK) mechanism was present in the toluene oxidation reaction over the Pt_{NC}@CeO₂ catalyst. Scheme 2 describes the reaction pathways of toluene catalytic oxidation over the Pt_{NC}@CeO₂ catalyst. After the passage of toluene, reactant molecules were adsorbed onto the oxygen vacancies, active species or active sites of the Pt_{NC}@CeO₂ catalyst.⁴³ Subsequently, the activated oxygen species interact with the C–H bonds of the methyl groups in toluene to form benzyl groups and further benzyl alcohol (C₆H₅–CH₂O–). Then, the reactive oxygen species would further interact with C₆H₅–CH₂O– to produce intermediates such as maleic anhydride, phenolate, and so on, and finally to generate carbon dioxide and water, which was well consistent with the MvK

Fig. 9 *In situ* DRIFTS spectra of toluene adsorption (a and b) for $\text{Pt}_{\text{NC}}/\text{CeO}_2$ catalyst at $100\text{ }^\circ\text{C}$ for different times under pure N_2 gas flow and the *in situ* DRIFTS spectra of $\text{Pt}_{\text{NC}}/\text{CeO}_2$ catalyst for different reaction temperatures with toluene/ N_2 gas (c) and toluene/air gas (d).

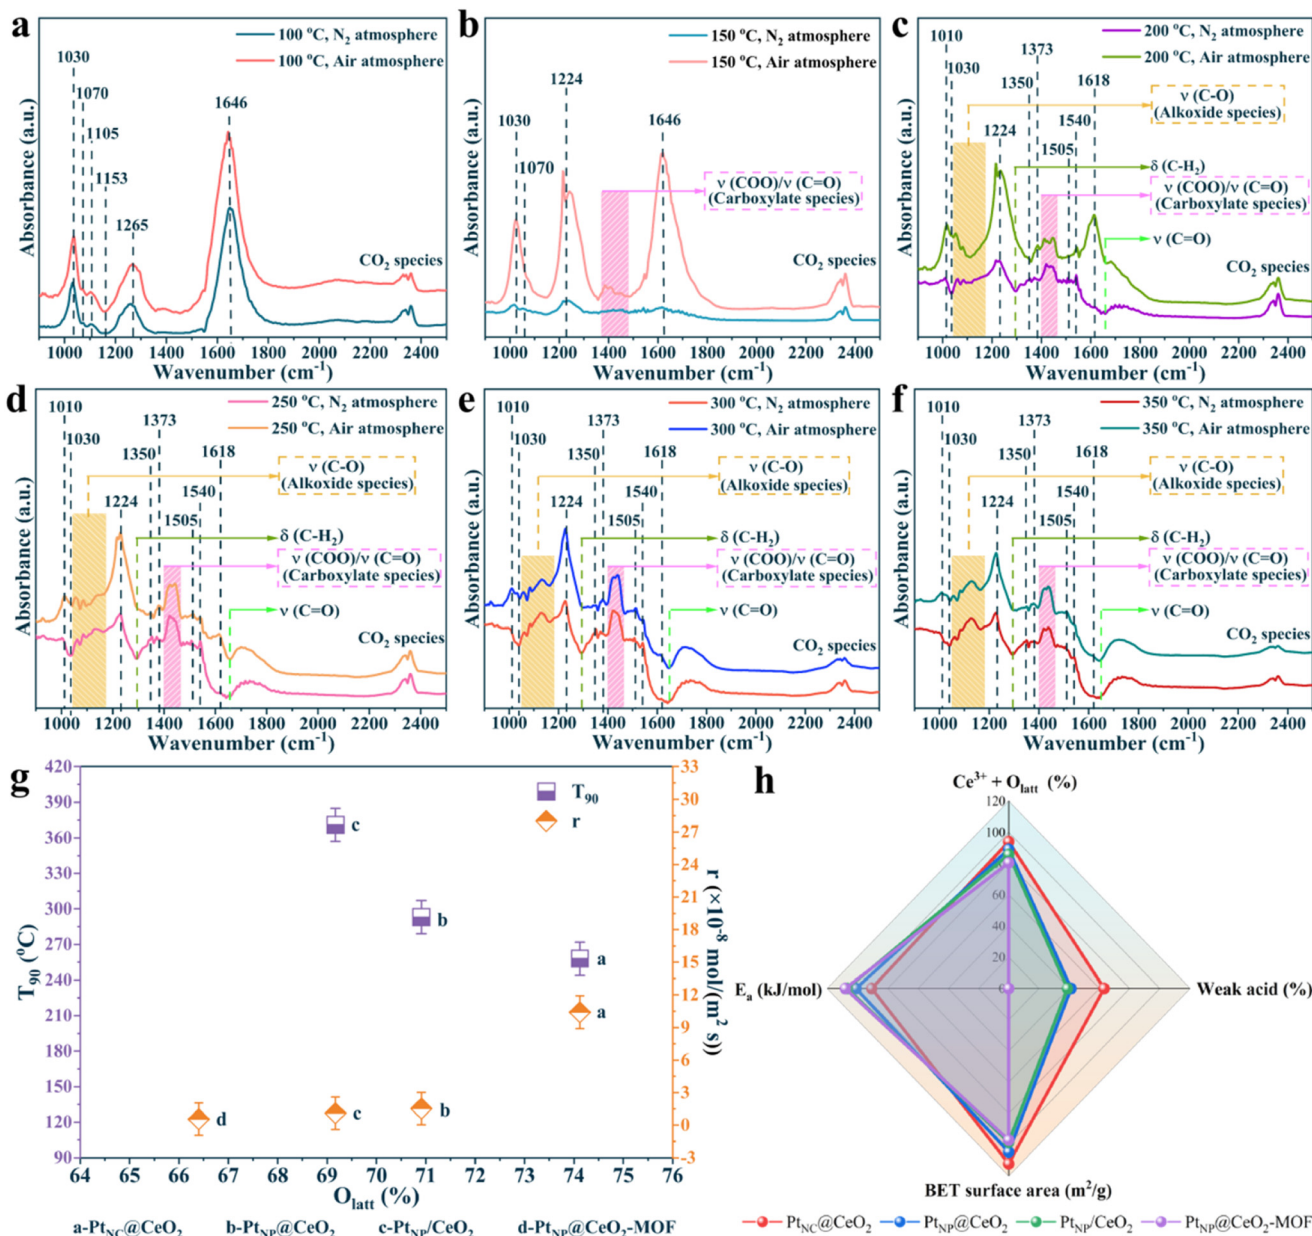

Fig. 10 *In situ* DRIFTS spectra under different atmospheres at different temperatures (a–f), the reaction rate and T_{90} versus O_{latt} (g), and the schematic diagram of E_a and frame of active sites over the catalysts (h).

mechanism. During the catalytic process, abundant oxygen vacancies were generated due to the consumption of lattice oxygen which was continuously replenished with the help of gas-phase oxygen, thus achieving a reciprocal cycle of reactions.⁷² It is of interest that the relationship between the lattice oxygen and the reaction rate and the relationship between T_{90} and lattice oxygen (Fig. 10g) both confirmed well the critical effect of lattice oxygen in the toluene elimination. Furthermore, the highly dispersed Pt nanoclusters in the Pt_{NC}@CeO₂ catalyst could be beneficial for adsorbing and becoming activated for the reactants, which may also be the reason for the ability of this type of catalyst to produce various intermediates at 100 °C. Hence, the Pt_{NC}@CeO₂

catalyst promoted the emission reduction of toluene due to the formation of Pt nanoclusters, which could expose more metal active sites derived from the rich Pt–O–Ce interface.

In short, the generation of Pt nanoclusters, more Ce³⁺ species, more lattice oxygen, more weak acid sites, larger specific surface area, and strong interfacial effect between Pt and CeO₂ combined to construct the Pt_{NC}@CeO₂ catalyst with the most excellent activity (Fig. 10h). To verify the activity for the catalysts, kinetic studies were performed (Fig. 11). It can be found that the R_s and R_m values of Pt_{NC}@CeO₂ were much higher than those of Pt_{NP}@CeO₂ under the same conditions in Fig. S12,[†] which also implied that Pt_{NC}@CeO₂ had superior catalytic activity.

4. Conclusion

In conclusion, Pt nanoclusters over the Pt_{NC}@CeO₂ catalyst were successfully obtained through an *in situ* confined encapsulation method for the toluene oxidation elimination. The size effect of Pt species on toluene catalytic oxidation was investigated systematically. It was found that Pt nanoclusters over the Pt_{NC}@CeO₂ catalyst provided efficient activity ($T_{90} = 272$ °C) and excellent stability during the toluene reaction. The reasons were attributed to the more active Ce³⁺ species, more lattice oxygen and more weak acid sites, which favored the generation of oxygen vacancies ($\text{Ce}^{3+} + \text{O}_{\text{latt}} \rightarrow \text{Ce}^{4+} + \text{O}_{\text{V}}$) and the adsorption of reactant molecules. More importantly, the construction of Pt nanoclusters exposed more active sites and effectively promoted the activity. It is also possible that Pt_{NC}@CeO₂ formed SMSIs, which led to more Pt–O–Ce bonding. The production of Pt nanoparticles led to the formation of the Pt_{NP}@CeO₂ catalyst with lower activity, which did not expose abundant catalytic active sites. Through characterization analyses, the Pt and Ce introduction methods had diverse effects on the size of Pt species, morphology and catalytic performance. It is verified that the Pt *in situ* introduction strategy could not only achieve the formation of Pt nanoclusters but also generate more oxygen vacancies, thus optimizing the catalyst performance. The results of *in situ* DRIFTS confirmed that the MvK mechanism was more applicable for toluene elimination over the Pt_{NC}@CeO₂ catalyst.
