# Mille-feuille shaped hard carbons derived from polyvinylpyrrolidone *via* environmentally friendly electrostatic spinning for sodium ion battery anodes

Ying Bai,<sup>\*ab</sup> Yuanchang Liu,<sup>a</sup> Yu Li,<sup>a</sup> Liming Ling,<sup>a</sup> Feng Wu<sup>ab</sup> and Chuan Wu<sup>ab</sup>

Pursuing low-cost and high-performance anode materials is of great importance for developing practical sodium ion batteries. In this work, mille-feuille shaped hard carbons derived from low-cost and environmentally friendly polyvinylpyrrolidone (PVP) nanofibres are fabricated *via* simple electrostatic spinning and followed by further pyrolysis at 800–1200 °C, as anode materials for sodium ion batteries. The optimized sample HC-1000 carbonized at 1000 °C shows better particle size and low surface area, and achieves a good reversible capacity of 271 mA h g<sup>-1</sup> with 94% capacity retention ratio over 100 cycles. In addition, HC-1000 exhibits satisfactory rate performance, namely, the discharge capacities are 304, 264, 209, 142, 109 and 70 mA h g<sup>-1</sup> at a current density of 20, 40, 100, 200, 500 and 1000 mA g<sup>-1</sup> after 10 cycles respectively. Even continuing with an additional 280 cycles at 200 mA g<sup>-1</sup>, the capacity retains 285 mA h g<sup>-1</sup> when the current recovers to 20 mA g<sup>-1</sup>. The mille-feuille shaped morphology, uniform particle size distribution and low surface area enable excellent electrochemical performances of PVP based hard carbon, which is expected to be a promising anode material for Na-ion batteries.

## Introduction

The storage and transformation of energy have become an important problem which restricts the sustainable development of the world economy.<sup>1,2</sup> Lithium ion batteries are the first choice for electric vehicles (including HEV and EV) and power supply for large-scale energy storage systems with the advantages of high working voltage, high capacity, small self-discharge, long cycle life and so on.<sup>3,4</sup> However, with the development of renewable energy generation technology, a large number of energy storage batteries are needed. However, the global lithium resources are not able to effectively meet the huge demand, due to the limitation of lithium resources. Therefore, it is very important to develop the related energy storage technology as a substitute for lithium ion batteries.<sup>1,5–8</sup> Recently, sodium ion batteries have attracted renewed interest as a potentially lower cost alternative to lithium ion batteries because of the wide abundance of sodium resources and similar chemical properties between lithium and sodium. But the Na ion is about 55% larger than the Li ion, it is difficult to develop suitable host materials with sufficiently large interstitial space to allow rapid insertion/extraction of Na<sup>+</sup>. Moreover, the

standard electrode potential of Na<sup>+</sup>/Na is −2.71 V (*vs.* S.H.E.), which is about 0.3 V higher than that of Li<sup>+</sup>/Li. Therefore, the energy density of the sodium ion battery is lower than that of lithium ion battery.<sup>9–12</sup> However, they can be considered for use in applications where the weight and footprint requirement is less drastic, such as storage of off-peak and essentially fluctuating renewable energies.<sup>13</sup>

Over the past few years, there has been made significant progress for sodium ion battery cathodes by updating the knowledge learned from lithium ion battery studies.<sup>8,14–17</sup> With respect to anodes, the graphite has been widely used in lithium ion battery, while the radius of the sodium is much larger so that the graphite carbon layer spacing (0.335 nm) is not suitable for the insertion of sodium ions, which were reported in previous studies.<sup>18,19</sup> But three-dimensional porous graphene materials facilitates significant performance for Na-ion batteries in recent research.<sup>20</sup> The other promising anode electrode materials mainly include alloys, carbon based materials, organic compounds and Ti-based oxides.<sup>19,21–23</sup> Of the above candidates, carbon-based material is a promising material as they are cheap, easily stable and non-toxic. As one kind of disorder carbon with larger layer spacing (0.35–0.38 nm) hard carbon has been widely studied.<sup>24–35</sup> Doeff<sup>24</sup> *et al.* showed the hard carbon can be a potential anode material in 1993. They studied the electrochemical insertion of sodium ion into a hard carbon made from petroleum coke, achieving a reversible capacity of 85 mA h g<sup>-1</sup>. Komaba's group<sup>28</sup> reported a reversible

<sup>b</sup>Collaborative Innovation Center of Electric Vehicles in Beijing, Beijing 100081, PR China

capacity value of  $240 \text{ mA h g}^{-1}$  by using commercially available hard carbon.

Generally hard carbon as one kind of disordered carbon has a widely dispersed particle size and a different morphology, which depend on appropriate carbon source and precursor morphology.<sup>24–32</sup> Shu *et al.*<sup>30</sup> obtained nano-sized hard carbon spherules by well dispersed nano-sized precursor particles during hydrothermal reaction, which showed high capacity retention ratio (92.7%) and a high reversible charge capacity ( $525 \text{ mA h g}^{-1}$ ) in lithium ion batteries. Li *et al.*<sup>31</sup> fabricated monodispersed hard carbon spherules with a uniform particle size, which exhibited highly reversible capacity of  $290 \text{ mA h g}^{-1}$  (after 100 cycles at  $30 \text{ mA g}^{-1}$ ), corresponding to capacity retention 93% in sodium ion batteries. Liu *et al.*<sup>32</sup> prepared floral variant of mesoporous carbon achieved excellent performance in sodium ion batteries ( $438.5 \text{ mA h g}^{-1}$  at  $30 \text{ mA g}^{-1}$ ) and lithium ion batteries ( $1370 \text{ mA h g}^{-1}$  at  $50 \text{ mA g}^{-1}$ ). And sodium ion full cell was reported with a layered  $\text{NaNi}_{0.5}\text{Ti}_{0.5}\text{O}_2$  cathode and a hard carbon anode exhibiting a reversible capacity of  $93 \text{ mA h g}^{-1}$ .<sup>33</sup>

Electrospinning has been used widely in both academic research and industrial applications as a simple and versatile technique. Polyacrylonitrile (PAN), polyvinyl chloride (PVC) and polyvinylpyrrolidone (PVP) are widely used in electrospinning to make uniform nanofibers/hollow nanowires.<sup>34–37</sup> In our previous work,<sup>34</sup> hard carbon prepared through pyrolysis of PVC nanofibers can achieve an initial reversible capacity of  $271 \text{ mA h g}^{-1}$  and retain  $215 \text{ mA h g}^{-1}$  after 120 cycles at the current of  $12 \text{ mA g}^{-1}$ . Chen<sup>36</sup> *et al.* reported a carbon nanofibers prepared by carbonization–activation PAN nanofibers using electrospun PAN fibers, which delivered a reversible capacity as high as  $233 \text{ mA h g}^{-1}$  and excellent cycling stability over 50 cycles at the current of  $50 \text{ mA g}^{-1}$ .

However, during the process of pyrolysis, PAN produces hydrogen cyanide (HCN) gas which is toxic and harmful to environment.<sup>38</sup> And hydrogen chloride and benzene are the main products of PVC.<sup>39</sup> But it is found that the vinyl pyrrolidone is the main volatile products of the pyrolysis of PVP that is less toxic and environmental friendly.<sup>40</sup> (Scheme 1).

Furthermore, as we know, the solubility parameter ( $\delta$ ) provides a good indication of solubility. Materials with similar values of  $\delta$  are likely to be miscible; and the solubility

Table 1 The solubility parameters of some solutes and solvent

Material $\delta/(\text{MPa}^{1/2})$	PVP	PAN	PVC	DMF <sup>a</sup>
	25.6	25.6–31	19.2–19.8	24.8

<sup>a</sup> DMF is used as the solvent.

parameters<sup>41</sup> of the materials are shown in Table 1. According to this parameter, it is notable that the solubility of PVP in *N,N*-dimethylformamide (DMF) is better than that of PAN and PVC, which suggests we can obtain a more homogeneous electrospinning solution and achieve a more uniform precursor if dissolving PVP in DMF.

In this work, we chose the PVP as the solute in DMF to prepare the electrospinning solution to get the hard carbon. The uniform nanofibers were prepared by electrospinning and mille-feuille shaped hard carbon material with a good particle size and low surface area was prepared after high temperature pyrolysis. Thus hard carbon by electrospinning with PVP as carbon source delivered satisfactory electrochemical performances.

## Experimental

### Synthesis of hard carbon

Typically, 3 g polyvinylpyrrolidone (average  $M_w$  1 300 000 Aldrich) was dissolved in 20 mL *N,N*-dimethylformamide to form a 15 w/v% solution by stirring at  $40^\circ\text{C}$  to be prepared as the electrospun solution. Then, the polymer solution was loaded into a 10 mL syringe which connected to a blunt tip needle. The needle tip was placed 15 cm in the front of the collector. Two high voltages of 14 kV and  $-4.00 \text{ kV}$  were applied to them, respectively. A syringe pump pushed the syringes at a flow rate of  $1 \text{ mL h}^{-1}$ . Al foil was used to cover the collector to collect nanofiber. The fibers were peeled off and dried in vacuum at  $80^\circ\text{C}$  overnight. Thereafter, the fibers were carbonized at 800, 900, 1000, 1100 and  $1200^\circ\text{C}$  for 2.5 h, respectively, with a heating rate of  $3^\circ\text{C min}^{-1}$ , as shown in Scheme 2. The atmosphere in the tube furnace was argon with a flow rate of  $200 \text{ cm}^3 \text{ min}^{-1}$ . The hard carbon (HC) samples were denoted as

Scheme 1 The main products of PAN, PVC and PVP in pyrolysis process.

Scheme 2 Schematic illustration of the synthesis process for the mille-feuille shaped hard carbons derived from PVP.

HC-800, HC-900, HC-1000, HC-1100 and HC-1200, respectively. For comparison, hard carbon was prepared by direct pyrolysis of commercial PVP at 1000 °C, named as CP-1000. The yield of hard carbon from PVP is about 6%.

### Characterizations

X-ray diffractometer (Rigaku DMAX2400) with Cu-K $\alpha$  radiations was used to characterize the structures of the samples in the  $2\theta$  range 10° to 80°. The interlayer distance  $d_{002}$  were calculated by the Bragg equations with XRD spectra. JSM-35C scanning electron microscope and HITACHI H-800 transmission electron microscope were used to observe the morphologies of the samples. LS-POP(9) laser scattering particle analyzer was used to analyse the particle size distribution of the materials. Carbon dioxide adsorption isotherms were determined by carbon dioxide physisorption at 273 K on a Micromeritics ASAP 2020 analyzer.

### Electrochemical measurements

The working electrode was prepared by mixing hard carbon powder, acetylene black and polyvinylidene fluoride (PVDF) at a weight ratio of 8 : 1 : 1 and coated on a copper foil collector. The loading mass of hard carbon electrode was 0.45 mg cm<sup>-2</sup>. The coin-type cells were assembled in an Ar-filled glovebox (MBRAUN-6020) under an argon atmosphere with oxygen and water of less than 0.5 ppm. The electrolyte was a solution of 1 M NaClO<sub>4</sub> in a solvent of propylene carbonate (PC) (Shenzhen Capchem technology Co., Ltd., China). The amount of electrolyte is about 0.2 mL in a coin cell. The counter electrode was sodium foil. The separator was the glass fiber. The galvanostatic cycling conducted with LAND-CT2011A battery tester at the current density of 20 mA g<sup>-1</sup> at a voltage interval of 0.01–2.5 V. Cyclic voltammograms (CV) were carried out by CHI608E electrochemical workstation at a scan rate of 0.1 mV s<sup>-1</sup>. Electrochemical impedance spectroscopy (EIS) measurements were conducted in the frequency range of 0.01 Hz to 10 kHz.

## Results and discussion

Fig. 1a shows the apparent morphologies of the PVP fibers from the scanning electron microscopy (SEM). The nanofibers display homogeneous length, interconnected and continuous fibrous morphology. The hard carbon particle shows an irregular shape with sharp edge in macroscopic (Fig. 1b–f). In this work, when samples were calcined from 800 °C to 1000 °C, the particle size decreases with increasing pyrolysis temperature due to the polymer main chain breaking down to monomer; when the temperature increases from 1000 °C to 1200 °C, the particle size increases again for the agglomeration with the formation of oligomer.<sup>40</sup> Therefore, HC-1000 shows the smallest particle size in the samples.

In Fig. 2a, the morphology of HC-1000 exhibits the stacking of thin slice as a mille-feuille even though the sample was ground, which is in favor of facile electrolyte permeation and rapid Na<sup>+</sup> diffusion. Whereas, CP-1000 particle without electrospinning only shows some wrinkles on its surface and an

Fig. 1 SEM images of PVP precursors and as-prepared samples at different temperature (a) PVP nanofibers prepared by electrospinning (b) HC-800 (c) HC-900 (d) HC-1000 (e) HC-1100 (f) HC-1200.

Fig. 2 SEM images of hard carbon particle after grinding (a) HC-1000 (b) CP-1000.

irregular morphology, as shown in Fig. 2b. It is obvious that the unique morphology of HC-1000 is originated from electrospinning and still keeps a mille-feuille shape well after grinding.

TEM pictures of the samples are shown in Fig. 3. Graphene layers with random orientation could be observed in the samples. The graphene domains tend to orient with the increasing temperature, because graphitization degree increases from 800 °C to 1200 °C.<sup>25</sup> CP-1000 shows more obvious graphitization than HC-1000, indicating the electrospinning could reduce the graphitization.<sup>34,35</sup>

From the particle distribution in Fig. 4a, the particle size of HC-1000 is the smallest, showing a peak at around 8 μm and all particles exhibit smaller than 20 μm. The other four samples show a centralized distribution at around 18 μm and particle sizes are from 0 to 100 μm. The small and uniform particle of HC-1000 is suitable to shorten the Na<sup>+</sup> diffusion path and achieve low impedance, which contributes to the rapid Na<sup>+</sup> insertion/extraction and enables the materials to exhibit excellent electrochemical performances.<sup>30,42–44</sup>

As shown in Fig. 4b, HC exhibits a BET surface area of 184, 63, 27, 21 and 12 m<sup>2</sup> g<sup>-1</sup> at the pyrolysis temperature of 800, 900, 1000, 1100 and 1200 °C, respectively. HC-800 and HC-900 show larger pore volume and surface area than the others, which would lead a serious decomposition of the electrolyte.<sup>45,46</sup> The micropore volume decreases with the increasing temperature from 800 to 1200 °C (Table 2), because the growth of graphene domains leads to the closure of micropores in the

Fig. 3 TEM images of hard carbon particle (a) HC-800 (b) HC-900 (c) HC-1000 (d) HC-1100 (e) HC-1200 (f) CP-1000. The insets show the selected area electron diffraction of corresponding samples.

sample.<sup>37,47</sup> These nanopores surrounded by randomly stacked graphene sheets are supposed to contribute to a main  $\text{Na}^+$  storage at around 0 V,<sup>24,28,48</sup> which cannot be detected by  $\text{CO}_2$  adsorption analysis, as shown in Fig. 4c.

The XRD patterns of hard carbon at different temperature are shown in Fig. 4d. All the hard carbon samples at different

temperature exhibit a typical amorphous carbon structure. Two broad peaks, namely, (002) and (101) diffractions, are observed in the XRD patterns. As shown in Table 2, the distance of interlayer ( $d_{002}$ ) is larger than that of graphite (0.335 nm) according to the calculation results, which is favorable for sodium ion storage and transport. Additionally, it also indicates

Table 2 Physical parameters of different hard carbon samples

Sample	Pyrolysis temperature (°C)	$2\theta/^\circ$	$d_{002}/\text{nm}$	$S_{\text{BET}}/\text{m}^2 \text{g}^{-1}$	$V_{\text{total}}/\text{cm}^3 \text{g}^{-1}$
HC-800	800 °C	24.46	0.364	184	0.055
HC-900	900 °C	24.32	0.366	63	0.02
HC-1000	1000 °C	23.48	0.378	27	0.01
HC-1100	1100 °C	24.02	0.370	21	0.008
HC-1200	1200 °C	24.26	0.368	12	0.005
CP-1000	1000 °C	25.02	0.356	—	—

that the temperature is a significant factor affecting the interlayer space during the synthetic process. The calculated interlayer distance increases gradually with the carbonized

temperature increasing from 800 °C to 1000 °C. However, when carbonized temperature further increases to 1100 °C and 1200 °C, the  $d_{002}$  values decrease, because the graphitization makes some narrow interlayer spacing close to graphite.<sup>26</sup> The interlayer space of HC-1000 is also larger than CP-1000 with only 0.356 nm because the nanofiber precursor achieves a lower graphitization during the pyrolysis process than the bulk without electrospinning, which is in agreement with XRD results.<sup>34,35</sup> Sample HC-1000 shows a highest value of  $d_{002}$ , which means that this material can accommodate more sodium ions storage and faster  $\text{Na}^+$  transport kinetics.<sup>36,37</sup>

Fig. 5a–e show the 1st, 2nd and 20th discharge–charge profiles of the HC-800, HC-900, HC-1000, CP-1000, HC-1100 and HC-1200 electrodes, respectively. The low initial coulombic

Fig. 5 Discharge–charge profiles of hard carbons at 20 mA g<sup>-1</sup> (a) HC-800 (b) HC-900 (c) HC-1000 and CP-1000 (d) HC-1100, and (e) HC-1200, (f) cycling performance of HC electrodes tested at 20 mA g<sup>-1</sup>, the voltage range is between 0.01 and 2.5 V.

efficiency is likely from the formation of SEI film and  $\text{Na}^+$  being trapped into the some voids and cavity sites or vicinity of residual heteroatoms.<sup>36</sup> The profiles can be divided into two regions with a slope from 1.0 to 0.1 V and a plateau close to 0 V. According to previous studies,<sup>28,37,49</sup> the sloping voltage profile above 0.1 V corresponds to sodium insertion between graphene layers. The plateau close to 0 V results from the sodium ions insertion into nanopores.

Fig. 5f shows the cycling performance of the HC electrodes and CP-1000 electrode at 20 mA  $\text{g}^{-1}$ . When calcined at 800 °C, the as-obtained material exhibits a low reversible capacity and is not stable in the subsequent cycles because of incomplete carbonization and serious decomposition of the electrolyte caused by large surface area. The reversible capacities of HCs increase with increasing carbonization temperature from 800 to 1000 °C. Whereas, the reversible capacity decreases when the carbonization temperature exceeds 1000 °C. This phenomenon can be explained by the largest interlayer spacing and appropriate structure of HC-1000, which is more favorable for sodium ion storage and transport.<sup>27,36</sup> The sample HC-1000 delivers superior electrochemical performances, initial discharge and charge capacities are 568 and 271 mA h  $\text{g}^{-1}$ , respectively. CP-1000 only shows an initial discharge and charge capacities of 382 and 158 mA h  $\text{g}^{-1}$  because of a low interlayer spacing caused by higher graphitization degree. HC-1000 retains a reversible capacity of 255 mA h  $\text{g}^{-1}$  after 100 cycles, corresponding to excellent capacity retention of 94%. In contrast, the

HC-800, HC-900, HC-1100 and HC-1200 electrodes exhibit inferior reversible capacities: about 119 mA h  $\text{g}^{-1}$ , 160 mA h  $\text{g}^{-1}$ , 220 mA h  $\text{g}^{-1}$  and 166 mA h  $\text{g}^{-1}$  remained after 100 cycles, respectively, with capacity retention of 82%, 80%, 84% and 69%. For the sample HC-1000, the coulombic efficiency after the 100 cycles remains approximately 99%, indicating hard carbon from PVP is very suitable as an anode for Na-ion batteries.

The cyclic voltammogram (CV) curves of HC-1000 can be seen in Fig. 6a. In the first cycle, two distinct reduction peaks at 0.89 V and 0.27 V can be observed, which are related to the decompositions of the solvent and electrolyte salt to form the SEI.<sup>50</sup> In the second and subsequent cycles, the reduction peaks at 0.89 V and 0.27 V disappear, which indicates that the irreversible reaction of the formation of SEI film is mainly accomplished in the initial cycle.<sup>51</sup> The broad reduction peak at 0.5 V corresponds to the insertion of sodium ions in the graphene layers. A pair of sharp redox peaks in the low potential region below 0.2 V are ascribed to  $\text{Na}^+$  insertion-extraction in the nanopores of the hard carbon.<sup>52,53</sup> The well overlapped CV curves indicate a satisfactory capacity retention of HC-1000 after the initial capacity loss.

Kinetic information of HC-1000 electrode during cycling is acquired by EIS measurements (Fig. 6b). The Nyquist plots are fitted and interpreted well based on the equivalent electric circuit<sup>54,55</sup> (Fig. 6c and d).  $R_s$  is the internal resistance of cell and has no obvious change after 20 cycles, as the fitting results of the equivalent circuit listed in Table 3. In the initial cycle, the

Fig. 6 (a) Cyclic voltammogram curves of sample HC-1000 at a scan rate of 0.1 mV  $\text{s}^{-1}$  between 0.01 and 2.5 V. (b) Nyquist plot deduced from EIS measurements of as prepared cells before cycle, after 1st, 10th and 20th cycle. (c) The fitline of Nyquist plot and equivalent circuit used to fit the EIS of sample HC-1000 before cycle and (d) after 20th cycle.

**Table 3** Kinetic parameters of HC-1000 obtained from the equivalent circuit fitting

		Before cycle	20th cycle
$R_s$ ( $\Omega$ )		6.9	7.2
$R_f$ ( $\Omega$ )		—	84.6
CPE1	$T$ ( $\Omega^{-1} s^n$ )	—	0.012
	$P$	—	0.89
$R_{ct}$ ( $\Omega$ )		2180	720.2
CPE	$T$ ( $\Omega^{-1} s^n$ )	$2.13 \times 10^{-6}$	$4.3 \times 10^{-6}$
	$P$	0.92	0.85
$Z_w$	$R$ ( $\Omega$ )	792	735
	$\tau$ (s)	0.25	0.12
	$P$	0.45	0.34

large semicircle is related to charge transfer resistance ( $R_{ct}$ ) and constant phase element (CPE),<sup>36,36</sup> which consists of another small high-frequency semicircle stemmed from  $R_f$  and CPE1 ascribed to the SEI layer after first cycle.  $Z_w$  is Warburg impedance. And a sloping straight line in the low frequency range is attributed to the mass-transfer process. Because the wettability between nonpolar carbon material and the polar liquid electrolyte is not good enough,<sup>57</sup> the electrode shows a transfer resistance of 2180  $\Omega$  before cycle. However, the  $R_{ct}$  decreases obviously (Fig. 6b) after the first cycle for the wetting process between the electrode material and the liquid electrolyte. And the transfer resistance tends to be stable in the next cycle with about 720.2  $\Omega$  after 20 cycles.

The sodium ion diffusion ( $D_{Na^+}$ ) in HC-1000 electrode can be calculated from the plots in the low-frequency region, and the equation can be expressed as:<sup>58,59</sup>

$$D = \frac{R^2 T^2}{2A^2 n^4 F^4 C^2 \sigma^2} \quad (1)$$

$$Z_{re} = R_e + R_{ct} + \sigma \omega^{-1/2} \quad (2)$$

where  $R$  is the ideal gas constant,  $T$  is the absolute temperature,  $A$  is the surface area,  $n$  is the number of electrons per molecule during oxidization,  $F$  is Faraday's constant,  $C$  is the concentration of sodium ion ( $4.9 \times 10^{-4}$  mol cm<sup>-3</sup>) and  $\sigma$  is the Warburg

**Fig. 7** The relationship between  $Z_{re}$  and  $\omega^{-1/2}$  at low frequencies of HC-1000 electrode.**Table 4** The sodium diffusion coefficients of HC-1000 electrode

	Before cycle	1st cycle	10th cycle	20th cycle
$D$ (cm <sup>2</sup> s <sup>-1</sup> )	$4.83 \times 10^{-14}$	$1.14 \times 10^{-13}$	$1.21 \times 10^{-13}$	$1.08 \times 10^{-13}$

**Fig. 8** Discharge capacities of HC-1000 at different current densities of 20, 40, 100, 200, 500 and 1000 mA g<sup>-1</sup>, respectively. A long-term cycling performance is recorded from the 70<sup>th</sup> to the 350<sup>th</sup> cycles at 200 mA g<sup>-1</sup> and SEM images of the HC-1000 electrodes before and after 360 cycles.

factor which is relative with  $Z_{re}$ . The relationship between  $Z_{re}$  and square root of frequency ( $\omega^{-1/2}$ ) in the low frequency is shown in Fig. 7. A linear characteristic could be seen for every curve and the Warburg coefficients are 1643, 1066, 1040 and 1097  $\Omega s^{-1/2}$ , respectively. Based on eqn (1) and (2), the diffusion coefficient of Na<sup>+</sup> can be calculated. As demonstrated in Table 4, the diffusion coefficient increases from  $4.83 \times 10^{-14}$  cm<sup>2</sup> s<sup>-1</sup> to  $1.14 \times 10^{-13}$  cm<sup>2</sup> s<sup>-1</sup> after the first cycle due to the wetting process. And a tendency to be stable after formation of SEI film can be observed.

The rate performance of the HC-1000 electrode is observed as showed in Fig. 8. At current densities of 20, 40, 100, 200, 500 and 1000 mA g<sup>-1</sup> after 10 cycles, the discharge capacities of 304, 264, 209, 142, 109 and 70 mA h g<sup>-1</sup> can be achieved. Furthermore, with additional 280 cycles at current density of 200 mA g<sup>-1</sup>, namely, from the 70<sup>th</sup> to the 350<sup>th</sup> cycles, an average coulombic efficiency of 99.7% is delivered. When the current density returns to 20 mA g<sup>-1</sup>, the capacity can recover to 285 mA h g<sup>-1</sup>. It can be observed that the sharp edge of hard carbon becomes smooth because of a homogeneous SEI coverage but the particle has no obvious pulverization after 360 cycles, indicating that the structure of hard carbon is not damaged. The HC-1000 electrode exhibits excellent rate capability and cycle stability, which is ascribed to the mille-feuille shaped morphology, uniform particle size, large interlayer distance and appropriate structure with porous channel for facile electrolyte permeation and rapid Na<sup>+</sup> insertion/extraction.

## Conclusions

Hard carbons originated from PVP are successfully prepared by environmentally friendly electrospinning combined with subsequent carbonization. And according to the “like dissolves like” principle, PVP has superior dissolubility in DMF solvent,

and thus results in uniform nanofiber precursor. The hard carbons as-prepared show a mille-feuille shaped morphology. Among all these samples, the optimized sample HC-1000 with a carbonization temperature of 1000 °C exhibits a uniform and the smallest particle distribution at around 8 µm and the largest interlayer distance of 0.378 nm, which are beneficial to shorten the Na<sup>+</sup> diffusion path and achieve low impedance and fast Na<sup>+</sup> diffusion. At a current of 20 mA g<sup>-1</sup>, initial reversible capacity of HC-1000 is 271 mA h g<sup>-1</sup>, which retains 255 mA h g<sup>-1</sup> after 100 cycles, corresponding to excellent capacity retention of 94%. At a high current of 1000 mA g<sup>-1</sup>, it still remains a reversible capacity of 70 mA h g<sup>-1</sup>. It is notable that even after an additional 280 cycles at current density of 200 mA g<sup>-1</sup>, an average coulombic efficiency of 99.7% is observed, and a high reversible capacity of 285 mA h g<sup>-1</sup> can still be achieved when the current density back to 20 mA g<sup>-1</sup>. The superior electrochemical performances are attributed to the mille-feuille shaped morphology, uniform particle size, large interlayer distance and appropriate structure with porous channel for facile electrolyte permeation and rapid Na<sup>+</sup> insertion/extraction.
