Porous organic polymers: a promising platform for efficient photocatalysis

 Ting Zhang, Guolong Xing, Weiben Chen and Long Chen *

Porous organic polymers (POPs) are a class of multi-dimensional porous network materials, which are built via strong covalent linkages between various organic building blocks with different geometries and topologies, and have recently become a rising research field in porous materials. POPs can be generally divided into two categories based on their degree of long-range order, including amorphous (e.g., CMPs, HCPs, PIMs, and PAFs) and crystalline (e.g., COFs). Owing to their advantages of light-weight, superior inherent porosity, excellent stability, pre-designable and tunable structures and functions, POPs have received increasing attention and research interest for their tremendous potential applications in gas storage/separation, heterogeneous catalysis, photoelectric conversion, chemical- and bio-sensing, energy storage and conversion, etc. Their porous structure, pore size, specific surface areas and functions can be directly designed and facily tuned by introducing specific functional building blocks. In this review article, we summarize the latest representative advances in the field of POPs, focusing on their design and synthetic strategies, with emphasis on their specific applications in photocatalysis, including photocatalytic chemical transformation, photodetoxification of contaminants from water, and water splitting.

1. Introduction

The limited resources and rapid consumption of fossil fuels have caused severe problems for human beings, including energy shortage, greenhouse effects, and environmental pollution. Thus, many efforts have been devoted to pursuing alternative clean and sustainable energy and technology to address these challenges. Among them, visible-light driven photocatalytic technology, which directly converts solar energy to chemical energy, is very promising and can effectively catalyze chemical transformations,^{1–5} removal of contaminants from water,^{6–9} water splitting for hydrogen evolution,^{10–18} etc. Therefore, developing efficient photocatalysts with high catalytic activity is of great importance. The past few decades have witnessed burgeoning development in photocatalysts, mainly focusing on inorganic semiconductors (e.g., TiO₂,^{19–21} CdSe,²² WO₃,^{23,24} ZnS,²⁵ and ZnO^{26–28}), metal complexes (e.g., ruthenium and iridium complexes^{29–31}) and organic dyes (e.g., fluorescein^{32,33} and rose bengal^{34,35}). However, the toxicity and high cost of rare metal components and the intrinsic drawback of not being recyclable limit the practical applications of homogenous photocatalysts. Furthermore, many of them are only active upon UV-light irradiation, and thus are not conducive to the full use of the sunlight. Porous organic polymers

(POPs)^{36–39} feature large pores, high specific surface areas, good stability and robustness in various solvents, which are favorable for mass transfer, providing more active sites, and the recycling process in photocatalysis. Thus, POPs have emerged as a promising platform for efficient photocatalysis.

POPs can be classified into either amorphous or crystalline. Amorphous POPs mainly include hyper-crosslinked polymers (HCPs),^{40–42} polymers of intrinsic microporosity (PIMs),^{43–45} conjugated microporous polymers (CMPs)^{46–48} and porous aromatic frameworks (PAFs),^{49,50} while crystalline POPs are represented by covalent organic frameworks (COFs).^{51–53} CMPs feature extended π -conjugated skeletons in comparison to other amorphous POPs, endowing them with attractive light-harvesting capability, which is advantageous for photocatalysis. On the other hand, COFs possessing periodic, ordered and extended skeletons with uniform nanopores enable the precise integration of various functional building blocks. Since the seminal work reported by O. M. Yaghi *et al.*,⁵¹ numerous COFs with different topologies have been extensively explored in gas storage^{54–56} and separation,⁵⁷ catalysis,^{58,59} and energy storage.^{60,61} By integrating organic semiconductor building blocks with photoelectric properties into the COF skeleton, the functions of the organic semiconductor can be retained or even amplified.^{62,63} Thus, COFs synthesized *via* the bottom-up strategy are usually photocatalytically active and can be applied for photocatalysis. Another special class of COFs, covalent triazine frameworks (CTFs), feature triazine rings, which are

Department of Chemistry, Institute of Molecular Plus, Tianjin Key Laboratory of Molecular Optoelectronic Science, Tianjin University, Tianjin 300072, China.
E-mail: long.chen@tju.edu.cn

usually formed by trimerization of aromatic nitriles.⁵³ However, compared to COFs with imine,^{64,65} boroxine or boronate ester,^{66,67} and azine linkages,^{68–70} the development of CTFs is hindered by the harsh synthetic conditions⁷¹ (e.g. high temperature of over 400 °C) and irreversible formation of aromatic 1,3,5-triazine rings. Thus, most reported CTFs have low crystallinity but excellent chemical stability and a high nitrogen content, making them attractive for photocatalysis applications. Recently, B. Tan *et al.* had great success in developing a low temperature polycondensation approach to construct CTFs under mild conditions, and further obtained CTFs with high crystallinity either *via* the *in situ* oxidation of alcohols to aldehyde monomers or controlling the monomer feeding rate.^{72–74} In addition, both amorphous CMPs and crystalline COFs exhibit remarkably tunable photocatalytic activity by proper molecular design. In this review, the applications of photocatalytic CMP and COFs in chemical transformations, removal of contaminants from water, and hydrogen evolution *via* water splitting are briefly summarized.

2. Principle

In general, as displayed in Scheme 1, when POPs absorb photons with energy equal or higher than their band gaps, the electrons at the valence bands (VB) are excited to the conduction bands (CB) and simultaneously leave holes at the VB, resulting in excited electrons and holes in the CB and VB, respectively.¹⁴ Subsequently, they transfer to the surface of the photocatalyst for redox reaction.^{14b} A series of reactive species including singlet oxygen (¹O₂), superoxide radical (O₂^{•−}), hydroxyl radical (•OH), hydrogen peroxide (H₂O₂), photogenerated hole (h⁺) and electron (e[−]) may participate in these photocatalytic processes. The possible reactive species are usually determined by control experiments with the addition of the corresponding scavenger.

3. Visible-light-driven chemical transformation

The photocatalytic systems based on poly(benzothiadiazoles) and their derivatives have been recently reviewed by K. A. I. Zhang *et al.*⁷⁵ As a strong electron-withdrawing unit, benzothiadiazole (BT) is

Scheme 1 General illustration for the mechanism of photocatalysis with POPs.

often used for the construction of CMPs, and thus BT-based CMPs have become dominant in CMP-photocatalytic chemical transformation. Here, we critically summarize some representative CMPs and COFs, focusing on their recent progress in photocatalytic transformations. For easy understanding, we simply divide the reactions (or chemical transformations) into two types (*i.e.*, oxidation reactions and other reactions) according to whether oxygen is involved.

3.1 Photodriven oxidation

Two main reactive species (*i.e.*, ¹O₂ and O₂^{•−}) may be involved in photodriven oxidation in the presence of oxygen when POPs are used as photocatalysts. They are formed through the energy transfer and charge transfer pathway from the photocatalyst to oxygen.⁷⁶ Sometimes ¹O₂ alone acts as an oxidant, while sometimes O₂^{•−} is the main oxidant.

3.1.1 ¹O₂ as an oxidant for photodriven oxidations. ¹O₂ is a type of molecular oxygen in the excited state and it plays an important role in the process of biological oxidation⁷⁷ and photocatalytic transformations.⁷⁸ As a photosensitizer, POPs can be converted to a singlet excited state after absorbing photons, and then effectively transformed into the triplet excited state through intersystem crossing to transfer energy to the triplet oxygen and make it a singlet excited state (¹O₂).⁷⁶ The generated ¹O₂ can directly oxidize some chemicals such as α -terpinene,^{79,80} furoic acid,⁸¹ organic sulfides,⁸² and 1,3-diphenylisobenzofuran (DPBF),⁸³ and thus some of them can also be used as trapping agents to detect the generation of ¹O₂.^{79–81,83}

F. Vilela *et al.* reported the first CMPs (CMP_X, where X indicates the amount of SiO₂NPs in mg mL^{−1} used for templating, Fig. 1a) as sensitizers to produce ¹O₂ and further to photocatalyze the oxidation of α -terpinene to ascaridole.⁷⁹ The introduction of a template greatly increased the Brunauer–Emmett–Teller (BET) surface areas and pore volumes. CMP_X possessed donor (D)–acceptor (A) built-in structures with benzothiadiazole (BT) as the strong electron acceptor and benzene as the weak electron donor, which were beneficial for preventing the fast recombination of excitons and conducive to the intersystem crossing process, thus favouring photosensitization. Among them, CMP_60 possessed the highest surface area. When it was dispersed in a solution (1 mg mL^{−1}) containing α -terpinene (0.1 M) and the mixture was pumped at a flow rate of 1 mL min^{−1} through a photoreactor under blue light (420 nm) irradiation in the presence of oxygen (2 equiv.), the conversion of α -terpinene was greater than 90%, much higher than that with the other CMP_X. Even though benzothiadiazole itself can work as a homogeneous photosensitizer for oxidation reactions, the heterogeneous CMPs showed attractive properties of easy separation and recycling.

Furthermore, by combining the high internal phase emulsion polymerization technique and micropore engineering by incorporating and removing a cleavable functional group (Boc) in the polymer network, CMPs (B-(NPh₂)₃, B-CB₃, and B-CB₂-BT) with increased surface area and porosity were reported (Fig. 1b).⁸² The obtained CMPs showed effective photocatalytic activity for the highly selective oxidation of organic sulfides under visible

light irradiation (Fig. 2a). However, the CMPs with or without Boc moieties exhibited no obvious differences in photocatalytic activity, while the activities of B-(Boc-NPh₂)₃ and B-(NPh₂)₃ were much worse, which can be attributed to their higher HOMO–LUMO band gaps, especially higher LUMO levels. As displayed in Fig. 2b, various phenyl sulfides bearing electron-donating (–CH₃, –OCH₃) or electron-withdrawing (–F, –Br, –Cl) substituents could be selectively converted to the desired mono-oxidized sulfoxides. The oxidation of sulfides was achieved by the photochemically generated ¹O₂.

Featuring extended skeletons with high crystallinity and porosity, COFs can also be used as photocatalysts. In 2013, D. Jiang *et al.* reported a squaraine-linked mesoporous COF (CuP-SQ COF, Fig. 1c) for singlet oxygen generation.⁸³ Benefiting from the zigzagged zwitterionic resonance structure of squaraines, the CuP-SQ COF possessed a zigzag conformation, which protected the extended π -conjugated layers from sideslip, thus rendering it with high stability. Also, it exhibited robust solvent stability with retained crystallinity after harsh treatments. Considering its strong light-harvesting ability, low band gap and ordered structure, CuP-SQ COF was used as a heterogeneous photocatalyst. CuP-SQ COF could effectively harvest visible light and activate molecular oxygen to generate singlet oxygen, and subsequently catalyze the conversion of 1,3-diphenylisobenzofuran (DPBF) to *o*-dibenzoylbenzene (ODB). Its photocatalytic activity was much higher than that of monomeric CuP,

demonstrating that the ordered structure was conducive to improve the catalytic activities.

3.1.2 O₂^{•−} as the main oxidant for photodriven oxidations. In addition to ¹O₂, many photodriven oxidation reactions catalyzed by POPs originate from the generation of reactive O₂^{•−}, while sometimes both ¹O₂ and O₂^{•−} contribute synergistically. The oxidation coupling reaction plays an important role in the synthesis of organic intermediates for drugs, pesticides, chemicals and materials.^{84,85} Imine is widely used for chemical transformations such as reduction, addition and cyclization reactions.⁸⁶ The oxidation coupling reaction of primary amines is an efficient and economical method to obtain imines (Fig. 3a).^{87–89} However, in most cases, catalysts containing unrecyclable toxic transition metals are needed for this transformation.^{87,90,91} In a recent example, by utilizing the excellent photoredox behaviors of benzodifurans (BDFs),⁹² a BDF-based CMP (BDF-MON, Fig. 3b) was prepared and its photocatalytic performance for the conversion of benzylamine to the corresponding imines was investigated.⁹³ Upon visible light irradiation for 40 h, the conversion efficiency reached about 97%, which was much higher than that without BDF-MON (4%) or using benzylamine as the catalyst (29%), indicating its high catalytic activity under

visible-light irradiation. BDF-MON could be recycled by simple centrifugation without a decline in its catalytic activity.

Improving photocatalytic activity is one of the key issues to develop efficient photocatalysts. In addition to variation in the building blocks, the VB and CB position of POPs can also be tuned by modifying the connectivity of the same building blocks, thus leading to modulation of photocatalytic performances. K. A. I. Zhang *et al.* prepared a series of benzooxadiazole-based CMPs (B-BO-1,3,5 B-BO-1,2,4 and B-BO-1,2,4,5) with the same building blocks; however, the electron-donating benzooxadiazole moieties were connected at different positions on the centered phenyl unit (Fig. 3c).⁹⁴ Among the three CMPs, B-BO-1,3,5 featuring a larger optical band gap and higher redox potential exhibited better photocatalytic activity than the other two CMPs (B-BO-1,2,4 and B-BO-1,2,4,5) for catalyzing the oxidation coupling reaction of benzylamine and also showed good catalytic efficiency even after 5 cycles.

Besides the oxidation of primary amide, Por-sp²c-COF reported by C. Wang *et al.* also exhibited excellent photocatalytic capacity towards the oxidation of secondary amine to imine (Fig. 4).⁶² Por-sp²c-COF featured sp²-carbon linked conjugated 2D skeletons, which are highly stable and exhibit excellent electrochemical and charge-transfer properties. Por-sp²c-COF was synthesized using 5,10,15,20-tetrakis(4-benzaldehyde)porphyrin (*p*-Por-CHO) and 1,4-phenylenediacetonitrile (PDAN) through Knoevenagel condensation, which was demonstrated before for preparation of COFs^{95–98} and CMPs.⁹⁹ Due to the fully sp²-carbon-conjugated

Fig. 4 Structure of Por-sp²c-COF and photocatalytic oxidation coupling of primary amine to imine and oxidation of secondary amine to imine. Modified from ref. 62 with permission from Wiley-VCH Verlag GmbH & Co. KGaA, Copyright 2019.

structure and high chemical stability, higher photocatalytic efficiency for the oxidation of secondary amine was achieved compared to its imine-based Por-COF counterpart. In addition, both the crystalline framework structure and photocatalytic activities of Por-sp²c-COF could be well retained after several reaction cycles.

The azo-Henry reaction is a typical oxidation coupling reaction to realize the C–H functionalization and is frequently used as a model reaction to evaluate the photocatalytic performance of CMPs or COFs (Fig. 5a).^{100–102} By virtue of the effective photocatalytic ability of rose bengal (RB) dye, a bottom-up strategy was adopted by A. I. Cooper *et al.* to prepare two CMPs (RB-CMP1 and RB-CMP2, Fig. 5b), which were further used for photocatalytic aza-Henry reaction.¹⁰⁰ As an example, *N*-substituted tetrahydroisoquinoline and CH_3NO_2 were used as substrates. In the presence of air and a 60 W bulb as the light source, the reaction afforded full conversion in 12 h using only 5 mol% CMP catalyst with comparable activity to its homogeneous counterpart (RB). Additionally, the catalyst was effective for the aza-Henry reaction over a wide scope of substrates. The two CMP catalysts also retained good recyclability for at least 10 times.

Some 2D COFs featuring excellent porosity, periodic columnar π -arrays and high crystallinity have also exhibited great potential applications for the oxidative azo-Henry reaction.^{101,102} X. Liu *et al.* reported a triazine-based COF (COF-JLU5, Fig. 5c) showcasing high photocatalytic activities for the aza-Henry reaction.¹⁰² COF-JLU5 exhibited a high BET surface area ($1632 \text{ m}^2 \text{ g}^{-1}$) and outstanding chemical stability. The built-in D–A skeleton facilitated the charge separation of photo-generated electron–hole pairs. Notably, various substrates bearing different substituents were subjected to the aza-Henry reaction and gave the desired products in high yields (Fig. 5d). Interestingly, besides the formation of the C–C bond, C–P bond formation could also be catalyzed when phosphonates were used as the nucleophilic reagents. The photocatalytic performances of COF-JLU5 was superior to most heterogeneous catalysts ever reported, and even comparable to the state-of-the-art homogeneous photocatalysts. Furthermore, it could be reused for at least 10 cycles without any obvious deterioration in its catalytic activities.

As mentioned above, the D-A structure is favorable to construct photocatalysts with good performances. However, for a D-A-type CMP, its energy levels can be further fine-tuned by simply regulating the content of electron-withdrawing building blocks during the copolymerization process. In 2016, a series of CMPs (P-BBT-0, P-BBT-10, P-BBT-50 and P-BBT-100, Fig. 6a) incorporating different amounts of the electron-withdrawing moiety benzobisthiadiazole (BBT) was systematically investigated.¹⁰³ With an increase in the content of BBT, the BET surface area and pore volume of the CMPs increased, while the corresponding reduction and oxidation potentials as well as the band gaps greatly decreased. Among the four POPs, P-BBT-10 exhibited the highest photocatalytic ability to generate $\text{O}_2^{\bullet-}$ due to its high redox potentials and suitable band gap for visible light absorption, which was further used for the synthesis of tetrahydroquinoline *via* the oxidative cyclization of *N*-methylanilines and maleimide (Fig. 6b). As expected, the oxidative cyclization catalyzed by P-BBT-10 led to the highest yield of 82%. Furthermore, P-BBT-10 exhibited good substrate tolerance and excellent recyclability after 5 cycles.

methods for the C-3 functionalization of indoles. G. Yu *et al.* reported three carbazole-based CMPs (CMP-CSU5, CMP-CSU6, and CMP-CSU7) and their use as photocatalysts for the C-3 functionalization of indoles (Fig. 7).¹⁰⁸ It was noteworthy that the effect of the electronic properties of the cores (*i.e.*, 1,4-dibenzyl, 1,3,5-tribenzyl, or 1,3,5-triazin-2,4,6-triyl) on the photocatalytic activities was investigated, which received little attention in previous works. Their reduction potentials were only slightly negative enough to reduce oxygen to generate $\text{O}_2^{\bullet-}$, while their oxidation potentials were quite different. CMP-CSU6 possessing the highest oxidation potential was the most effective in the photocatalytic reactions. Under the optimized reaction conditions, CMP-CSU6 was able to catalyze the C-3 formylation and thiocyanation of a series of indoles in high yields. The catalytic activity of CMP-CSU6 was comparable

Fig. 7 Structures of CMP-CSU5, CMP-CSU6, CMP-CSU7 and photocatalytic C-3 functionalization of indoles. Modified from ref. 108 with permission from the American Chemical Society, Copyright 2018.

or even better than the well-established catalysts such as rose bengal, I_2 for the formylation of *N*-methylindole, and $Ru(bpy)_3Cl_2$ and $Ir(ppy)_3$ for the thiocyanation of 1*H*-indole. In addition, CMP-CSU6 could function at room temperature without the aid of acid, base or strong oxidant and showed good recyclability for at least 5 continuous cycles.

Even though some outstanding works have shown great prospects for the application of COFs in visible-light-driven photocatalysis, they still face the severe problem of relatively poor photo-stability and reusability, which limit their practical applications.¹⁰¹ Hence, it is attractive to design robust COFs for photocatalysis. Instead of applying the classical reversible reaction to fabricate COF, three benzoxazole-linked ultrastable COFs (*i.e.*, LZU-190, LZU-191, and LZU-192) were prepared by utilizing reversible/irreversible cascade reactions to form a benzoxazole ring (Fig. 8).⁶³ All three COFs showed great thermal and chemical stability and also exhibited excellent photostability under continuous visible light irradiation (20 W white LED). Among the three COFs, LZU-190 could catalyze the aerobic reaction of 4-carboxyphenylboronic acid to 4-hydroxybenzoic acid with a high yield of 99% when i -Pr₂NEt was used as the sacrificial agent (86% in the absence of i -Pr₂NEt) and presented no obvious changes in crystallinity, morphology, porosity and photocatalytic activity even after 20 runs. This outstanding work not only presented a prototypical COF with extraordinary performance, but also inspired us to design and synthesize more robust photocatalytic COFs using irreversible condensation reactions.

3.2 Other reactions photocatalyzed by POPs

Some chemical transformations can also be photocatalyzed by POPs without the aid of oxygen, which are mostly reduction reactions. For example, organic bromides represent a type of important intermediate, but may cause serious pollution and are harmful to humans.¹⁰⁹ Reductive dehalogenation of organic

bromides is an effective way to detoxify organic bromides.¹¹⁰ Using the high internal phase polymerization strategy, two conjugated porous polymers, B₂-FL₃ and B₂-FL₂-BBT (Fig. 9a) were prepared and further used for the photoreductive dehalogenation of various α -bromoacetophenone derivatives bearing substituents with varying electronic properties in high conversion efficiencies.¹¹¹ With the electron-withdrawing benzobisthiadiazole (BBT), B₂-FL₂-BBT exhibited higher photocatalytic activity. The proposed reaction mechanism is shown in Fig. 9b. The photogenerated hole was firstly captured by amine (DIPEA) to form a radical cation. Then the photogenerated electron reacted with α -bromoacetophenone to form phenone radicals with cleaving of the Br leaving group. Later, the Hantzsch ester donated a hydrogen radical to the phenone radical to afford the final product. Meanwhile, pyridine ester and ammonium bromide were obtained as side products, which originated from the reaction of the dehydrogenated Hantzsch ester radical and the DIPEA radical cation. Another imine-based D-A type COF (COF-JLU22) reported by X. Liu *et al.* was also utilized for the photoreductive dehalogenation of phenacyl bromide.¹¹² The D-A structure rendered the COF-JLU22 with red-shifted absorption and also enhanced photocatalytic activity. Meanwhile, its high crystallinity was well-retained after continuous green light (30 W) irradiation, indicating its high photochemical stability. In view of the above advantages, COF-JLU22 efficiently

photocatalyzed the reductive dehalogenation of phenacyl bromide in a high yield of 85% in DMF and many α -bromoacetophenones were able to convert to the corresponding acetophenone in high yields by utilizing the optimized conditions (Fig. 9c). In addition, COF-JLU22 could also effectively photocatalyze the enantioselective α -alkylation of aldehydes (Fig. 9c). Also, in both reactions, COF-JLU22 exhibited high tolerance to a large number of substrates, excellent stabilities and recycling performances.

Photopolymerization is an efficient way to convert small monomers to high molecular weight polymers, which are widely used as adhesives, coatings, etc.¹¹³ Numerous photoinitiators have been developed for photopolymerization, but most of them are UV-light-triggered photoinitiators.^{114,115} In 2014, a porous polymer (B-(Boc-CB)₂-BO) obtained *via* high internal phase emulsion (HIPE) polymerization, which was used as a visible light photoinitiator for the free radical polymerization of methyl methacrylate (MMA).¹¹⁶ Benefiting from the π -conjugated structure as well as the strong electron acceptor BO, which is beneficial for the efficient separation of excitons, the obtained B-(Boc-CB)₂-BO exhibited high photocatalytic activity under visible light. The free polymerization of MMA reached as high as 82% conversion when B-(BOC-CB)₂-BO was employed as the photoinitiator.

A fully conjugated 2D sp²-carbon COF (TP-COF) was recently reported by Z. Li *et al.*, which served as an artificial photosystem I for the synthesis of L-glutamate *via* the photocatalysis of NADH regeneration (Fig. 10).^{117a} TP-COF features a band gap of 2.36 eV and a high reduction potential of 3.23 eV. Upon irradiation with sunlight, TP-COF is excited to generate excited electron/hole pairs. Subsequently, NAD⁺ is reduced to NADH with the help of an electron mediator. Also, NADH could further initiate the chemical transformation of α -ketoglutarate to L-glutamate with a yield up to 97% within 12 min, which is among the best performances to date in this field.

The reduction of CO₂ with H₂O to value-added chemicals and renewable fuels utilizing sunlight is an appealing approach to solve the energy shortage and global warming problems caused by the emitted CO₂ from daily life.^{117b} Ideal photocatalysts to promote this conversion should possess strong CO₂ adsorption capacity together with high catalytic activity.^{117c} Upon light irradiation, the photogenerated holes of photocatalysts are

captured by H₂O to form O₂ and H⁺, and the photogenerated electrons in the CB reduce CO₂ *via* a sequence of complex reactions to produce valuable chemicals, including HCHO, HCOOH, CH₃OH and CH₄, depending on the energy level correlation between the photocatalysts and the redox agents.^{117d} With large surface areas and abundant nitrogen content, the two azine-based COFs (N₃-COF and ACOF-1) reported by W. Zhu *et al.* showed superior performances towards the adsorption and subsequent conversion of CO₂ into CH₃OH.^{117b} Due to their extended structures, they are highly visible light-active compared to the commonly used inorganic photocatalysts. Besides, they are thermally and chemically stable, enabling the use of water as the reductant and avoiding the use of sacrificial agents. Moreover, for practical light-harvesting application, a triazine-based COF (2D CTF) film was developed by J.-O. Baeg *et al.* for converting CO₂ to HCOOH.^{117e} Thus, these pioneering works will trigger wider studies on solar energy conversion.

In addition, some POPs can efficiently photocatalyze both oxidation and reduction reactions. J. Zhang *et al.* reported a carbazole-based conjugated porous polymer (Cz-POF-1).¹¹⁸ Cz-POF-1 was prepared *via* the FeCl₃-assisted oxidative polymerization of carbazole-based monomers. Cz-POF-1 exhibited a high BET surface area of 2065 m² g⁻¹ and large pore volume of 1.57 mL g⁻¹ (72% mesopores), which are beneficial for mass transfer. As shown in Fig. 11a, the calculated $E_{1/2}$ of the Cz-POF-1⁺/*Cz-POF-1 couple ($E_{1/2}^{\text{red}} = -1.53$ V) was sufficiently negative, thus phenacyl bromide ($E_{1/2}^{\text{red}} = -0.49$ V) and oxygen ($E_{1/2}^{\text{red}} = -0.86$ V) could be reduced through singlet electron transfer, while the POF-1⁺ intermediate ($E_{1/2}^{\text{red}} = +1.38$ V) was a good oxidant for oxidizing the Hantzsch ester ($E_{1/2}^{\text{red}} = +0.72$ V). Thus, Cz-POF-1 was

capable of photocatalyzing three prototypic organic transformations in mild conditions, including net reductive dehalogenation of phenacyl bromide, net oxidative hydroxylation of arylboronic acids, and redox-neutral α -alkylation of aldehydes (Fig. 11b). In addition, the above three reactions photocatalyzed by Cz-POF-1 exhibited a good tolerance to various substrates and the photocatalyst could be easily recovered for reuse. Benefiting from its large conjugated structure and porous structure, Cz-POF-1 exhibited better catalytic activity compared to the linear and non-porous carbazole-based polymer.

4. Treatment of pollutants in water

Water pollution not only affects the growth of aquatic organisms but also poses a threat to the health of human beings. Organic dyes and heavy metal ions with nonbiodegradability and chemical stability are the two major types of water pollutants.¹¹⁹ To date, various methods such as sorption,¹¹⁹ ion exchange,¹²⁰ and photocatalysis¹²¹ have been employed to remove or degrade organic dyes in aqueous solution. Adsorption is one of the most costless, effective and eco-friendly methods. Many porous materials including zeolites^{122,123} and activated carbon^{124,125} have been widely used as sorbents, while CMPs together with COFs as burgeoning new POPs have recently been explored for removing pollutants from water.^{126–131} Our group also reported several CMPs with strong adsorption capacity towards pollutants in water.^{129,132} However, these sorbents often suffer from limited adsorption capacities. Benefiting from the large electron delocalized network structure, efficient light absorption and charge carrier transportation, many CMPs and COFs can act as both sorbents and photocatalysts for the removal of dyes or photodetoxification of heavy metal ions for water remediation, which make them attractive.

4.1 Photodegradation of organic dyes

The release of common organic dyes such as methyl orange (MO), rhodamine B (RhB), methylene blue (MB), and Congo Red (CR) from the paper, leather and food industries into the ecosystem is highly toxic to aquatic life and causes serious threats to the environment. When CMPs or COFs are used as photocatalysts, one or several active species (*i.e.*, superoxide radical ($O_2^{\bullet-}$), singlet oxygen (1O_2), photogenerated hole (h^+), and $\bullet OH$) generated by light irradiation may be involved to photodegrade dyes in water. The general process can be summarized as follows: (1) upon light irradiation, the electron in the VB is excited to the CB, leaving holes in the VB; (2) two active oxygen species, $O_2^{\bullet-}$ and 1O_2 , are generated through singlet electron transfer (SET) and energy transfer (ET) from the excited photocatalyst to molecular oxygen; (3) $O_2^{\bullet-}$ reacts with water to form $\bullet OH$, another active species, while the holes spread over the whole polymer and further catch pollutants, facilitating the separation of excitons; and (4) the dyes are degraded by one or more of the generated reactive oxidative species.

Our group reported two polyoxometalate built-in CMPs (POM-CMPs, *i.e.*, Bn-Anderson-CMP and Th-Anderson-CMP, Fig. 12a)

Fig. 12 (a) Chemical structures of Bn-Anderson-CMP and Th-Anderson-CMP. (b) Photocatalytic degradation of RhB in the presence of POM-CMPs in water and the insert shows the corresponding color changes. (c) Reusability of Bn-Anderson-CMP for the photocatalytic degradation of MB in water under visible light irradiation. Reproduced from ref. 133 with permission from the Royal Society of Chemistry, Copyright 2017.

for the photodegradation of organic dyes.¹³³ Both CMPs showcased broad UV/vis absorption, which is crucial for photocatalysis. Due to the fascinating photochemical properties of polyoxometalates (POMs), high porosity and good reusability of CMPs, the hybrid materials showed higher photocatalytic activity than both building blocks. Additionally, under similar reaction conditions, due to the strong electrostatic interactions between the positively charged Anderson-POMs and the negatively charged dyes (RhB and MB), the photocatalytic activities of these POM-CMPs were comparable or even higher than that of benzothiadiazole-based CMP nanoparticles and porous carbon nitride (C_3N_4). Furthermore, Bn-Anderson-CMP exhibited higher photocatalytic activity than that of Th-Anderson-CMP with less time needed to reach the same degradation efficiency of RhB upon irradiation, which can be attributed to its higher BET surface area, providing more reactive sites during the photocatalytic process (Fig. 12b). 1O_2 and H_2O_2 were determined to be the main active species participating in the photodegradation of RhB and POM-CMPs maintained high catalytic activity during this process (Fig. 12c).

The presence of metal in organic/inorganic hybrid porous materials may not only affect the photocatalytic activities of materials, but also induce secondary pollution. Thus, a series of metal-free porous polymers BF-CMPs (Py-BF-CMP, TPE-BF-CMP and TPA-BF-CMP, Fig. 13a) with the D–A structure was also reported for the photodegradation organic dyes in water.¹³⁴ The main difference among these CMPs is the electronic nature of the electron donor units. Due to the strong electron-donating property and extended conjugation between the pyrene (Py) and bifluorenylidene (BF) units, Py-BF-CMP possessed the lowest band gap, together with the highest surface area and largest pore volume. Thus, Py-BF-CMPs are not only a sorbent but also serve as a photocatalyst (Fig. 13b). For example, the maximum adsorption capacity of the three BF-CMPs for RhB

Fig. 13 (a) Chemical structures of BF-CMPs and pictures of the BF-CMPs powder. (b) Adsorption and photocatalytic degradation capacities of Py-BF-CMP towards RhB. Reproduced from ref. 134 with permission from the American Chemical Society, Copyright 2018.

was calculated to be 1905, 1024, and 926 mg g^{-1} for Py-BF-CMP, TPA-BF-CMP and TPE-BF-CMP, respectively. Then, the photocatalytic activity of these BF-CMPs for the degradation RhB was explored, and the contribution of adsorption was evaluated with the same mixture in the dark. Py-BF-CMP showed the highest photocatalytic activity among the three BF-CMPs under continuous visible light ($>450 \text{ nm}$) irradiation for 30 min, where more than 81% of RhB was degraded, which is comparable or even better than that of some reported porous polymers (C_3N_4 , and POM-based CMPs (Bn-Anderson-CMP)). $\text{O}_2^{\bullet-}$ was the primary active species during the photodegradation process and it was noteworthy that Py-BF-CMP exhibited high stability and recyclability both as an adsorbent and photocatalyst.

Besides CMPs, a series of imine-linked COFs ($\text{COF}_{\text{A+C}}$, $\text{COF}_{\text{A+B}}$ and $\text{COF}_{\text{A+D}}$, Fig. 14) reported by Y. Cai *et al.* have been used for the photodegradation of water pollutants and the structure–property relationship was investigated in detail.¹³⁵

Fig. 14 Synthesis and structures of $\text{COF}_{\text{A+B}}$, $\text{COF}_{\text{A+C}}$ and $\text{COF}_{\text{A+D}}$. Modified from ref. 135 with permission from Elsevier, Copyright 2018.

The COFs were synthesized *via* Schiff base chemistry with the same aldehyde (A) but different NH_2 -terminated building blocks (B, C, and D). All the COFs were thermally stable up to 300°C . Dark adsorption tests for the three COFs towards MO dye were firstly conducted. Generally, a higher BET surface area and larger pore volume result in better adsorption capacity. In this work, the author demonstrated that the existence of noncovalent interactions such as π - π stacking and hydrogen bonding between the porous polymer skeleton and dye molecules promoted the adsorption process. It was estimated that π - π stacking and H-bonding interactions may exist between MO and the polymers, while the former interaction played a decisive role. Thus, the existence of the largest amount of benzene rings in $\text{COF}_{\text{A+B}}$ rendered it with the highest adsorption ability toward MO. On the other hand, since the $-\text{NH}-$ group in $\text{COF}_{\text{A+D}}$ can form H-bonds with the azo groups ($-\text{N}=\text{N}-$) of MO, $\text{COF}_{\text{A+D}}$ exhibited a higher adsorption capacity than $\text{COF}_{\text{A+B}}$. Accordingly, the adsorption capacity of these COFs towards MO followed the order of $\text{COF}_{\text{A+B}} > \text{COF}_{\text{A+D}} > \text{COF}_{\text{A+C}}$. Then the COFs were further evaluated for degrading MO under visible light. After irradiation with visible light for 30 min, MO was completely degraded by $\text{COF}_{\text{A+C}}$ and the performance of $\text{COF}_{\text{A+C}}$ was superior to the other COFs. Under the same conditions, only 29.6% MO was removed by $\text{COF}_{\text{A+B}}$ while almost no MO was degraded in the presence of $\text{COF}_{\text{A+D}}$. Based on the control experiments, it is deduced that the photodegradation of organic pollutants was mainly driven by the superoxide radicals ($\text{O}_2^{\bullet-}$) with the assistance of hydroxyl radicals ($\bullet\text{OH}$).

4.2 Photodegradation of heavy metal ions

Hexavalent chromium ($\text{Cr}(\text{VI})$), which is known as a toxic heavy metal due to its mutagenic and carcinogenic effect, is widely used in the leather tanning, printing, and pigment industries.^{136,137} Thus, groundwater pollutants containing $\text{Cr}(\text{VI})$ may cause great damage to human health. However, when $\text{Cr}(\text{VI})$ is reduced to $\text{Cr}(\text{III})$, the toxicity is reduced by 500–1000 times.¹³⁸ Therefore, photocatalytic reduction is an effective way to detoxify wastewater that contains $\text{Cr}(\text{VI})$ heavy metal ions.

Benefiting from the photocatalytic activity of Bi_2MoO_6 for environmental decontamination and the high photocatalytic activity and stability of CMPs, a porous polymer (BBT) was synthesized *in situ* on the surface Bi_2MoO_6 nanosheets, resulting in a Z-scheme heterojunction (BBT-BMO, Fig. 15a).¹³⁹ The construction of the Z-scheme heterojunction facilitated the separation of charge carriers, thus improving the photocatalytic ability (Fig. 15b). BBT-BMO-10% with a mass ratio of 10% (BBT to BMO) exhibited the maximum photocatalytic rate. It had a relatively high BET surface area of $35.9 \text{ m}^2 \text{g}^{-1}$ and a broader absorption spectrum, providing more active sites. In addition, the weaker fluorescence intensity, lower photocurrent and structure-resulting efficient exciton separation indicated that more photogenerated holes and electrons were available, further enhancing the photocatalytic performance. During the photocatalytic process, both photogenerated electrons and $\text{O}_2^{\bullet-}$ contributed to the reduction of $\text{Cr}(\text{VI})$ and the photocatalyst could be reused after at least 3 runs.

Fig. 15 (a) Preparation of BBT–BMO. (b) Proposed photocatalytic mechanism for the photoreduction of Cr(vi) using BBT–BMO. Reproduced from ref. 139 with permission from Elsevier, Copyright 2017.

Fig. 16 Structures of BT-COFs and pictures of the corresponding powder and photographs of the photocatalytic reduction using TPB-BT-COF and TAPT-BT-COF. Reproduced from ref. 140 with permission from the Royal Society of Chemistry, Copyright 2019.

Our group developed two D–A-type BT-based COFs (BT-COFs, *i.e.*, TPB-BT-COF and TAPT-BT-COF, Fig. 16), which were further applied for the photoreduction of Cr(vi).¹⁴⁰ Both BT-COFs were not soluble in common solvents and displayed good chemical stability in various harsh conditions. Fortunately, the conduction bands of these two BT-COFs were negative enough for the reduction of Cr(vi). The concentration of Cr(vi) in solution was detected with the assistance of DPC and sulfuric acid. With a more negative conduction band as well as a narrower band gap, TPB-BT-COF exhibited a faster photocatalytic rate. Cr(vi) was totally reduced upon visible light irradiation for 75 min without any hole scavenger and no additional acid or base was needed to adjust the pH during the photocatalytic process.

Notably, the influence of photocatalyst structures on photocatalytic activity for the treatment of pollutants in water can be concluded from the following aspects:

1. Generation of reactive oxygen species

Suitable energy levels are needed for generating reactive oxygen species, particularly the CB edge potential of COFs should be lower than the standard redox potential $E_{(\text{O}_2/\text{O}_2^{\bullet-})}$ (-0.33 vs. NHE). Besides, the hydrophilicity of porous polymers also affects the production of reactive oxygen species (mainly $\bullet\text{OH}$).

2. Available active sites

More active sites tend to generate more excitons, thus affecting the photocatalytic ability, which can be deduced from the transient photocurrent intensity. A higher transient photocurrent intensity indicates more visible-light active centres, which is beneficial for the generation of photoexcited charge carriers.

3. Effective exciton separation

Effective separation of photoinduced electron–hole pairs is a prerequisite to initiate photocatalysis. First, it can be inferred from the theoretical calculation whether there is a clear separation between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO). In addition, fully quenched photoluminescence (PL) emissions originating from the recombination of free charge carriers corresponds to a high separation efficiency of photogenerated electron–hole pairs. Furthermore, a small arc radius obtained from the electrochemical impedance spectroscopy (EIS) Nyquist plot also reflects the good separation of electron–hole pairs.

Besides the above aspects, the generation of stable reaction intermediates is necessary for efficient photocatalysis.

5. Hydrogen evolution

Hydrogen fuel is a type of clean energy because it only produces safe and pollution-free water and a tremendous amount of heat upon combustion, which is expected to be a potential alternative to fossil fuels. The abundant water resources on earth provide a wide range of sources for hydrogen production. However, the hydrogen obtained from water undergoes an energy-raising (uphill) reaction that requires an energy of 1.23 eV and a high activation barrier to cross, and thus catalysts are needed to lower the activation barrier of the reaction.^{12,141,142} Most of the reported photocatalysts for hydrogen evolution are inorganic semiconductors such as TiO_2 ¹⁹ and noble metal catalysts;¹⁴³ however, they suffer from the disadvantages of expensive metal components and low catalytic activity under visible light. Thus, organic semiconductors with diverse synthetic strategies, tunable electronic structures, wide visible-light absorption and high carrier mobility have attracted great research interest. Typically, C_3N_4 ^{144,145} has been widely used as a photocatalyst for hydrogen production. However, its structure and energy levels are not easy to adjust and its synthetic temperature is usually high. In contrast, CMPs and COFs are structurally tunable and can be easily prepared, and thus, an increasing number of CMPs and COFs have recently been reported as efficient photocatalysts for hydrogen evolution, which is critically summarized below.

5.1 General mechanism

As shown in Scheme 2, the general process of photocatalytic hydrogen evolution can be roughly divided into three steps:¹⁴²

Scheme 2 General photocatalytic hydrogen evolution process. Reproduced from ref. 142 with permission from the American Chemical Society, Copyright 2013.

(1) firstly, generation of excited electrons and holes (excitons) under light irradiation; (2) excitons are separated and migrate to the active sites on the catalyst surface; and (3) finally, water undergoes a redox reaction on the surface of the catalyst releasing hydrogen as a product.

Usually, the hydrogen evolution rate (HER) is an important parameter to evaluate the photocatalytic activity towards the evolution of hydrogen from water. Furthermore, to investigate the mechanism, an isotope-labelling experiment is additionally conducted using D_2O instead of H_2O to confirm that the produced hydrogen comes from water.

It is well accepted that whether a photocatalyst can be applied for hydrogen evolution depends on the compatibility of the energy levels of its VB and CB with the oxidation potential of H_2O/H_2 . A promising photocatalyst should possess the following elements: (1) strong visible light absorption for the utilization of sunlight; (2) high photocatalytic activity; (3) good chemical stability; and (4) excellent reusability. The band gap can be narrowed to fit the visible region *via* proper structural design. Effective exciton separation is an efficient way to improve the photocatalytic activity. In addition to optimizing the structure and morphology (*e.g.*, surface morphology and structural defects) of the catalyst to promote exciton separation, sacrificial electron donors (SEDs) are often added to the catalytic system to inhibit the recombination of electrons and holes. Besides, co-catalysts (such as Pt nanoparticles) are usually deposited, and the transfer of electrons from the photocatalyst to co-catalyst is greatly promoted due to the existence of heterojunctions between Pt and the photocatalyst.¹⁴²

In the following section, we will introduce the recent research progress of CMPs and COFs (representative structures are listed in Scheme 3) for photocatalytic hydrogen evolution.

5.2 Representative examples

CMPs, due to their high stability, tunable chemical structures and electron properties, have been recognized as promising candidates for hydrogen evolution. The influence of modulating building blocks on the hydrogen evolution rate (HER) has been systematically investigated, as shown in Scheme 3a–f.

With two or three of four monomers (M_1 , M_2 , M_3 , and M_4) as building blocks, A. I. Cooper *et al.* documented a library of

pyrene-based CMPs (CP-CMP1–15, Scheme 3a) with varying ratios of building blocks, which were further used for photocatalytic hydrogen production.¹⁴⁶ The difference in compositions led to great modulations in their absorption (420 to 640 nm, Fig. 17a), and emission spectra (445 to 588 nm, from blue to red emission, as shown in Fig. 17b), BET surface areas (600 to $1700\text{ m}^2\text{ g}^{-1}$) and band gaps (1.94–2.95 eV). In the presence of diethylamine as a sacrificial electron donor, the photocatalytic hydrogen production rate of CP-CMP1–15 increased first and then decreased with an increase in optical gap under visible light ($> 420\text{ nm}$) irradiation. This can be attributed to the fact that with an increase in pyrene content, the energy level for charge transfer became lower, and meanwhile the recombination of electrons-holes became easier and became the dominant factor limiting the photocatalytic activity of the CMPs. Therefore, CP-CMP10 with a medium optical gap (2.33 eV) and moderate pyrene content exhibited the highest HER of $174 \pm 9\text{ }\mu\text{mol g}^{-1}\text{ h}^{-1}$. Notably, the obtained CMPs were mainly active in the visible range (Fig. 17a) and could achieve effective photocatalytic hydrogen evolution without the addition of co-catalysts. The strategy of composition variation was an effective way to regulate the optical bands of CMPs, providing a new idea for further improving the photocatalytic hydrogen evolution capacity of CMPs.

Although modulating the bandgap is a very effective way to improve photocatalytic activity, to further improve the efficiency, the photogenerated electrons and holes should be effectively separated.¹³ Inspired by the fact that intrachain charge transfer is beneficial for exciton dissociation and charge generation, a series of CMPs (PCP1x, PCP2x, PCP3x, and PCP4x, Scheme 3b) with alternating building blocks with different electronic properties were synthesized.¹⁵³ PCP4e constructed using the strong electron-donating M_8 and the weak electron-withdrawing bipyridyl (bpy) monomer featured a D–A structure and exhibited higher photocatalytic ability with an HER of $9.43\text{ mmol g}^{-1}\text{ h}^{-1}$. Besides, the D–A structure induced an improvement in electron-hole pair separation, and the higher wettability originating from the hydrogen bonding between the N atoms on bpy and H atoms of water led to a higher concentration of H_2O molecules around the catalytic sites for reduction. Finally, it was observed that the residual Pd after the preparation of CMPs may also contribute to their photocatalytic activity (Fig. 18).

Internal polarization is also crucial for effective charge separation, which is highly related to hydrogen evolution.¹⁴⁸ L. Yu *et al.* synthesized a broad scope of CMPs (PCP0–11, Scheme 3c) in D–D-type or D–A-type to illustrate how the internal polarization affects the photocatalytic hydrogen evolution performance.¹⁴⁹ Furthermore, benzene or biphenyl was introduced as π crosslinkers to construct a series of D– π –A-type CMPs (Scheme 3d) to further promote the charge separation for better photocatalytic performance.^{150a} Besides, highly conjugated 1,3-diyne-linked CMPs (*i.e.*, TEPB and TEB, Scheme 3e) possess high charge carrier mobilities and can effectively narrow the band gaps for visible photocatalysis.^{150b}

Taking the advantages of the strong electron-withdrawing property and rigid, planar structure of benzothioephene dioxide

Scheme 3 Representative (a–f) CMPs and (g–m) COFs as photocatalysts for hydrogen evolution.

(DBTD), three CMPs containing DBTD with cross-linkers in different lengths (*i.e.*, DBTD-CMP1, DBTD-CMP2, and DBTD-CMP3, Scheme 3f) were reported by J.-X. Jiang *et al.* and were further used for photocatalytic hydrogen evolution.¹⁵¹

Surprisingly, even the linear conjugated polymer counterparts, P7 and P10, with DBTD units in their backbone (Fig. 19a) exhibited a high HER of $1.49 \text{ mmol g}^{-1} \text{ h}^{-1}$ and $3.26 \text{ mmol g}^{-1} \text{ h}^{-1}$, respectively. The photocatalytic performance of the CMPs increased

Fig. 17 (a) UV-vis absorption spectra of CP-CMP1-15 powder and (b) corresponding images under irradiation with UV light ($\lambda = 365$ nm). Reproduced from ref. 146 with permission from the American Chemical Society, Copyright 2015.

with a decrease in cross-linker length, as explained by the spectra (UV-vis spectra and fluorescent spectra) and the DFT calculation. DBTD-CMP1 with the shortest benzene cross-linker exhibited a greater redshifted absorption, lower fluorescence emission intensity, shorter excitation lifetime and greater LUMO orbital distribution on DBTD, thus resulting in a higher conjugation degree, more efficient charge carrier separation and more reactive sites. All these characters led to a higher photocatalytic performance. Remarkably, DBTD-CMP1 exhibited an attractively high HER of $2460 \mu\text{mol g}^{-1} \text{h}^{-1}$ ($\lambda > 420$ nm) without Pt co-catalyst and an even higher HER of $4600 \mu\text{mol g}^{-1} \text{h}^{-1}$ when Pt was loaded, which is superior to most reported POP-based photocatalysts. Notably, the Pt-loaded DBTD-CMP1 showed an HER of $9200 \mu\text{mol g}^{-1} \text{h}^{-1}$ under UV-vis light illumination (Fig. 19b). Furthermore, DBTD-CMP1 exhibited long-term stability and excellent reproducibility.

Similarly, COFs with an ordered structure, excellent photoelectric properties and tunable energy levels, have also been

Fig. 18 Effect of residual of Pd content on the hydrogen production rate using PCP4e as a photocatalyst. Reproduced from ref. 147 with permission from the American Chemical Society, Copyright 2016.

Fig. 19 (a) Structures of the linear polymers P7 and P10. (b) HER of the DBTD-CMP1 photocatalyst under different conditions. Reproduced from ref. 151 with permission from the American Chemical Society, Copyright 2018.

used as photocatalysts for hydrogen evolution. Although with limited examples, the use of COFs in photocatalytic hydrogen evolution has shown promising results. Triazines with a high electron mobility and strong electron affinity are widely used in photoelectric devices.¹⁵² The dihedral angle between the benzene and triazine rings in 2,4,6-triphenyl-1,3,5-triazine (TPT) is much smaller than that with benzene as the centre core, which is conducive to the construction of COFs with π -extended structures and tighter interlayer stacking, endowing them with high crystallinity and strong light absorption.¹⁵³ B.V. Lotsch *et al.* reported a hydrazone-linked COF (TFPT-COF, Scheme 3g) containing TPT blocks and systematically investigated its performance in photocatalytic hydrogen evolution.¹⁵⁴ As expected, TFPT-COF was highly crystalline and possessed large mesopores of 3.8 nm in diameter together with a high BET surface area of $1603 \text{ m}^2 \text{ g}^{-1}$. Due to its suitable energy levels, TFPT-COF was able to photocatalytically split water into hydrogen under visible light irradiation. In the presence of 10 vol% aqueous triethanolamine (TEOA) solution as the sacrificial electron donor and with Pt as the co-photocatalyst, the photocatalytic system showcased continuous and stable hydrogen production as high as $1970 \mu\text{mol g}^{-1} \text{h}^{-1}$ during the first 5 h under standard basic conditions, even higher than that of Pt-modified amorphous melon, and $\text{g-C}_3\text{N}_4$. Although TFPT-COF lost its long-term order after ultrasonic treatment in water, it still remained stable photocatalytic activity, and its HER performance did not exhibit any obvious change after three cycles. It was hypothesized that the triazine moieties primarily acted as photoactive sites and thus played important roles in the catalytic hydrogen evolution.

To better understand the effect of the 1,3,5-triazine moiety on the HER performance, a series of hydrazine-linked COF counterparts (N_0 , N_1 , N_2 and N_3 -COF, Scheme 3h) containing different triphenylaryl units with 0–3 nitrogen atoms on the central aromatic ring was prepared by the same group, realizing the regulation of photoelectric properties and photocatalytic hydrogen production performance at the molecular level.⁶⁸

The integration of nitrogen atoms in the aromatic central aryl rings led to a significant change in the dihedral angle between the peripheral phenyl and central aryl ring (Fig. 20a), and thereby a variation in the planarity of the skeleton. In addition, when the number of nitrogen atoms increased from 0 to 3, the electron density in the central aromatic ring of the COF gradually decreased. While, the electron-deficient properties of the azine moiety could effectively stabilize the photogenerated electrons, facilitating the separation of electron-hole pairs and the subsequent migration to the active sites, thus promoting the hydrogen generation process. The average HERs photocatalyzed by N_0 , N_1 , N_2 and N_3 -COF were 23, 90, 438 and 1703 $\mu\text{mol g}^{-1} \text{h}^{-1}$, respectively. The observed trend was explained by theoretical calculations, and meanwhile two possible pathways after photoexcitation on N_x -COFs were proposed (Fig. 20b). It is estimated that it was more likely to go through the radical anion pathway and the stabilization of the radical anion contributed to the photocatalytic process. The increase in nitrogen numbers resulted in the electron-poor character of the core, which effectively stabilized the radical anion and transferred it to the nearest Pt nanoparticles. Therefore, N_3 -COF exhibited the highest photocatalytic activity, which was comparable to that of carbonitride photocatalysts and even better than that of Pt-modified amorphous melon ($720 \mu\text{mol g}^{-1} \text{h}^{-1}$), $g\text{-C}_3\text{N}_4$ ($840 \mu\text{mol g}^{-1} \text{h}^{-1}$) and crystalline poly (triazine imide) ($864 \mu\text{mol g}^{-1} \text{h}^{-1}$).

Diacetylene-bridged COFs, which possess highly conjugated structures and strong electron migration ability, are expected to be excellent photocatalysts.¹⁵⁵ However, owing to the decreased formation rate of COFs originating from their larger pore size and weaker interlayer attraction, their synthesis seems to be very challenging.¹⁵⁶ A. Thomas *et al.* recently developed a diacetylene-bridged β -ketoenamine COF (TP-BDDA, Scheme 3i) together with an acetylene-bridged COF counterpart (TP-EDDA in Scheme 3i) for comparison.¹⁵⁷ Theoretically, the optical band gaps for both COFs were sufficient for photocatalytic hydrogen evolution. However, as shown in Fig. 21a, using a home-made reactor set-up (Fig. 21b) and in the presence of TEOA and the co-catalyst, only TP-BDDA could efficiently catalyze hydrogen evolution with an average HER of $324 \pm 10 \mu\text{mol g}^{-1} \text{h}^{-1}$ under visible light irradiation ($\geq 395 \text{ nm}$). In contrast, only negligible H_2 evolution ($30 \pm 5 \mu\text{mol g}^{-1} \text{h}^{-1}$) was detected when

Fig. 21 (a) Photocatalytic hydrogen evolution rates of TP-EDDA and TP-BDDA. (b) Reactor setup for hydrogen evolution experiments. Reproduced from ref. 157 with permission from American Chemical Society, Copyright 2018.

TP-EDDA was used as the photocatalyst, illustrating that the conjugated diacetylene moiety played a crucial role in improving the photochemical water reduction activity. Interestingly, the quantum efficiency for the TP-BDDA catalyzed hydrogen evolution even reached up to 1.8% upon 520 nm light irradiation. Notably, TP-BDDA was the first example of COF without any heteronuclear atoms in its structure for photocatalytic hydrogen evolution.

The integration of DBTD monomer into COFs (FS-COF and S-COF, Scheme 3j) also greatly improved their photocatalytic activity towards hydrogen production (compared to TP-COF, Scheme 3j).¹⁵⁸ FS-COF features a long-range ordering structure, a high BET surface area ($1288 \text{ m}^2 \text{g}^{-1}$), wettable mesopores (3.2 nm, a contact angle of $\sim 23.6^\circ$) and strong visible light absorption, which were favorable for visible light catalytic hydrogen evolution. The HER of FS-COF for visible light catalysis ($> 420 \text{ nm}$) was up to $10.1 \text{ mmol g}^{-1} \text{h}^{-1}$ with ascorbic acid as the sacrificial electron donor and Pt as the co-catalyst, and it could still reach as high as $1.32 \text{ mmol g}^{-1} \text{h}^{-1}$ without the addition of Pt. Moreover, FS-COF showed a high external quantum yield of 3.2% at 420 nm, excellent optical stability, and a good photostability and steady photoactivity under continuous visible light irradiation during the photocatalytic process. The much improved photocatalytic hydrogen evolution of FS-COF compared to the other analogues was illustrated through electronic structure calculations (Fig. 22a and b). Among the four COF counterparts, FS-COF exhibited the smallest optical gap, which facilitated the visible photon absorption and exciton generation. Notably, the HER could be further increased to $16.3 \text{ mmol g}^{-1} \text{h}^{-1}$ when FS-COF was dye-sensitized by loading a near-infrared absorbing dye.

Considering the excellent photocatalytic hydrogen evolution performance of FS-COF, thin films of FS-COF by deposition of its colloidal solution onto glass substrate were further fabricated (Fig. 22c). The photocatalytic HER ($\lambda > 420 \text{ nm}$, 0.1 M ascorbic acid, 5 h irradiation) was highly dependent on the film thickness and reached up to $24.9 \text{ mmol h}^{-1} \text{m}^{-2}$, which is a step further for real application. To date, FS-COF exhibited the highest photocatalytic HER performance compared to other reported COFs.

sp²-carbon-linked COFs featured with π -delocalization over 2D networks exhibit unique photophysical properties and have attracted considerable attention for photocatalytic hydrogen evolution. sp²-COF was prepared as shown in Scheme 3k.¹⁵⁹ To further modulate its absorbance and band-gap, the electron-withdrawing group 3-ethylrhodanine (ERDN) was used as an end-capping group to introduce a push-pull effect to the 2D networks (sp²-COF_{ERDN} in Scheme 3k). Both COFs exhibited high stability, crystallinity, porosity, π -conjugation and suitable range of energy levels for hydrogen evolution *via* water splitting. sp²-COF provided an HER of 1360 $\mu\text{mol g}^{-1} \text{h}^{-1}$ in the presence of 10 vol% triethanolamine (TEOA) sacrificial donor and Pt nanoparticles under irradiation ($\geq 420 \text{ nm}$). Specially, it could quickly respond to a broad range of visible light from 400 nm to 590 nm. Remarkably, sp²-COF_{ERDN} exhibited greatly enhanced activity with HERs of 2120 ($\geq 420 \text{ nm}$) and 1240 $\mu\text{mol g}^{-1} \text{h}^{-1}$ ($\geq 498 \text{ nm}$) which originated from its improved light-harvesting capability (exceptionally broad absorbance centred at 530 nm and even extended to 800 nm), band-gap structure, and built-in heterojunction interface.

To date, most of the reported sp²-COFs have been obtained based on the Knoevenagel reaction between benzaldehyde and phenylacetonitrile (Fig. 23a). Very recently, F. Zhang *et al.* developed a scalable solution-processing approach to fabricate sp²-COFs.¹⁶⁰ Three COFs (g-C₄₀N₃-COF, g-C₃₁N₃-COF and g-C₃₇N₃-COF, Scheme 3l) were synthesized with the key building block 3,5-dicyano-2,4,6-trimethylpyridine (DCTMP) and linear/trigonal

Fig. 23 (a) Model Knoevenagel condensation reaction to construct sp²-COF in previous works and (b) new strategy used for sp²-COF by F. Zhang *et al.* Modified from ref. 160 with permission from Nature Publishing Group, Copyright 2019.

aldehyde (4,4''-diformyl-*p*-terphenyl, 4,4'-diformyl-1,1'-biphenyl or 1,3,5-tris(4-formylphenyl)benzene) utilizing the model reaction of the Knoevenagel condensation reaction between benzaldehyde and 2-methylnicotinonitrile (Fig. 23b). These COFs possessed high crystallinity, especially g-C₄₀N₃-COF. The conjugated structure and the incorporated pyridine rendered them with excellent light-harvesting characteristics. Additionally, with its suitable band gap of 2.36 eV and a high reduction potential of 5.83 eV (*vs.* vacuum level) together with a high oxidation potential of 3.47 eV (*vs.* vacuum level), g-C₄₀N₃-COF is an ideal photocatalyst for water splitting with two half-reactions in the presence of sacrificial reagents. The HER (50 mg) was 4.12 mmol g⁻¹ h⁻¹, with an apparent quantum yield (AQY) of 4.84% at $\lambda = 420 \text{ nm}$, which is even superior most promising POPs such as N₃-COF, FS-COF.

CTFs have shown great potential in photocatalytic hydrogen production due to their high physicochemical stability and high nitrogen content. However, the conventional ionothermal conditions used to synthesize CTFs may cause partial carbonization of the structures and with a large energy penalty. B. Tan *et al.* provided an alternative strategy to construct CTFs *via* the low temperature condensation of aldehydes and amidines involving Schiff base formation followed by Michael addition (Fig. 24a).⁷⁴ Four CTFs named CTF-HUST-1, CTF-HUST-2, CTF-HUST-3 and CTF-HUST-4 (Scheme 3m) were obtained and further explored as photocatalysts for hydrogen evolution. With layered structures, CTF-HUSTs showed a higher HER compared to the CTF-1 prepared by the ionothermal method and among which, CTF-HUST-2 exhibited the maximum HER of 2647 $\mu\text{mol g}^{-1} \text{h}^{-1}$ in sacrificial photocatalytic hydrogen evolution under visible light irradiation ($> 420 \text{ nm}$). Nevertheless, the frameworks lacked long-range order, although their enhanced crystallinity can improve charge transport in the framework, which is beneficial for photoelectric properties. In 2018, the same group adopted a strategy of *in situ* oxidation of alcohols to aldehyde monomers (Fig. 24b).⁷² The method was effective to construct a series of crystalline CTFs (CTF-HUST-C1, CTF-HUST-C5, and CTF-HUST-C6) due in the fact that a decrease in nucleation rate and generation of a lower concentration of nuclei are the key to improving the crystallization. Under the same conditions, the three CTFs exhibited HERs of 5100, 2400 and 650 $\mu\text{mol g}^{-1} \text{h}^{-1}$, respectively. CTF-HUST-C1 possessed

Fig. 24 Reaction mechanisms for (a) CTF-HUSTs and (b) CTF-CX synthesis. Modified from ref. 72 and 74 with permission from Wiley-VCH Verlag GmbH & Co. KGaA, Copyright 2017 and 2018, respectively.

the highest photocatalytic activity towards hydrogen evolution among the three, which was higher than that of CTF-HUST-1 and other amorphous CTFs.

For better comparison, the photocatalytic activities of the above CMPs and COFs are summarized in Table 1.

6. Outlook and future perspectives

POPs, as a new type of heterogeneous photocatalysts, possess the advantage of easy separation for recycling in comparison to their homogeneous counterparts. Among them, CMPs and COFs known as representatives of amorphous and crystalline POPs, possess unique features both in structure and functions modification to favor photocatalysis.¹⁶¹ Indeed, great advances have been achieved in recent years; however, the catalytic performances still cannot meet the demand for practical applications due to the unsatisfactory photocatalytic activity. Donor-acceptor structures are favorable for the separation of photoexcited electron-hole pairs, and thus enhance photocatalytic activity. In addition, many aforementioned aspects such as specific nanostructures, composition, dipole orientation and connectivity of the building blocks also exert significant impacts on the eventual performance. However, there are several challenges that need to be addressed before POP-based photocatalysts can be developed further for real applications. Among them, we mainly consider the following two aspects.

6.1 Design and synthesis

A general strategy for the design of POP-based photocatalysts is required to integrate proper photosensitizers into the frameworks. Some typical moieties used in optoelectronics with strong electron-withdrawing properties are often used. For example, benzothiadiazoles and their derivatives are usually utilized as electron acceptors for the construction of CMPs. On the other

hand, nitrogen-rich triazines are frequently applied as building blocks for COFs. Most CMPs are generally prepared *via* metal-assisted C–C cross-coupling reactions (*e.g.*, Suzuki,^{80,82,146,147,149–151} Sonogashira,^{79,81,100,111,117} Heck,¹⁶² Glaser,^{150b} and Yamamoto¹⁶³ cross-coupling). The residue of metal species may cause potential interference and detrimental contamination for photocatalytic applications.¹⁶⁴ In comparison, COFs are usually synthesized under conditions without noble metal catalysts and are mostly constructed based on dynamic covalent chemistry (DCC). The reversible formation of covalent bonds guarantees high crystallinity, while this will consequently lead to low stability of the COF skeleton. Hence, as outlined above, although the photocatalytic activity of COFs remains nearly unchanged after several catalytic cycles, their crystallinity often decreases significantly after photocatalysis. Thus, a remaining challenge is to enhance the robustness of COFs. The utilization of irreversible chemical transformations (*e.g.*, tautomerism and oxidation)^{63,165,166} or intramolecular hydrogen bonding is an effective way to prepare robust COFs. Another alternative strategy is connecting building blocks using more stable C=C linkages^{62,95–98} instead of the relatively labile C=N^{167,168} and B–O¹⁶⁹ bonds. However, in both cases, only limited examples have been realized, and they still suffer from either complicated preparation procedures or harsh reaction conditions. Therefore, there is much room for the further development of new synthetic strategies for POPs, including exploring novel building blocks, new linkages, and facile synthetic techniques.

6.2 Applications for photocatalysis

Benefiting from flexible structures, the band gaps of POPs may fall in the visible-light range through structural adjustment, holding great promise for solar-energy utilization. POP-based photocatalysts are able to mediate a series of reactions under visible light irradiation, such as the selective oxidation of organic sulfides,^{82,170} oxidation coupling of primary amines,^{93,94,170} aza-Henry reaction,^{102,104} hydroxylation of aryl-boronic acids,^{63,118,164} C-3 formylation and thiocyanation of indoles,¹⁰⁸ selective bromination of aromatic compounds,¹⁷¹ reductive dehalogenation of organic bromide,^{113,114,118,172} and free radical polymerization of methyl methacrylate (MMA).¹¹⁶ Also, usually high transformation efficiency and excellent tolerance to a wide scope of substrates have been achieved in these cases. In addition, a variety of reactive species are produced, including singlet oxygen, which can be used in photodynamic therapy.¹⁷³ However, the photocatalytic application of most POPs for chemical transformation is limited to a narrow scope of redox reactions. Thus, to explore the scope of their applications, POPs with extremely high redox potentials are desirable, which may come at a cost in terms of visible-light utilization efficiency.¹⁶¹ Thanks to their large porosity and excellent photocatalytic activity, POPs can be used not only as adsorbents but also as photocatalysts for the treatment of water pollutants. Moreover, POP-based photocatalysts have attracted increasing research interests in photocatalytic hydrogen evolution. Recently, it has been reported that DBTD-containing CMPs (DBTD-CMP1) and COFs (FS-COF) exhibited the highest HER among two

Table 1 Summary of the hydrogen evolution activity of the CMPs and COFs mentioned herein

	Co-catalyst	SED	Solvent	Light (nm)	HER ($\mu\text{mol g}^{-1} \text{h}^{-1}$)	AQE	Ref.
CP-CMP10	—	20 vol% DEA	Water	>420	174 (6 h)	—	146

types of POPs.^{151,158} These photocatalysts are highly competitive with the existing catalysts and have excellent stability and recyclability.^{151,158}

In the case of photocatalytic applications, the most important issue is to improve the efficiency of photocatalysts. The whole photocatalytic process involves a number of elementary photochemical processes including light harvesting, photo-induced electron-hole separation and charge migration to the surface of the photocatalyst. Thus, it is vital to increase the efficiency of each step and reduce the energy loss among these steps for through solar energy conversion.¹⁷⁴

(1) The chemical structures of POPs determine their efficiency of sunlight utilization. Highly conjugated structures with narrow band gaps enabling absorption covering the visible-light range or even near-infrared region are desired. Besides the structures of building blocks, it has been demonstrated that the geometry of knots affects the conjugation over the 2D sheet of 2D COFs also. For example, an azine-linked COF with tetragonal topology possessed extended conjugation over the 2D sheet, while that with a hexagonal structure yielded a finite degree of conjugation.^{68,174}

(2) During the migration process, electrons and holes may recombine, and thus lower the solar conversion efficiency, and

therefore, the lifetime of excitons is another important element that needs to be considered. Great efforts have been devoted to enhancing the electric conductivity and shortening the charge transfer distance to reduce the recombination of excitons.^{14b} Over the past years, many strategies have been developed, such as placing some type of electron/hole sink (*e.g.*, sacrificial electron donor) at the surface to remove the electron/hole from the recombination arena, constructing nanostructures to shorten the charge transport distance,^{150b} reducing defects inside the POPs to ensure that excitons migrate to the surface of photocatalysts, and forming donor-acceptor structures.^{79,112}

(3) The last step for photocatalysis is the redox reaction at the interface of catalysts and the reaction mixture. Sufficient surface area is needed for the exposure of more active sites for redox reaction. Whereas, the accumulation of carriers on the surface would definitely increase the charge recombination, and meanwhile damage the long-term stability of photocatalysts. Thus, the surface kinetics should be accelerated, while the introduction of co-catalysts is also an effective way to address this problem.^{14b}

Finally, photocatalysts need to be stable and robust for long-term photocatalytic cycling processes.

As an important aspect of the photocatalytic application, photosensitized singlet oxygen ($^1\text{O}_2$) has attracted tremendous research interest. The application of POPs as a photosensitizer for $^1\text{O}_2$ generation involves an intersystem crossing (ISC) from the lowest singlet excited state (S1) to the lowest triplet excited state (T1), and enhancing the ISC process is vital for enhancing the performance of photosensitizers. The introduction of heavy atoms that enhancing spin-orbit coupling will promote this process, but at the expense of safety. Another effective method is to lower the energy gap between S1 and T1. The “polymerization-enhanced photosensitization” concept was recently proposed to design highly effective photosensitizers since conjugated polymers possess many energy levels in each energy band.¹⁷⁵ Therefore, the conjugation of POPs should be well adjusted for better performances as photosensitizers.

An urgent problem that needs to be solved is the dispersion of photocatalysts. Especially for water pollution treatment and photocatalytic hydrogen production, catalysts need to have good water wettability.^{161,176} B. V. Lotsch *et al.* highlighted this issue in the report entitled “The wetter the better”.¹⁷⁷ F. Vilela *et al.* provided a valid solution of post-modification strategies to address this problem.⁸³ Introducing water-compatible groups within the polymer is another approach to achieve the target. In a recent perspective,¹⁷⁸ D. Jiang *et al.* scrutinized the design concept and synthetic strategy for COFs used for light-driven hydrogen production, and a glorious vision was proposed for overall water splitting to produce both hydrogen and oxygen by a single and scalable COF photocatalyst. Currently, the reported CMPs are all amorphous, while most of the COFs are obtained as microcrystalline powders. The structures of COFs are mainly deduced by combining theoretical PXRD simulation results with the experimental data. However, exact structure determinations are crucial for better understanding the structure-property relationship for further design and synthesis. Although a few COFs with resolved single crystal structures were recently reported,^{167,179,180} it is highly desirable to develop reliable strategies to construct COF crystals,⁷⁵ especially 2D COFs. POP-based devices are another important direction that requires further development for realizing real applications in sensing, emitting and catalysis, *etc.* Nevertheless, due to their insolubility in most common solvents, powdered POPs are difficult for processing. A. I. Cooper *et al.*¹⁸¹ and A. Hu *et al.*¹⁸² proposed novel strategies of hyperbranched structuring and size control to improve the “solubility” of POPs, respectively. While D. Jiang *et al.*¹⁸³ and S. Dai *et al.*¹⁸⁴ separately prepared POP-based thin films or membranes by electropolymerization or *in situ* polymerization. Thus, more efforts should be devoted to developing new methods for processing POPs or fabricating POP-based films for device-directed applications. Finally, the real charge transfer pathway during the photocatalysis process is unclear, and therefore, more photophysical analysis and molecular simulation are required for better understanding the reaction mechanism.

In summary, with excellent photocatalytic performance and good reusability, POPs (especially CMPs and COFs) represent a promising platform for efficient photocatalysis. We anticipate

that POPs have a promising future with more efficient photocatalytic POPs emerging for to practical applications.
