Stabilisers, such as surfactants, polymers and polyaromatic molecules, offer an effective way to produce graphene dispersions in water by Liquid Phase Exfoliation (LPE) without degrading the properties of graphene. In particular, pyrene derivatives provide better exfoliation efficiency than traditional surfactants and polymers. A stabiliser is expected to be relatively soluble in order to disperse hydrophobic graphene in water. Here, we show that exfoliation can also be achieved with insoluble pyrene stabilisers if appropriately designed. In particular, bis-pyrene stabilisers (BPSs) functionalised with pyrrolidine provide a higher exfoliation efficiency and percentage of single layers compared to traditional pyrene derivatives under the same experimental conditions. This is attributed to the enhanced interactions between BPS and graphene, provided by the presence of two pyrene binding groups. This approach is therefore attractive not only to produce highly concentrated graphene, but also to use graphene to disperse insoluble molecules in water. The enhanced adsorption of BPS on graphene, however, is reflected in higher toxicity towards human epithelial bronchial immortalized cells, limiting the use of this material for biomedical applications.

Introduction

Graphene, a single layer of graphite, shows great potential for numerous applications due to its outstanding properties, including extreme mechanical strength and exceptionally high electronic and thermal conductivity.¹ Out of all of the graphene

synthesis techniques, Liquid-Phase Exfoliation (LPE)² allows for mass-scalable, cost-effective and versatile production of graphene formulations suitable for a wide range of practical uses, ranging from composites to biomedical applications.^{1,3–5}

Liquid phase exfoliation relies on the use of solvents with surface tension comparable to that of graphene.² Thus, *N*-methyl-2-pyrrolidone (NMP) is typically the solvent of choice.² However, its toxicity, high cost and boiling point do not make it an ideal solvent. Water is a low cost and environmentally friendly solvent, required in many applications. However, in order to effectively exfoliate graphite in water, the graphene surface needs to be altered, either covalently or non-covalently.^{6–8} The use of stabilisers offers an effective method to functionalise the material without introducing defects, hence maintaining the intrinsic properties of graphene, while allowing dispersibility in water.^{9–11} Different types of stabiliser, including surfactants,^{9,12–14} polymers^{15–17} and polyaromatic molecules^{10,18,19} have been investigated.

Stabilisers are typically amphiphilic, *i.e.* they have a hydrophobic binding group, which adsorbs onto the graphene surface through van der Waals interactions, and a hydrophilic group, which prevents re-stacking of exfoliated graphene nanosheets through steric hindrance and/or electrostatic stabilisation.^{10,20} Out of all stabilisers, pyrene derivatives have been shown to be very effective at exfoliating graphite, when compared to typical surfactants and polymers, due to the effective adsorption of pyrene on graphene through π – π interactions.^{10,11,21–23} In particular, in our group, we have extensively used 1-pyrenesulfonic acid sodium salt (PS1) to obtain biocompatible and inkjet-printable graphene dispersions in water.^{4,21,24}

Despite the wide use of pyrene derivatives as stabilisers, the effective mechanisms leading to exfoliation are very poorly understood. Seminal works have shown that not all pyrene derivatives are effective exfoliating agents.^{10,11,25} Exfoliation efficiency, as defined by the concentration of graphene, depends strongly on many factors, such as type and number of functional groups, and the charge distribution in the stabiliser. These determine the thermodynamics of the interaction between the stabiliser and graphene, *e.g.* the adsorption of the pyrene binding group on the graphene surface, the affinity of the functional groups for the solvent medium, and the effectiveness of deterring the re-stacking of the graphene sheets.^{9,10,26–28} Since the affinity of the functional groups for the solvent medium is one of the key parameters, stabilisers with relatively good aqueous solubility have been used up to now.

In this work, we show that pyrene derivatives with extremely low solubility can be exceptionally efficient as exfoliating agents, contradicting the common assumption that an effective stabiliser needs to be soluble in water. A bis-pyrene stabiliser (BPS), functionalized with a pyrrolidine central group (Scheme 1), was designed and synthesized *ad hoc* for this study. Its exfoliation efficiency was compared to that of two pyrene derivatives with the same functional group: one with longer linking chains between the pyrene binding groups and the functional group (LBPS), and the other with a mono-pyrene binding group (MPS) (Scheme 1). BPS has been found to be insoluble in aqueous media, *i.e.* the aqueous solubility of BPS is under the detection limit of NMR. Despite this, the BPS molecule showed an exfoliation efficiency up to 3–5 times higher than that obtained with PS1 or MPS. Furthermore, the graphene dispersion prepared with BPS showed a higher percentage of single layer graphene (SLG) compared to PS1. The enhanced exfoliation efficiency of BPS compared to the other stabilisers is attributed to the higher interaction strength between BPS and graphene, driven by stronger π – π

Scheme 1 General schematic plan for the synthesis of the pyrene stabilisers.

interactions due to the presence of two pyrene binding groups in BPS, and the insolubility of BPS in water (as confirmed by Nuclear Magnetic Resonance (NMR)). Finally, cytotoxicity studies on the graphene dispersions prepared with BPS show the toxicity of graphene to be dependent on the initial BPS concentration, whereas the graphene dispersion prepared with MPS showed no cytotoxic effect. Since the sizes of the nanosheets prepared with BPS and MPS are comparable, the difference in toxicity is attributed to the presence of the two pyrene binding groups in BPS, which may affect how these molecules assemble on graphene, in particular at high BPS concentrations.

Methods

Materials

Preparation of pyrene derivatives. The details of the synthesis routes for the pyrene stabilisers and all characterisation methods used for identification of the structure and purity of the compounds are given in the ESI.†

Preparation of graphene dispersions. Natural graphite crystals were provided by Graphexel Ltd. Graphene dispersions were prepared by LPE in water following the protocol developed in previous works.^{4,21,29} In detail, 300 mg of graphite and varying amount of stabilisers were added to 100 mL of de-ionized (DI) water. The mixture was then sonicated at 600 W for 7 days using a Hilsonic bath sonicator. Afterwards, un-exfoliated graphite was removed by two-step centrifugation (using a Sigma 1–14k refrigerated centrifuge) at 3500 rpm (903 g) for 20 min. After each centrifugation step, the supernatant containing graphene in water was collected. For cytotoxicity studies, the prepared graphene dispersions were further centrifuged at 15 000 rpm (16 600 g) for 60 min to increase the concentration further by collecting the sediment and re-dispersing in a smaller volume of DI water. In the case of the graphene dispersions prepared with BPS, the supernatant was also collected for characterisation. In the case of the graphene dispersions prepared with MPS, the second centrifugation step was repeated twice to remove excess pyrene from the solution.

Characterization

UV-vis spectroscopy. The concentration of graphene dispersed in the solution was determined using UV-vis spectroscopy. The UV-vis spectrum of graphene

appears flat and featureless in the visible-IR region,² so the absorption was measured at 660 nm for estimation of the graphene nanosheet concentration using the Beer–Lambert law. Despite the extensive work done towards accurately estimating the absorption coefficient, this is still the subject of considerable debate.³⁰ In this study, an absorption coefficient of $2460 \text{ L g}^{-1} \text{ m}^{-1}$ was used for estimating the graphene concentration.^{9,12,31} A PerkinElmer l-900 UV-vis-NIR spectrophotometer was used to acquire the spectra.

Zeta potential measurements. Electrophoretic mobility (μ) was measured using a ZetaSizer Nano ZS (Malvern Instruments, UK) after dilution of samples with water in the folded capillary cells (Malvern Instruments, UK). Default instrument settings for a water-based system and automatic analysis were used for all measurements, which were performed at 25°C and at natural pH. The equipment software automatically converted the mobility μ to zeta potential (ζ) values by Henry's equation: $\mu = 2\varepsilon\zeta F(\kappa a)/3\eta$, where ε is the dielectric constant, η is the solution viscosity and $F(\kappa a)$ is Henry's function, approximated to the value of 1.5 using the Smoluchowski approximation for polar media, valid for dispersed particles of any shape including plate-like particles.³² All values for the samples are mean $\pm$ standard deviation (SD), calculated from triplicate measurements.

Atomic force microscopy (AFM). A Bruker Atomic Force Microscope (Multi-Mode 8) in peak force tapping mode, equipped with ScanAsyst-Air tips, was used to determine the lateral size distribution of the flakes. The sample was prepared by drop casting the solution onto a clean silicon substrate; areas of 10 to $400 \mu\text{m}^2$ were scanned and typically 200 or more flakes were selected for lateral size analysis. Lateral dimension and thickness distribution of graphene nanosheets were carried out using Gwyddion scanning probe microscopy data processing software.

Transmission electron microscopy (TEM). TEM imaging was performed using a FEI Talos 200X operating at an acceleration voltage of 200 kV, and TEM images were acquired using a FEI CETA CMOS (complementary metal–oxide semiconductor) camera. TEM samples were prepared by dip coating the graphene dispersions either on a lacey carbon copper grid or on a 3 nm ultrathin carbon film supported on a lacey carbon copper grid. Measurements of the number of layers were performed by High Resolution TEM (HRTEM) imaging of free-standing graphene flakes on the lacey carbon film. The graphene dispersion deposited on an ultrathin carbon film was used for the measurement of the lateral size of the graphene flakes.

Raman spectroscopy. Raman measurements were performed using a Renishaw Invia Raman spectrometer equipped with a 514.5 nm excitation line and 2.0 mW laser power. Graphene dispersions were drop-cast onto silicon substrates and measurements were performed on isolated and individual flakes. The Raman spectra were taken with a $100\times$ NA0.85 objective lens and 2400 grooves per mm grating. Typically, 30–50 flakes were measured for each sample. The Raman peaks were fitted with a Lorentzian lineshape. The Raman analysis was performed using a qualitative protocol developed for graphene produced by LPE in our group.^{13,26,27,33,34} In detail, the shape of the 2D peak is used for determination of the thickness distribution. The 2D peak is fitted with a single Lorentzian lineshape, and by evaluating the fit residual (R^2), the spectrum is attributed to single-layer graphene (SLG), few-layer sheets (FLG), or graphitic material (>10 layers with AB stacking) in the following way. A single symmetric 2D

peak with $R^2 > 0.987$ is attributed to the spectrum of SLG; a single asymmetric peak with $R^2 < 0.987$ is attributed to FLG; and graphitic material is identified by its characteristic peak shape, characterized by a low-wavenumber shoulder.

Nuclear magnetic resonance. All nuclear magnetic resonance spectra reported were acquired at a nominal temperature of 25 °C using a VNMR5 500 spectrometer operating at 499.826 MHz for ^1H . The standard ^1H spectrum was acquired in 1.3 h using 90° pulses, a spectral width of 10 kHz, 32 768 complex data points, and a recycle time of 3.4 s. The diffusion-ordered spectroscopy (DOSY) data were acquired in a total time of 11 h using the Oneshot pulse sequence,³⁵ with a spectral width of 19.8 kHz, a recycle delay of 5 s, and 32 768 complex data points, and processed with the manufacturer's VnmrJ software. The Oneshot pulse sequence used a total diffusion-encoding gradient pulse duration of 2 ms (*i.e.* two encoding and two decoding pulses, each of 1 ms duration), a diffusion time of 0.1 s, and 8 diffusion-encoding gradient amplitudes ranging from nominal values of 6 to 54 G cm⁻¹ in equal increments of gradient squared. The graphene dispersion used for the DOSY experiment was produced *via* the same LPE process as the rest of this study. Exfoliation of 60 mg of graphite with 12 mg of BPS in 20 mL of D₂O allowed the production of a dispersion with a final concentration of 0.8 mg mL⁻¹.

Cell culture. Human epithelial bronchial immortalized cells (BEAS-2B, CRL-9609, ATCC, LGC standards, UK) were maintained in RPMI-1640 cell culture medium (Sigma-Aldrich), supplemented with 10% foetal bovine serum (FBS) (Gibco, Thermo Fisher Scientific), 1000 units penicillin, and 1 mg mL⁻¹ streptomycin (Sigma-Aldrich) at 37 °C in a humidified 5% CO₂ incubator. Cells were subcultured when reaching 80% confluence, with 0.05% trypsin-EDTA (Sigma-Aldrich), and 10% FBS was used to stop the activity of trypsin-EDTA.

Treatment of the cells. BEAS-2B cells were seeded in P12-well plates (Corning, Costar, Sigma-Aldrich) in complete RPMI medium at 37 °C in a humidified 5% CO₂ incubator for 24 h. After 24 h, BEAS-2B cells reached a confluence of ~80% and were treated with the graphene dispersions prepared with BPS at 0.2 mg mL⁻¹, BPS at 0.6 mg mL⁻¹, BPS at 1.0 mg mL⁻¹ and MPS at 0.4 mg mL⁻¹ (25, 50, 75 and 100 µg mL⁻¹, 1 mL per well) in serum-free RPMI medium for 4 h. Following 4 h of incubation, FBS (100 µL per well) was added and the cells were further incubated for an additional 20 h. BEAS-2B cells were washed (RPMI w FBS, 1 mL per well) before analysis with a ZEISS Primovert microscope.

Results and discussion

Synthesis of pyrene derivatives

In a general synthetic approach, the stabilisers were synthesised *via* alkylation of pyrrolidine **2a–b** using the parent (1-pyrenyl)bromoalkane **1a–b** for MPS or two consecutive alkylations for BPS and LBPS.

Amination of (1-pyrenyl)bromoalkane. To a vial charged with a stirring suspension of (1-pyrenyl)bromoalkane **1a–b** (1.0 equiv.) in dry hexane (1.20 mL) at 0 °C was added a secondary amine substrate (4.0 equiv.). The reaction mixture was stirred at 50 °C for 18 h. The crude product was cooled down to room temperature and dissolved in CH₂Cl₂ (50 mL) and washed with saturated aqueous NaHCO₃. The aqueous layer was extracted with CH₂Cl₂ (2 × 50 mL) and the combined

organic fractions were dried (MgSO_4) and concentrated under vacuum to afford the corresponding amine products **3ab–bb**.

Preparation of BPS. The crude secondary amines **3ab/3bb** or *N*-methylpyrrolidine **2a** were stirred with (1-pyrenyl)bromoalkane **1a–b** in THF at 60 °C for 18 h. After this time, the reaction mixture was cooled to room temperature and the precipitate was filtered under vacuum, washed with THF and then Et_2O to afford the desired pyrene stabiliser BPS, LBPS or MPS.

Liquid-phase exfoliation

To compare the exfoliation efficiency of BPS, MPS and LBPS, the graphene dispersions were prepared with the same initial stabiliser concentration (0.4 mg mL^{-1}). Fig. 1(a) shows that a graphene concentration of 0.72 mg mL^{-1} was achieved by BPS, compared to 0.28 mg mL^{-1} obtained with MPS and 0.06 mg mL^{-1} with LBPS. The higher exfoliation efficiency of BPS compared to MPS is attributed to the presence of two pyrene binding groups. This improves the π – π interactions between the molecules and graphene, and also affects the solubility of BPS in water (details in ESI†), driving the BPS molecules to minimize their interaction with water by adsorbing on graphene. It is interesting to note that the concentration obtained with MPS is comparable to that obtained by PS1 (Fig. 1(a)), possibly because the two molecules have relatively good solubility

Fig. 1 (a) Graphene concentrations obtained for different graphene dispersions. Inset: photographs of graphene dispersions prepared with different stabilisers. (details in ESI†) and a similar structure. Remarkably, LBPS, which also has two pyrene binding groups and is also insoluble in water, showed almost negligible exfoliation efficiency (Fig. 1(a)). This could be attributed to the different ways that these molecules are expected to assemble on graphene. The long chain connecting the pyrene binding groups in LBPS gives rise to some conformational freedom for the two pyrene binding groups, which may result in disruption of the controlled adsorption of the LBPS molecules due to possible interaction between the two pyrene bases. In the case of BPS, due to the relatively short carbon linking chain between the pyrene binding group and the functional group, the BPS molecule is more rigid. This allows more controlled assembly of BPS on graphene as well as adsorption of both the pyrene binding groups, exposing the charged functional group towards the water solvent. Alternatively, the poorer exfoliation efficiency of MPS could be attributed to intramolecular π - π stacking of the molecules in solution.

The stability of the graphene dispersions was estimated by measuring the zeta potential at ambient conditions. Typically, aqueous suspensions with $|\zeta| > 30$ mV are regarded as stable suspensions.²⁸ The zeta potentials of all the dispersions prepared in this study are between 30 and 50 mV, indicating very good stability (Table 1 and Fig. S2†).

The enhanced exfoliation efficiency of BPS is attributed to the ability of these molecules to adsorb better on graphene. This is also supported by the observed trend of increasing concentration of the exfoliated graphene with increasing initial BPS concentration, reaching saturation above 0.4 mg mL^{-1} of BPS (Fig. 1(a) and S1†). UV-vis spectroscopy, in particular, shows clear BPS residual peaks (Fig. 1(b)). It is interesting to compare the spectra obtained with BPS and MPS. Note that for better comparison of the intensities of the absorbance peaks of pyrene in the region between 250 nm and 400 nm, the spectra have been normalised against graphene absorbance at 660 nm. The prominent pyrene absorption peak in the dispersions obtained by MPS can easily be removed by a washing step (see the Methods section), leaving no residual pyrene peaks in the UV-vis spectrum after washing. In the case of BPS, however, there was no noticeable change of absorbance in that region after the washing step (Fig. S3†). As BPS is insoluble, this signal can only be attributed to the BPS adsorbed on the nanosheets. Furthermore, as shown in Fig. 1(b), an increase in pyrene absorbance

Table 1 Summary of the properties of the selected graphene dispersions and related supernatants

	BPS at 0.4 mg mL^{-1}	BPS at 0.6 mg mL^{-1}	MPS at 0.4 mg mL^{-1}
Concentration of dispersion (mg mL^{-1})	0.72	0.78	0.28
Concentration of supernatant (mg mL^{-1})	0.06	0.06	—
Zeta potential of dispersion (mV)	40	38	39
Zeta potential of supernatant (mV)	47	40	—
% SLG of dispersion	~58%	~44%	16%
% SLG of supernatant	~90%	~97%	—
Av. flake size of dispersion (nm)	124	121	230
Av. flake size of supernatant (nm)	44	50	—

is observed with increasing initial PBS concentration, which should be attributed to the increased amount of BPS molecules adsorbed on the graphene surface.

In order to confirm that all BPS molecules are adsorbed on graphene, we performed 1D and DOSY ^1H NMR experiments. DOSY uses measurements of diffusion to enable the separation of the NMR signals of different components in a mixture, and can be used to probe interactions between components.^{36,37} Initially, a standard ^1H spectrum of a graphene dispersion with a BPS concentration of 0.6 mg mL^{-1} was collected, shown in Fig. 1(c). This spectrum is dominated by the 0.2% of protons present in the D_2O used and no pyrene aromatic signals are seen. The DOSY spectrum of Fig. 1(d) shows only the signals of rapidly diffusing water and trace acetone. No free BPS is detected, indicating that the pyrene present is tightly bound to the graphene nanosheets, which tumble slowly in solution, and hence shows rapid spin–spin relaxation. A wide ^1H spectrum (Fig. S4†) confirmed that most of the ^1H signal intensity comes from very broad signals.

Characterisation of the exfoliated graphene nanosheets

Three graphene dispersions (BPS at 0.4 mg mL^{-1} , BPS at 0.6 mg mL^{-1} and MPS at 0.4 mg mL^{-1}) were chosen for further characterisation of the exfoliated graphene flakes by Raman spectroscopy, AFM and TEM. Supernatants collected for the two BPS dispersions were also characterised for comparison. Note that a higher exfoliation yield is not necessarily an indication of a higher percentage of single layers, hence further characterisation is mandatory. The results are summarised in Table 1.

Raman spectroscopy is the most commonly used characterization tool for graphene.³⁸ The Raman spectrum of graphene is characterized by the G, D and 2D peaks, lying at $\sim 1580\text{ cm}^{-1}$, $\sim 1350\text{ cm}^{-1}$, and 2680 cm^{-1} , respectively. In the case of graphene produced by LPE, which typically has a size smaller than 500 nm , the D peak is activated by the edges of the nanosheets,³⁹ thus the intensity ratio between D and G peaks, $I(\text{D})/I(\text{G})$, changes with the size of the flakes.^{13,26,27,33} The 2D peak shape is typically used to identify single layer graphene.⁴⁰ However, this identification method cannot be applied with the same accuracy to graphene produced by LPE, as the shape of the 2D peak is affected by edge effects, solvent or stabiliser doping and/or re-stacking of flakes.^{21,41} Here we performed qualitative thickness analysis using a protocol developed and tested in our group, based on Lorentzian fitting of the 2D peak (details in the Methods section).^{13,26,27,33,34} Fig. 2(a) shows representative Raman spectra obtained from the BPS at 0.6 mg mL^{-1} dispersion and supernatant. The Raman analysis shows that BPS is highly efficient at exfoliating graphene: both the dispersions had a SLG percentage between 40 and 60%, compared to 16% measured for the MPS dispersion. Thus, BPS gives a high exfoliation yield, as well as a high percentage of single and few layers, compared to traditional pyrene derivatives. Moreover, Fig. 2(a) shows that the flakes in the supernatant are characterised by a higher R^2 value as well as higher $I(\text{D})/I(\text{G})$. Thus, the supernatant is expected to contain thinner flakes, mostly single-layers and of smaller size, compared to the dispersion. This is confirmed by AFM, see Fig. 2(c) and (d). These figures show the lateral size distribution for the dispersion and supernatant of the same sample (AFM images used for statistical analysis and the distribution histograms for the other samples

Fig. 2 Characterisation of graphene dispersion prepared with BPS at 0.6 mg mL^{-1} . (a) Representative Raman spectra taken from the dispersion and the supernatant of BPS at 0.6 mg mL^{-1} . The fit of the 2D peak is also shown (red line). (b) $I(\text{D})/I(\text{G})$ vs. fit residual of the 2D peak plot for both dispersions and supernatant samples. (c and d) Lateral size distribution histograms measured by AFM for dispersion and supernatant samples, respectively.

are shown in the ESI†). AFM results show that the average flake size of the two BPS dispersions are in both cases centered at $\sim 125 \text{ nm}$, slightly smaller than the average size of the flakes in the MPS dispersion, which peaks at $\sim 230 \text{ nm}$. This is in agreement with previous studies.^{4,11,21,29} The average flake size of the two supernatant dispersions obtained with BPS was about $\sim 50 \text{ nm}$, which is expected, as smaller and thinner flakes are likely to be found in the supernatant. Note that with traditional pyrene derivatives, the concentration of graphene in the supernatant is too small, typically below 0.01 mg mL^{-1} , for further use; in contrast, LPE with BPS offers a very simple way to achieve concentrated and enriched graphene dispersions, although of much reduced flake size.

Thickness distributions obtained by AFM (Fig. S5 and S6†) confirm the Raman analysis, showing that BPS dispersions contain a higher number of thinner flakes than dispersions made with MPS. However, the thickness distribution obtained by AFM should be viewed with caution as the adsorption of stabilisers and solvent molecules on the surface of graphene flakes leads to higher thicknesses than those theoretically expected.^{21,42,43} Because of this, the BPS at 0.6 mg mL^{-1} sample was further characterised by TEM. Fig. 3(a) shows the lateral size distribution histogram obtained from TEM analysis, which is in good agreement with that obtained from AFM (Fig. 2(c)).

Fig. 3(b) shows the thickness distribution histogram, collected for statistical analysis of more than 200 individual flakes: the dispersion is mostly composed of thin (<10 layers) flakes. It should be noted that the discrepancy between the SLG percentages estimated by Raman and by TEM analysis is attributable to the

Fig. 3 TEM characterisation of graphene dispersion prepared with BPS at 0.6 mg mL^{-1} : (a) lateral size and (b) thickness distribution, (c) HRTEM image of a three-layer-thick graphene flake and (d) overview TEM image of graphene flakes.

different sample preparation: the Raman sample was prepared by drop casting on silicon wafer whereas the TEM sample was prepared by dip-coating on a lacey carbon grid. However, despite the discrepancy, both techniques show that the graphene dispersion prepared with BPS is well exfoliated, mostly containing thin layers, as further confirmed in Fig. 3(c) and (d).

Biocompatibility study

Previous work from our group⁴ has shown that graphene flakes prepared by LPE with PS1 are highly biocompatible *in vitro*, with no cytotoxicity observed for concentrations up to $100 \text{ } \mu\text{g mL}^{-1}$. It is, however, unclear whether the cytotoxicity is related to the type of pyrene derivative used. Thus, here we compare the cytotoxicity of the dispersions obtained with MPS and BPS, which have the same functional group, but different numbers of pyrene binding groups. As the nanosheets of the graphene dispersions produced by BPS and MPS have comparable size, the comparison of cytotoxicity between the two samples allows to study the effect of the stabiliser, which determines the surface chemistry, on cellular interactions.

To establish the cytotoxicity profile, optical microscopy was used with BEAS-2B cell lines as *in vitro* model for four different graphene dispersions prepared in this study: three graphene dispersions prepared with BPS (BPS at 0.2 mg mL^{-1} , BPS at 0.6 mg mL^{-1} , and BPS at 1.0 mg mL^{-1} , to determine the effect of BPS concentration), and one graphene dispersion prepared with MPS (MPS at 0.4 mg mL^{-1}). Cells were exposed to increasing concentrations of graphene, from $25 \text{ } \mu\text{g mL}^{-1}$ to $100 \text{ } \mu\text{g mL}^{-1}$. As a control, untreated cells were also observed (Fig. 4, top left panel).

Fig. 4 shows the optical images of the cells exposed to graphene flakes and morphological changes/cellular detachment, as indicators of cell death. Fig. 4 clearly shows that the cytotoxicity of graphene flakes increases with increasing

Fig. 4 Optical images of BEAS-2B cells, exposed to 4 different graphene dispersions: BPS at 0.2 mg mL^{-1} , BPS at 0.6 mg mL^{-1} , BPS at 1.0 mg mL^{-1} , and MPS at 0.4 mg mL^{-1} , at 4 different concentrations: $25 \text{ } \mu\text{g mL}^{-1}$, $50 \text{ } \mu\text{g mL}^{-1}$, $75 \text{ } \mu\text{g mL}^{-1}$, and $100 \text{ } \mu\text{g mL}^{-1}$. Cells were observed for morphological changes and loss of viability indicated by detachment from the support, in comparison to untreated cells. The scale bar is $10 \text{ } \mu\text{m}$.

concentration of BPS. No noticeable changes in cell morphology were observed for BPS at 0.2 mg mL^{-1} at any of the graphene concentrations used. However, for BPS at 0.6 mg mL^{-1} , the appearance of the vesicles is visible already at a dose of $25 \text{ } \mu\text{g mL}^{-1}$, indicating cellular stress and lysosomal swelling. Dose dependent toxic effects on the cells were also observed: at $75 \text{ } \mu\text{g mL}^{-1}$ rounding of the cells is apparent, indicating apoptotic cell death as well as detachment of dead cells from the support. As expected, highly stressed cells were observed using BPS at 1.0 mg mL^{-1} even at the lowest dose of $25 \text{ } \mu\text{g mL}^{-1}$ (high numbers of vesicles appearing in the cells), while cell death and detachment from the support occurred at the dose of $50 \text{ } \mu\text{g mL}^{-1}$ using the same sample.

On the other hand, cells exposed to MPS at 0.4 mg mL^{-1} showed no evident morphological changes or detachment from the support, with few vesicles appearing inside the cells, demonstrating good biocompatibility at high dose ($100 \text{ } \mu\text{g mL}^{-1}$) after 24 h of treatment.

These results clearly demonstrate the cytotoxic effect of BPS. The simplest explanation is to attribute the higher cytotoxicity to the higher number of molecules adsorbed (Fig. 1(b)). However, it is interesting to note that BPS and MPS are characterised by the same functional group interacting with the cells, but graphene produced by MPS does not show any cytotoxicity even at high concentrations. Thus, a more complex scenario may be possible. In the case of soluble MPS, not all stabiliser is adsorbed on graphene, and the free MPS molecules in water are removed during the washing steps. In the case of the insoluble BPS, the stabiliser needs to be adsorbed on graphene. However, after a certain BPS concentration, the graphene surface could reach complete coverage. As these molecules

Fig. 5 Possible adsorption of BPS at high concentration, giving rise to higher graphene cytotoxicity, compared to MPS.

are insoluble, they will still want to interact with graphene and therefore may be accommodated on its surface by adopting a frustrated configuration, in which only one pyrene binding group is adsorbed on graphene. As the other pyrene group is now exposed to the water, this reflects an effective increase in concentration of pyrene accessible to cells in solution at high BPS concentrations (Fig. 5), giving rise to a higher cytotoxic effect compared to the case of the MPS molecules. However, this would not affect graphene concentration, as there are enough BPS molecules completely adsorbed on graphene, providing electrostatic stabilization. Alternatively, the molecules may start interacting with each other, forming large aggregates on graphene, which may affect the cytotoxicity. Further studies are required to fully understand the exact mechanism of the increased cytotoxicity observed with BPS molecules.

Conclusion

In summary, we have demonstrated the use of an insoluble stabiliser to achieve highly concentrated aqueous graphene dispersions, mostly containing single or few layer flakes. Although their use in biomedical applications is limited by their reduced biocompatibility, these graphene dispersions are still suitable for many applications, where water is the preferred solvent. Our work also shows that the LPE of graphene can be used to disperse insoluble molecules in water, as graphene and the hydrophobic side of the molecules self-assemble together to minimize interactions with water molecules, similar to micellization.

Contribution statement

CC, IL, and KK conceived and supervised the project. YY and MB performed the exfoliation experiments and related data analysis. AP and XJ-B made the pyrene derivatives and performed their characterization. YC and SV performed the biological studies and related data analysis. XL and EP performed the electron microscopy measurements and related data analysis. GM performed DOSY NMR and related data analysis. MZ performed AFM measurements and related data analysis. The manuscript was written with contributions from all authors.

Conflicts of interest

There are no conflicts of interest to declare.

Acknowledgements

This work was supported by the EPSRC in the framework of the project 2D Health (EP/P00119X/1). MB acknowledges financial support by the European Research Council (ERC) in the framework of the European Union's Horizon 2020 research and innovation program under the grant agreement No. 648471. MZ acknowledges the Hewlett-Packard Company for financial support in the framework of the Graphene NowNano Doctoral Training Center.
