# A polyoxometalate cluster-based single-atom catalyst for NH<sub>3</sub> synthesis *via* an enzymatic mechanism†

Shamraiz Hussain Talib,<sup>a</sup> Xiaohu Yu,<sup>ID</sup> \*<sup>b</sup> Zhansheng Lu,<sup>ID</sup> <sup>a</sup> Khalil Ahmad,<sup>ID</sup> <sup>c</sup> Tongtong Yang,<sup>d</sup> Hai Xiao<sup>ID</sup> <sup>d</sup> and Jun Li<sup>ID</sup> \*<sup>de</sup>

NH<sub>3</sub> synthesis by the electrochemical N<sub>2</sub> reduction reaction (eNRR) under mild conditions has attracted much attention. Here, by means of the first principles calculations, we propose a new strategy using a transition metal single-atom catalyst (SAC) anchored on a phosphomolybdic acid (PMA) cluster as a heterogeneous catalyst for the eNRR. We have systematically studied three reaction mechanisms, *i.e.*, distal, alternating, and enzymatic pathways, respectively, for the eNRR on a Mo<sub>1</sub>/PMA SAC *via* a six-proton and six-electron process, and found that the preferred mechanism is the enzymatic pathway with the smallest overpotential ( $\eta$ ) of 0.19 V. N<sub>2</sub> is first strongly adsorbed on Mo<sub>1</sub>/PMA and then dissociated by the subsequent protonation process. In addition, we found that Mo<sub>1</sub>/PMA can impede the hydrogen evolution reaction (HER) process and thus promotes the eNRR selectivity. The high catalytic activity of Mo<sub>1</sub>/PMA for the eNRR is attributed to the high spin density on Mo, enhanced N<sub>2</sub> adsorption, stabilization of the N<sub>2</sub>H\* species, and the destabilization of the NH<sub>2</sub>\* species. The present work is further extended to investigate the kinetics of the conversion of N<sub>2</sub> to ammonia on Mo<sub>1</sub>/PMA *via* an enzymatic mechanism. Our results expose that the calculated activation energy barrier for the protonation of N<sub>2</sub> to form the N<sub>2</sub>H<sub>4</sub>\* species is kinetically and thermodynamically more favorable compared with other elementary steps. These results provide valuable guidance for NH<sub>3</sub> synthesis using SACs at ambient temperature with high efficiency and low cost.

## 1. Introduction

Ammonia (NH<sub>3</sub>) is essential to increase food resources for the increasing worldwide population,<sup>1,2</sup> and it is also considered a chief hydrogen energy transporter<sup>3,4</sup> due to its high hydrogen density, easy catalytic decomposition and the existence of well-developed technologies for production and distribution. Compared to other energy storage materials, NH<sub>3</sub> has the benefit of no CO<sub>2</sub> emission at the point of use.<sup>5,6</sup> It is well known that NH<sub>3</sub> is widely synthesized from atmospheric dinitrogen *via* the Haber–Bosch process (1), which is one of the most

important developments in the nineteenth century.<sup>7,8</sup> Currently, approximately 500 million tons of NH<sub>3</sub> are synthesized per year. In this process, the reactants are H<sub>2</sub> and N<sub>2</sub> gases:<sup>9</sup> H<sub>2</sub> comes from the steam reforming of natural gas (2) at high temperatures or the water gas shift process (3). N<sub>2</sub> comes from the atmosphere, and requires cryogenic separation from O<sub>2</sub> and thus a large amount of energy.<sup>10,11</sup>

The electrochemical nitrogen reduction reaction (eNRR), which resembles N<sub>2</sub> reduction with nitrogenases in bacteria, is fairly encouraging for nitrogen fixation on the grounds that the production of NH<sub>3</sub> can occur at ambient pressure and temperature.<sup>12,13</sup> Particularly, there is no hydrogen feed gas that requires separation from the NH<sub>3</sub> product, and the eNRR process can be effectively tuned by the working potential, pH, electrolyte, *etc.*, for optimizing the production yield of NH<sub>3</sub>.<sup>14,15</sup>

† Electronic supplementary information (ESI) available. See DOI: 10.1039/d1ta07903d

In recent years, Shi *et al.* reported that Au nanoparticles anchored on the CeO<sub>x</sub>-RGO hybrid support (Au/CeO<sub>x</sub>-RGO) exhibit excellent catalytic performances for the eNRR under the ambient environment.<sup>16</sup> Liu *et al.*<sup>17</sup> studied experimentally and theoretically the eNRR under ambient conditions using N-doped porous carbon (NPC) as the catalyst. They found that pyridinic and pyrrolic N are active sites, indicating that their contents are critical for stimulating ammonia production on NPC. Chen *et al.* studied iron supported on carbon nanotubes (CNTs) as the electrocatalyst for NH<sub>3</sub> synthesis and found that the active sites may be related to specific carbon sites formed at the interface between the iron particles and CNTs.<sup>18</sup>

Transition metal (Mo-, Fe-, Ru-, and Co-) based materials are commonly used catalysts for the thermocatalytic activation of inert N<sub>2</sub>.<sup>19-28</sup> Nishibayashi's group proposed that transition metal (Fe, Co, and Mo) dinitrogen complexes with an anionic PNP-pincer (PNP = 2,5-bis(ditertbutylphosphinomethyl)pyrrolidine) ligand can catalyze N<sub>2</sub> fixation under mild reaction conditions.<sup>29</sup> Jacobsen *et al.* for the first time prepared an effective and active cobalt-molybdenum nitride (Co<sub>3</sub>Mo<sub>3</sub>N) catalyst for the synthesis of ammonia.<sup>30,31</sup> Manjunatha and Schechter reported that the RuPt/C catalyst shows better specificity and stability regarding the eNRR for the formation of NH<sub>3</sub> at ambient pressure and temperature.<sup>32</sup>

For the development of efficient catalysts, both experimental and theoretical investigations play an important role. The notable current development<sup>33,34</sup> of single-atom catalysts (SACs) and single-cluster catalysts (SCCs) has attracted significant interest in heterogeneous catalysis due to their high activity and selectivity. Therefore, significant efforts on SACs have been made for developing appropriate supports that can effectively anchor single metal atoms,<sup>35</sup> without decreasing the performance of the appropriate support.<sup>36,37</sup> Recently, SACs have become a hot topic due to their unique performances, large precise surface area, numerous active centers, and maximum atom utilization.<sup>38-40</sup> The catalytic performance of various single transition metal atoms anchored on different supports has been extensively explored both experimentally and theoretically.<sup>41-44</sup> Qiao and co-workers, for the first time, reported that the single Pt atom supported on iron oxide exhibits excellent catalytic activity and stability for both CO oxidation and superior oxidation of CO in H<sub>2</sub>.<sup>45</sup> Recently, Talib *et al.* reported that a single Cr atom embedded over a graphyne Cr<sub>1</sub>/GY surface is an efficient catalyst for the NO oxidation and reduction reaction under normal reaction conditions.<sup>46</sup> Prior investigation proved that SACs exhibit massive potential in many catalytic reactions, such as CO oxidation, CO<sub>2</sub> reduction reaction (CO<sub>2</sub>RR), oxygen evolution/reduction (OER/ORR), NO oxidation, and reduction reaction. For this reason, SACs arouse significant curiosity in N<sub>2</sub> fixation and catalytic conversion of N<sub>2</sub> into NH<sub>3</sub>.

Particularly, the notable advance in large-scale density functional theory calculations not only facilitates the exploration of efficient catalysts for N<sub>2</sub> reduction but also brings further improvements in eNRR mechanisms.<sup>47-49</sup> Zhao *et al.* reported that a single Mo atom anchored on a defective boron nitride monolayer is an efficient catalyst for N<sub>2</sub> fixation, *via* an enzymatic pathway with a small overpotential value of 0.19 V.<sup>50</sup> Luo

*et al.* proposed an electrocatalyst of FeN<sub>3</sub>-embedded graphene for N<sub>2</sub> fixation, and found that the highly spin-polarized FeN<sub>3</sub> active center is accessible to catalyze N<sub>2</sub> into NH<sub>3</sub>.<sup>51</sup> By first-principles calculations and microkinetic investigation, Li and co-workers found that the Fe<sub>3</sub> cluster on the  $\theta$ -Al<sub>2</sub>O<sub>3</sub>(010) surface can be heterogeneous catalysts for ammonia synthesis.<sup>52</sup> In addition, they reported biomimetic N<sub>2</sub>-to-NH<sub>3</sub> thermal conversion on singly dispersed bimetallic catalyst Rh<sub>1</sub>Co<sub>3</sub>/CoO (011).<sup>53</sup>

However, there is no such report of SACs supported on clusters as catalysts for the eNRR. Herein, we carried out systematic theoretical studies of the electrocatalytic eNRR on Mo<sub>1</sub>/PMA under ambient conditions, *via* three possible pathways: alternating, distal and enzymatic mechanisms, respectively. The PMA cluster was reported to be an attractive support to stabilize transition metal atoms.<sup>54-60</sup> Our results reveal that the enzymatic mechanism has the lowest overpotential ( $\eta$ ) of 0.19 V, and thus demonstrate that Mo<sub>1</sub>/PMA is a promising SAC for the eNRR.

## 2. Computational details

Geometry optimizations and energy calculations were performed by employing spin-polarized density functional theory (DFT) methods as implemented in the Vienna *ab initio* simulation package (VASP).<sup>61,62</sup> To improve the calculation efficiency, projector augmented wave (PAW) pseudo-potentials were employed to define the interactions between the valence and core electrons.<sup>63-65</sup> In this work, the generalized gradient approximation (GGA) using the Perdew, Burke and Ernzerhof (PBE) exchange-correlation functional was employed.<sup>66,67</sup> The valence electrons were described by nd<sup>x</sup> ns<sup>x</sup> for 3d, 4d, and 5d transition metal atoms (see ESI<sup>†</sup>), 4d<sup>5</sup>5s<sup>1</sup> for Mo, 2s<sup>2</sup>2p<sup>4</sup> for O, 3s<sup>2</sup>3p<sup>3</sup> for P, 2s<sup>2</sup>2p<sup>3</sup> for N, and 1s<sup>1</sup> for H. The Kohn-Sham orbitals were expanded using plane-wave basis sets with an energy cutoff of 400 eV. The geometry optimizations were done with a convergence criterion of 10<sup>-5</sup> eV for the total energy and the maximum force less than 0.02 eVÅ<sup>-1</sup>. The Brillouin zone integration was performed with a 1 × 1 × 1 *k*-point grid to gain the required accuracy.<sup>68</sup> The Bader charge analysis was performed to characterize the electron charge transfer.<sup>69-71</sup> The PMA cluster was generated in a cubic unit cell (with 12 Mo atoms, one P atom and 40 O atoms), verified to be sufficient for inspecting the reaction mechanisms.<sup>57-60</sup> A vacuum space of 20 Å was used to avoid the interaction among the complex bodies and their images.

In the eNRR process, six proton-coupled electron transfer (PCET) steps are involved, as shown by the following equation:

Each PCET step involves the transfer of one proton combined with an electron from a solution to an adsorbed species on the surface of catalysts. This is modeled by the computational hydrogen electrode (CHE) method proposed by Norskov *et al.*<sup>72-74</sup> The Gibbs free energy change ( $\Delta G$ ) of every elementary step is calculated as follows:

$$\Delta G = \Delta E + \Delta ZPE - T\Delta S + \Delta G_U + \Delta G_{pH} \quad (5)$$

where  $\Delta E$  corresponds to the electronic energy difference directly obtained from DFT calculations,  $\Delta ZPE$  is the adjustment from the zero-point energies,  $T$  is the temperature ( $T = 298.15$  K),  $\Delta S$  is the entropy change,  $\Delta G_U$  corresponds to the free energy contribution associated with the electrode potential ( $U$ ), and  $\Delta G_{pH}$  is the free energy contribution of  $H^+$  ions, respectively. The  $\Delta G_{pH}$  value can be determined as follows:<sup>72–74</sup>

$$\Delta G_{pH} = \ln(10) \times k_B T \times \text{pH} \quad (\text{or } 0.059 \text{ eV} \times \text{pH}) \quad (6)$$

where  $k_B$  is the Boltzmann constant, and the pH value was assumed to be zero because the overpotential is pH-independent here. The entropies and zero-point energies of the eNRR species were computed from the vibrational frequencies, in which just the adsorbate vibrational modes were explicitly considered while the catalyst cluster was fixed. The values for vibrational frequencies and entropies of molecules in the gas phase were taken from the NIST database.<sup>75</sup> In this work, the dimer method<sup>76,77</sup> has been applied to search for the transition states (TSS) *via* the minimum energy path. All the TSS were further confirmed by vibrational frequency analysis. In this study, only one imaginary frequency was found in each TS configuration.

### 3. Results and discussion

In this work, the PMA cluster was selected as the support to study single transition metal atom (TM = Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Zr, Nb, Mo, Tc, Ru, Rh, Pd, Ag, W, Re, Os, Ir, Pt, and Au) catalysts for the eNRR, since PMA has appeared to be an attractive support to anchor transition metal atoms.<sup>78</sup> It is notable that the Keggin-type PMA cluster is built by 12  $\text{MoO}_6$  octahedra that connect their corners or edges to a central  $\text{PO}_4$  tetrahedron, and its fully optimized structure is shown in Fig. S1.† There are various possible coordination positions on the external oxygen atoms of the PMA cluster (see Fig. S1†), including two 3-fold

hollow sites ( $3\text{H-O}_c$  and  $3\text{H-O}_{\text{bri}}$ ), one 4-fold hollow site ( $4\text{H}$ ) and one bridge site ( $\text{b-O}_c\text{-O}_{\text{bri}}$ ), respectively. It is found that transition metal atoms prefer to locate at the  $4\text{H}$  site on the PMA cluster surface in a distorted square-planar geometry, which accords exactly with former work.<sup>54–56</sup> Table S1† presents the key geometry parameters of transition metal atoms anchored on PMA. In PMA, the bond lengths of  $\text{P-O}$ ,  $\text{Mo-O}_c$ , and  $\text{Mo-O}_{\text{bri}}$  are 1.55 Å, 1.70 Å, and 1.93 Å, respectively. These results are in good agreement with previously reported experimental and theoretical studies.<sup>54–56</sup> To find out an ideal catalyst for the eNRR, a series of transition metals (TM = Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Zr, Nb, Mo, Tc, Ru, Rh, Pd, Ag, W, Re, Os, Ir, Pt, and Au) atoms from the periodic table were tested. As shown in Fig. S2,† all the TM atoms considered in this work are expected to anchor at the  $4\text{H}$  site on the PMA cluster surface, which is consistent with previous theoretical calculations.<sup>54–56</sup> The calculated binding energies for TM atoms embedded on the PMA surface vary from  $-4$  to  $-17$  eV (Fig. 1a and Table S2†), indicating that these single metal atoms are strongly bound to the PMA support and our designed SACs exhibit high stability. The large binding energy indicates that TM adatoms can be robustly bound on the PMA cluster and are highly stable. To gain deeper insight into the strong binding interaction of the computed  $\text{M}_1/\text{PMA}$  catalysts, we have performed the Bader charge analysis after doping TM adatoms. According to the Bader charge analysis, the result (Fig. 1b and Table S2†) shows that the electron transfer from the TM adatoms to the PMA support usually decreases with the increase of atomicity in the same period. For transition metals binding on PMA, a correlation has been found between binding energies and transferred charge, that is, the more transferred charge from transition metal atoms, the stronger the transition metal atom binding energy. Among all researched TM atoms, only Zn does not follow the rule.

From previous computational studies,<sup>50</sup> the high catalytic activity of transition metal atoms on the PMA cluster for the eNRR can be anticipated by the following criteria: enhanced  $\text{N}_2$  adsorption, stabilization of the  $\text{N}_2\text{H}^*$  species, and destabilization of the  $\text{NH}_2^*$  species.

Fig. 1 (a) The calculated binding energies of transition metal (TM = Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Zr, Nb, Mo, Tc, Ru, Rh, Pd, Ag, W, Re, Os, Ir, Pt, and Au) adatoms anchoring on the PMA cluster, and (b) the relationship between the calculated binding energies and Bader charge of TM adatoms anchored on the PMA cluster. All energies are specified in eV.

According to the above criteria, to search for an optimal catalytic system for the eNRR, a series of transition metals (TM = Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Zr, Nb, Mo, Tc, Ru, Rh, Pd, Ag, W, Re, Os, Ir, Pt, and Au) supported on  $M_1$ /PMA are tested. At first, we calculated the  $\Delta G$  value of  $N_2$  adsorption on the  $M_1$ /PMA cluster (Fig. 2), in which only a small coverage of  $N_2$  molecules is considered. Presented in Fig. S3 and S4† are the computed geometries of the resultant  $N_2$  adsorption for both end-on and side-on configurations. After geometrical optimization, most of the side-on configurations (Sc, Ti, Mn, Fe, Co, Ni, Cu, Zn, Zr, Pd, and Ag) are changed to the end-on configurations. Our results showed that mostly these  $M_1$  are decent  $N_2$  adsorbers as indicated by the negative  $\Delta G$  value, except Cr, Rh, and Ir which have positive  $\Delta G$  values. Meanwhile, the positive  $\Delta G$  value of the  $N_2$  adsorber means weak chemical adsorption, and the nominated atoms, Cr, Rh, and Ir, were not considered as SACs for the eNRR. Secondly, we further calculated the  $\Delta G$  value for  $N_2H^*$  adsorbed over the  $M_1$ /PMA cluster with the end-on configuration. As shown in Fig. 2, TM (Sc, Ti, Cr, Mn, Fe, Ni, Cu, Zn, Zr, Pd, Ag, Ir, Pt, and Au) candidates are ruled out as eNRR catalysts because large energy ( $\Delta G > 1.0$  eV) is required for the formation of the  $N_2H^*$  species. Compared with the other candidates, these catalysts are not suitable for the eNRR owing to the second criteria. Finally, nine  $M_1$  (V, Co, Nb, Mo, Tc, Ru, W, Re, and Os) systems were studied to make comparisons of the final elimination of the  $NH_3$  species. Our results showed that  $Co_1$ /PMA and  $W_1$ /PMA clusters are not eligible for the eNRR because large energy ( $\Delta G > 1.0$  eV) is required to destabilize the  $NH_2^*$  species (see Fig. 2). Thus, V, Nb, Mo, Tc, Ru, Re, and Os anchored on the PMA cluster serve as electrocatalysts eligible for the eNRR. These  $M_1$ /PMA SACs show considerable adsorption strengths with  $N_2$ ,  $N_2H^*$  and  $NH_2^*$  species, which is necessary for the initiation of the eNRR. Consequently, to check their catalytic performance for the eNRR, we have studied in

detail the reaction mechanism of the eNRR on these  $M_1$ /PMA SACs under ambient reaction conditions.

### 3.1 Hydrogen evolution reaction (HER)

The hydrogen evolution reaction (HER) is a chief side reaction for the eNRR and can compete with the eNRR for the consumption of electrons and protons, subsequently reducing the energy efficiency and Faraday efficiency.<sup>79</sup> Previously, the activity of  $M_1$ /PMA ( $M_1 =$  Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Zr, Nb, Mo, Tc, Ru, Rh, Pd, Ag, W, Re, Os, Ir, Pt, and Au) was assessed; it would be good to analyze the overpotential of the HER on the  $M_1$ /PMA cluster. The HER occurs through the Tafel step [ $2H_{ads} \rightarrow H_2$ ] or Heyrovsky step [ $H_{ads} + (H^+ + e^-) \rightarrow H_2$ ], with  $H_{ads}$  denoting prevailing hydrogen bonded with  $M_1$ . To accomplish the best HER activity, the  $\Delta G_{H^*}$  value should be close to an ideal value ( $\Delta G_{H^*} = 0$ ). A more positive or more negative value means strong or weak adsorption of hydrogen on the catalysts. In both cases, the inverse effect impedes the chemical reaction. In addition, it is helpful to examine whether  $M_1$ /PMA is an important electrocatalyst for  $N_2$  adsorption. The HER activity of the PMA cluster was first explored for comparison. The value of  $\Delta G_{H^*}$  for the O site of the PMA cluster is  $-2.32$  eV, which implies that the  $H^*$  atom binds with O (4H-site) too strongly. Therefore, the O site of the PMA cluster is not suitable for the HER. The  $\Delta G$  values were calculated for adsorbed  $H^*$  on the  $M_1$ /PMA system to evaluate its HER activity. Fig. 3a shows a volcano curve for the relationship between  $\Delta G_{H^*}$  and the exchange current ( $i_0$ ) density. Typically, the principles for deciding whether a catalyst is suitable for HER performance follow the standard rule of  $|\Delta G_{H^*}| \leq 0.20$  eV.<sup>80,81</sup> In this work, it is found that Pt, V, Ru, Tc, and Ti catalysts reside on the top of the volcano curve with the highest catalytic activity and near to zero hydrogen adsorption energy. The other catalysts such as Nb, W, Re, Cu, Ir, Os, and Mo with negative  $\Delta G_{H^*}$  values are situated around the left side of the volcano curve. The interactions of  $H^*$  with these catalysts are too strong owing to very large negative  $\Delta G_{H^*}$  values, which are situated at the bottom of the left side of the volcano curve with a very low  $i_0$  value. The  $M_1$ /PMA ( $M_1 =$  Sc, Zn, Ag, Fe, Au, Mn, Co, Ni, Pd, Cr, Zr, and Rh) catalysts have positive  $\Delta G_{H^*}$  values, signifying that it is difficult for the proton to adsorb on these systems, and are located at the bottom of the right side with also a very low  $i_0$  rate. Pt, Ru, V, Tc, and Ti atoms with  $\Delta G_{H^*}$  values near zero achieve the maximum  $i_0$  rate, as they are located at the top of the volcano curve. As shown in Fig. 3b–d, for Sc, Zn, Ag, Fe, Mn, Au, Ni, Co, Zr, Cr, Pd, and Rh, the  $\Delta G_{H^*}$  values are positive and above 0.2 eV at the 4H site, far away from the optimal value, signifying that these systems are not appropriate for the HER, while the values of  $\Delta G_{H^*}$  for Nb, Cu, Ir, Os, Re, Mo, and W are all negative, indicating that the interaction of  $H^*$  with  $M_1$ /PMA is very strong, with a negative  $\Delta G_{H^*}$  value. Consequently, the release of hydrogen inhibits the HER activity on these catalysts. On the other hand, the  $\Delta G_{H^*}$  value for Pt, Ru, V, Ti, and V is less than 0.2 eV, which implies that the interaction of  $H^*$  with these systems is weak, indicating that these catalysts could be active for the HER. To assess the selectivity of the  $M_1$ /PMA catalysts, we firstly compared the  $\Delta G$  values of  $H^*$  and  $*N_2$  species on the  $M_1$ /PMA cluster. The trends for the

Fig. 2 Calculated Gibbs free energies of  $N_2$ ,  $N_2H^*$ , and  $NH_2^*$  species on various  $M_1$  (Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Zr, Nb, Mo, Tc, Ru, Rh, Pd, Ag, W, Re, Os, Ir, Pt, and Au) atoms supported on the PMA cluster.

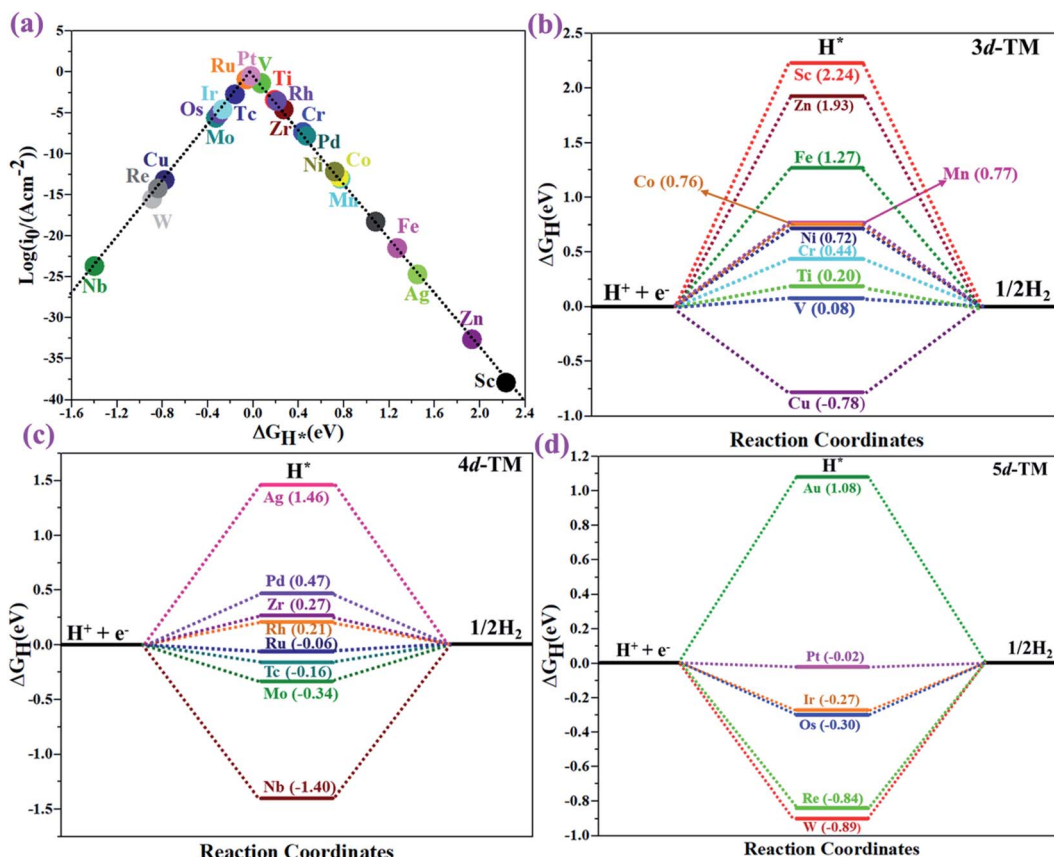

Fig. 3 (a) The volcano curve of the exchange current related to the free energy ( $\Delta G_{H^*}$ ) for hydrogen binding on a 4H site over the  $M_1/PMA$  cluster. (b–d) Calculated free energy ( $\Delta G_{H^*}$ ) diagram for the HER at the equilibrium potential ( $U = 0.0$  V) for the  $M_1/PMA$  cluster.

$\Delta G$  values of dinitrogen and hydrogen species adsorbed over the  $M_1/PMA$  cluster are presented in Fig. 4. The  $\text{N}_2$  molecule prefers to adsorb mainly with the end-on configuration rather than the side-on configuration on all the  $M_1/PMA$  systems studied. Fig. 4

demonstrates that Ru, Mo, Tc, and Re catalysts lie between the HER and eNRR dominant regions. The calculated Gibbs free energies of  $^*\text{N}_2$  on  $\text{Mo}_1$  (−0.59 eV),  $\text{Tc}_1$  (−0.51 eV),  $\text{Ru}_1$  (−0.54 eV) and  $\text{Re}_1$  (−0.89 eV), respectively. These energies are much higher than the  $\Delta G$  values of  $\text{H}^*$  on  $\text{Mo}_1$  (−0.34 eV),  $\text{Tc}_1$  (−0.16 eV),  $\text{Ru}_1$  (−0.06 eV), and  $\text{Re}_1$  (−0.84 eV), respectively. For  $M = \text{Mo}, \text{Tc}$ , and  $\text{Ru}$ , the difference for the  $\Delta G$  of  $^*\text{N}_2$  and  $^*\text{H}$  ranges from 0.25 eV to 0.50 eV. For  $\text{Re}_1/PMA$ , the  $\Delta G$  values of  $^*\text{N}_2$  and  $^*\text{H}$  are almost close. As presented in Fig S5,<sup>†</sup>  $\text{N}_2$  favorably adsorbs on the catalytic surface of  $\text{Mo}_1/PMA$ ,  $\text{Ru}_1/PMA$ , and  $\text{Tc}_1/PMA$  systems compared to  $\text{H}^*$ , signifying that the selectivity of the eNRR is higher than that of the HER. Even at the limiting potential of the NRR on  $\text{Mo}$  (−0.35 V), the adsorption energy of  $^*\text{H}$  (−0.69 eV) is only a little stronger than that of  $^*\text{N}_2$  on  $\text{Mo}$  (−0.59 eV), indicating that adsorption of  $^*\text{H}$  and  $^*\text{N}_2$  is competitive adsorption. In addition, there are many strategies of suppressing the HER to boost the NRR selectivity: (a) limiting the proton and electron supply;<sup>82</sup> (b) intentional design of the catalyst by incorporated  $\text{Li}^+$ .<sup>83</sup> Notably, all these catalysts possess negative  $\Delta G$  values of  $^*\text{N}_2$ , indicating that they play a key role in activating the  $\text{N}_2$  molecule. It is rational to suggest that these  $M_1/PMA$  catalysts can sustain high eNRR selectivity under experimental working environments. For Os, V, and Nb systems, the HER is dominant after applying voltage, indicating that the adsorption and activation of  $\text{N}_2$  in these systems are weak. Therefore, these catalysts

Fig. 4 Calculated Gibbs free energies of  $\text{N}_2$  and  $\text{H}_2$  adsorbed on the  $M_1/PMA$  cluster, which are divided into the eNRR region ( $\Delta G_{\text{H}^*} > \Delta G_{^*\text{N}_2}$ ) and HER region ( $\Delta G_{\text{H}^*} < \Delta G_{^*\text{N}_2}$ ).

are excluded as efficient eNRR catalyst candidates. In the following sections, we only select the Mo<sub>1</sub>/PMA SAC to explore the great advantage and electrocatalytic activity of the eNRR due to the following reasons: (1) Tc<sub>1</sub> is a radioactive element, and Ru<sub>1</sub> and Os<sub>1</sub> are noble metals; (2) Mo<sub>1</sub> is a non-noble metal and also a constituent of the FeMo cofactor<sup>84,85</sup> which plays a significant role in the biological enzymatic N<sub>2</sub> fixation; (3) compared with the calculated overpotential results, (see Fig. S6–S10†) Mo<sub>1</sub>/PMA has a lower overpotential than V<sub>1</sub>/PMA and Re<sub>1</sub>/PMA *via* distal, alternating and enzymatic pathways. Based on the above conversation, we establish that the adsorption of N<sub>2</sub> is favorable on the Mo<sub>1</sub>/PMA catalyst.

### 3.2 Geometric and electronic structure of Mo<sub>1</sub>/PMA

The optimized structure of the most stable Mo<sub>1</sub>/PMA cluster is shown in Fig. 5a. It is found that the Mo<sub>1</sub> atom prefers to locate on the 4-hollow (4H) site of PMA, with a binding energy of

−11.47 eV and bond lengths of Mo<sub>1</sub>–O of 1.95 and 1.92 Å, respectively. The most stable adsorption of the Mo atom on the 4H site shows that the Mo atom lies close to the PMA cluster and forms a strong bond with the neighboring oxygen atoms. The large binding energy implies that a strong chemisorption character has been built between the Mo atom and the PMA cluster. According to the Bader charge analysis, the Mo<sub>1</sub> atom anchored on the PMA cluster is positively charged, with an atomic charge of +2.49|e| (see Table S2†). Remarkably, there is significant charge transfer from the Mo<sub>1</sub> atom to the PMA cluster, which is consistent with the fact that the Mo<sub>1</sub>/PMA cluster possesses higher binding energy and strong stabilization of the Mo<sub>1</sub> single atom. Fig. 5b shows the charge density difference of the Mo<sub>1</sub>/PMA cluster. It is observed that there is a loss of electron density on the Mo<sub>1</sub> atom, which shows that the electron density flows from the Mo<sub>1</sub> atom towards the nearest oxygen atoms. The charge transfer from the Mo<sub>1</sub> center atom to

Fig. 5 Optimized structures of (a) Mo<sub>1</sub>/PMA, (d) N<sub>2</sub> end-on, and (g) side-on adsorption on Mo<sub>1</sub>/PMA. Charge density differences of (b) Mo<sub>1</sub>/PMA, (e) N<sub>2</sub> end-on, and (h) side-on adsorption on Mo<sub>1</sub>/PMA. The charge accumulation (depletion) regions are represented in green (purple) for the contour plots. The contour value of the charge difference density is ±0.05 a.u. (c), (f), and (i) the spin-polarized PDOS projected on the Mo<sub>1</sub>-4d and 5s (magenta and red) and O-2p (nearest oxygen atoms) and N-2p (ads) (blue) states. The Fermi level is set to zero.

the PMA cluster accounts for the strong interaction between the Mo<sub>1</sub> atom and PMA. Remarkably, the magnetic moment of the Mo<sub>1</sub> atom is 1.54 μ<sub>B</sub> and the oxygen atom is −0.02 μ<sub>B</sub>, which suggests that the spin density is mainly located on the Mo<sub>1</sub> atom, with minor spin density on the neighboring O atoms. Such a large spin density on the Mo<sub>1</sub> site may act as a key factor in activating the N<sub>2</sub> molecule. To gain a deeper understanding of why the Mo<sub>1</sub> atom binds so strongly on the PMA cluster, the spin-polarized PDOS was calculated as shown in Fig. 5c. The 4d orbital of the Mo<sub>1</sub> atom is found to be strongly mixed with the 2p orbital of the PMA oxygen atoms, explaining the strong covalent metal–support interaction (CMSI) between the Mo<sub>1</sub> and oxygen atoms at the 4H site of PMA. The spin-up and spin-down PDOS of the Mo<sub>1</sub>-4d orbital is asymmetric around the Fermi level. The presence of this partially occupied Mo<sub>1</sub>-4d orbital near the Fermi level indicates high reactivity, suggesting that it may play an important role in adsorbing and activating the adsorbates during the catalytic reaction.

### 3.3 Adsorption of N<sub>2</sub> on Mo<sub>1</sub>/PMA

After studying the geometric structure, electronic structure, and stability of the Mo<sub>1</sub>/PMA cluster, we then move to examine its catalytic activity for the eNRR. N<sub>2</sub> adsorption on Mo<sub>1</sub>/PMA is the first step to initialize the eNRR, and it plays a vital role in the consequent reaction pathway. Thus, we studied N<sub>2</sub> adsorption on the Mo<sub>1</sub>/PMA cluster with end-on and side-on configurations, respectively.

For simplicity, the Mo<sub>1</sub>/PMA cluster was used as a support to study N<sub>2</sub> adsorption behavior. Fig. 5d and g show the end-on and side-on configurations of N<sub>2</sub> on Mo<sub>1</sub>/PMA with the ΔG values of −0.64 and −0.59 eV, respectively. Thus, the end-on N<sub>2</sub> adsorption is more favorable energetically than the side-on N<sub>2</sub> adsorption. Additionally, the newly formed Mo<sub>1</sub>–N bond length of the end-on configuration is 2.08 Å, and bond lengths of the side-on configuration are 2.06 and 2.06 Å, respectively. The bond length of adsorbed N<sub>2</sub> is elongated from 1.11 Å (free N<sub>2</sub> molecule) to 1.13 and 1.21 Å, respectively, indicating that the N<sub>2</sub> molecule is activated. We also investigate the adsorption of H<sub>2</sub>O on Mo<sub>1</sub>/PMA to compare with the adsorption of N<sub>2</sub>. The calculated ΔG value of H<sub>2</sub>O is −0.31 eV, which implies that the adsorption of H<sub>2</sub>O is much weaker than the adsorption of N<sub>2</sub>. This indicates that the H<sub>2</sub>O molecule can't block the active site during the eNRR. According to the Bader charge analysis, 0.25 |e| end-on and 0.66 |e| side-on transfer from Mo<sub>1</sub>/PMA to the N<sub>2</sub> molecule, which indicates that the activation of the N<sub>2</sub> bond agrees well with the transferred charge. To further confirm such behavior, we also calculated the charge density difference of N<sub>2</sub> on Mo<sub>1</sub>/PMA, as shown in Fig. 5 (e and h), respectively. The lone pair electron transferred from N<sub>2</sub> to the empty Mo<sub>1</sub>-4d orbital, and also there is back donation of electrons from the Mo<sub>1</sub>-4d orbital to the π\*orbital of N<sub>2</sub>. Remarkably, the magnetic moments of Mo<sub>1</sub> after N<sub>2</sub> adsorption are 0.58 end-on and 0.61 μ<sub>B</sub> side-on, respectively, and a little magnetic moment was found on the adsorbed N<sub>2</sub> molecule: −0.15 end-on and 0.02 μ<sub>B</sub> side-on, respectively. Hence, the large spin polarization on the Mo<sub>1</sub>/PMA cluster is responsible for the activation of N<sub>2</sub>. To gain

more insight into the interaction between Mo<sub>1</sub>/PMA and the N<sub>2</sub> molecule, the spin-polarized PDOS was examined, as shown in Fig. 5 (f and i), respectively. The transferred electrons mainly occupied the π\* anti-bonding orbitals of N<sub>2</sub>. Then, the partial occupation of the anti-bonding orbitals of N<sub>2</sub> causes the weakening of the N–N triple bond. Also, by comparing the Mo<sub>1</sub>-4d orbitals in Mo<sub>1</sub>/PMA, it can be seen that the spin crossover and the magnetic moment significantly decrease near the Fermi level after N<sub>2</sub> adsorption on Mo<sub>1</sub>/PMA. Therefore, the consequent process to convert the activated N<sub>2</sub> to NH<sub>3</sub> by protonation is highly probable.

### 3.4 eNRR on Mo<sub>1</sub>/PMA

In general, we have considered that the eNRR mainly proceeds *via* three well-known possible pathways, namely distal, alternating, and enzymatic mechanisms, respectively. The six sequential protonation and reduction processes are involved in all three mechanisms, as shown in Fig. 6. In the following, we investigate all three mechanisms.

**3.4.1 Distal pathway.** Fig. 7a and b illustrate the free energy profile and the corresponding optimized geometries of the elementary steps involved in the distal pathway, respectively. The pre-adsorbed end-on configuration of N<sub>2</sub> on the Mo<sub>1</sub>/PMA cluster will be hydrogenated by adsorbing a proton coupled with transfer of an electron to form the N<sub>2</sub>H\* species, with the proton attached to the distal nitrogen site. The bond length of N–H is 1.04 Å, and the bond length of N–N is 1.23 Å, which is further elongated compared to the pre-adsorbed N<sub>2</sub> on the Mo<sub>1</sub>/PMA cluster (1.13 Å). The first step is slightly uphill in the free energy profile by 0.45 eV. In the second step, the proton coupled with an electron sequentially attacks the distal N<sub>2</sub>H\* species. As a result, the N<sub>2</sub>H<sub>2</sub>\* species is formed, and the Gibbs free energy profile is downhill by 0.80 eV. The bond length of N–H is 1.02 Å, and the bond length of the N–N is further elongated to 1.30 Å. In the third step, the first NH<sub>3</sub> is released by the consecutive attacks of the proton-coupled with an electron in the pre-hydrogenated N site of the N<sub>2</sub>H<sub>2</sub>\* species. While another N adatom remains on the Mo<sub>1</sub> atom

Fig. 6 Schematic description of the three typical pathways for N<sub>2</sub> reduction to NH<sub>3</sub> on the Mo<sub>1</sub>/PMA cluster.

Fig. 7 (a) Free energy profile for the eNRR at zero and applied potentials (limiting potential) and (b) optimized geometric structures of various elementary steps of the eNRR pathway through a distal mechanism on the  $\text{Mo}_1/\text{PMA}$  cluster. All bond lengths are given in Å.

with the  $\text{Mo}_1\text{-N}$  bond length of 1.67 Å, the Gibbs free energy profile is uphill 0.43 eV by the reduction of the  $\text{N}_2\text{H}_2^*$  species to  $\text{NH}_3 + \text{N}^*$  species. In the fourth step, the N adatom remaining on the  $\text{Mo}_1/\text{PMA}$  cluster reacts with another proton-coupled with an electron to form the  $\text{NH}^*$  species, and the Gibbs free energy profile decreases by 1.79 eV. The bond length of N-H is 1.02 Å, and the bond length of  $\text{Mo}_1\text{-N}$  is 1.73 Å, respectively. In the fifth step, the proton-coupled with an electron consecutively attacks the distal  $\text{NH}^*$  species to form the  $\text{NH}_2^*$  species, and the energy profile further decreases by 0.51 eV. The bond length of N-H is 1.02 Å, and the bond length of  $\text{Mo}_1\text{-N}$  is elongated up to 1.91 Å, respectively. In the last step, the sixth proton-coupled with an electron attacks the distal  $\text{NH}_2^*$  species to remove the second  $\text{NH}_3$  molecule from the  $\text{Mo}_1/\text{PMA}$  cluster, and the Gibbs free energy value is 0.48 eV. Remarkably, the protonation of  $^*\text{NH}_2$  to form the  $^*\text{NH}_3$  species in this distal pathway is potentially a limiting step due to the large  $\Delta G$  values (0.48 eV) among all elementary steps.

**3.4.2 Alternating pathway.** Fig. 8a shows the Gibbs free energy profile for the alternating mechanism, and the optimized geometries of the corresponding elementary steps involved in the alternating pathway are shown in Fig. 8b. In the alternating mechanism, the pre-adsorbed end-on configuration of  $\text{N}_2$  on the  $\text{Mo}_1/\text{PMA}$  cluster will be hydrogenated by adsorbing a proton coupled with transfer of an electron to form an  $\text{N}_2\text{H}^*$  species, with the proton attached to one nitrogen atom. The bond length of N-H is 1.04 Å, and the bond length of N-N is 1.23 Å, respectively. The first step is slightly uphill in the free energy profile by 0.45 eV. In the second step, the proton coupled with an electron sequentially attacks the second nitrogen atom, and as a result the  $\text{N}_2\text{H}_2^*$  species is formed because the protonation alternatively occurs between the two nitrogen atoms in an alternating mechanism. The first  $\text{NH}_3$  molecule is released in the sixth step (schematic description). The bond lengths between the N-N atoms increase in every elementary step up to the release of the first  $\text{NH}_3$  molecule ( $\text{N}_2\text{H}^*$  1.23 Å,  $\text{N}_2\text{H}_2^*$  1.31 Å,  $\text{N}_2\text{H}_3^*$  1.40 Å, and  $\text{N}_2\text{H}_4^*$  1.47 Å), respectively.

Fig. 8 (a) Free energy profile for the eNRR at zero and applied potentials (limiting potential) and (b) optimized geometric structures of various elementary steps of the eNRR pathway through an alternating mechanism on the  $\text{Mo}_1/\text{PMA}$  cluster. All bond lengths are given in Å.

Therefore, in the alternating pathway the protonation of  $N_2$  to form the  $N_2H_4^*$  species is potentially a limiting step due to the large  $\Delta G$  values of 0.54 eV between all elementary steps.

**3.4.3 Enzymatic mechanism.** In our proposed enzymatic pathway, protonation between the two nitrogen atoms occurs consecutively, and the release of the first ammonia ( $NH_3$ ) molecule occurs at the sixth step (schematic description). Fig. 9(a and b) show the Gibbs free energy profile and the optimized structures of the corresponding fundamental steps involved in the enzymatic pathway, respectively. In the enzymatic mechanism, the side-on configuration of  $N_2$  on the  $Mo_1/PMA$  cluster will be hydrogenated by adsorbing a proton coupled with transfer of an electron to form an  $N_2H^*$  species. The bond length of N–H is 1.02 Å, and the bond length of N–N is 1.29 Å, respectively. The bond lengths among N–N increase in every elementary step up to the release of the first  $NH_3$  molecule (1.29 Å  $N_2H^*$ , 1.38 Å  $N_2H_2^*$ , 1.40 Å  $N_2H_3^*$ , and 1.43 Å  $N_2H_4^*$ ), respectively. In the enzymatic pathway, the key energy barrier for the protonation of the  $N_2^*$  species to  $NH_3^*$  is 0.35 eV ( $N_2H_3^*$  to  $N_2H_4^*$ ), which is lower than that of distal (0.48 eV) and alternating (0.54 eV) pathways, respectively. Noticeably, the eNRR occurs over  $Mo_1/PMA$  *via* the enzymatic pathway due to the lower overpotential.

**3.4.4 Mixed pathway.** A new pathway has recently been proposed for the eNRR<sup>86–90</sup> in which the  $N_2H_2^*$  species in the distal pathway would travel to an alternating pathway (denoted by arrows in the schematic description). Therefore, we also studied the mixed pathway on the  $Mo_1/PMA$  cluster. According to our theoretical results, the Gibbs free energy for the protonation of adsorbed  $N_2$  to the  $N_2H^*$  species is unchanged (0.45 eV) in this mixed mechanism. In the mixed mechanism, the potential determining step is larger than that of the enzymatic mechanism, which is 0.35 eV. Thus, the enzymatic mechanism is more favorable than the mixed pathway.

The comparison of the different reaction mechanisms in the electrocatalytic synthesis of ammonia on the  $Mo_1/PMA$  cluster is summarized in Fig. 10. The calculated  $\Delta G$  values of all the elementary steps are presented in Table S3.† The results

Fig. 10 The free energy surfaces for all three pathways of the eNRR on the  $Mo_1/PMA$  cluster at zero potential *via* distal, alternating, and enzymatic mechanisms, respectively.

indicate that the enzymatic pathway 0.35 eV has a lower energy barrier than the distal (0.48 eV) and alternating (0.54 eV) pathways, respectively. Thus, under ambient reaction conditions, the  $Mo_1/PMA$  single-atom catalyst is potentially the more active catalyst for the eNRR.

To describe the catalytic reactivity of the  $Mo_1/PMA$  cluster, the overpotential ( $\eta$ ) is calculated since it is a good indicator for the eNRR. A smaller value indicates a faster eNRR reaction. According to the computational hydrogen electrode (CHE) model, the value can be calculated using the following equation:  $\eta = U_{equilibrium} - U_{limiting}$ , where  $U_{equilibrium}$  is the equilibrium potential of the eNRR. The equilibrium potential calculated in this work is  $-0.16$  V for such a reaction. The  $U_{limiting}$  is the applied potential that can be determined by eliminating the energy barrier of the rate-limiting step.  $U_{limiting} = \Delta G/e$ , where  $\Delta G$  is the Gibbs free energy of the potential of the limiting step.

Fig. 9 (a) Free energy profile for the eNRR at zero and applied potentials (limiting potential) and (b) optimized geometric structures of various elementary steps of the eNRR pathway through an enzymatic mechanism on the  $Mo_1/PMA$  cluster. All bond lengths are given in Å.

The limiting potentials of the eNRR on the Mo<sub>1</sub>/PMA cluster *via* the three mechanisms discussed above are  $-0.48$ ,  $-0.54$ , and  $-0.35$  V, respectively. Thus, the overpotential ( $\eta$ ) values of these mechanisms are distal  $(-0.16) - (-0.48) = 0.32$  V, alternating  $(-0.16) - (-0.54) = 0.38$  V and enzymatic  $(-0.16) - (-0.35) = 0.19$  V, respectively. Therefore, the eNRR occurring on an isolated Mo<sub>1</sub>/PMA cluster prefers to proceed *via* the enzymatic mechanism due to the minimum overpotential ( $\eta$ ) 0.19 V value. These values are smaller than that of the well-known Re (111) surface (0.50 V),<sup>86</sup> and equal to that of the Mo–boron nitride monolayer (0.19 V).<sup>50</sup> Therefore, a single Mo<sub>1</sub>/PMA cluster is likely to be a very promising SAC for the eNRR.

To gain more insights into the catalytic performance of the Mo<sub>1</sub>/PMA cluster for the eNRR, we have performed the Bader charge analysis in each elementary step (see Table S4<sup>†</sup>). Fig. 11a shows that each intermediate can be divided into their moieties: four oxygen atoms on the PMA cluster which are around the Mo<sub>1</sub> atom (moiety 1), the single metal atom (Mo<sub>1</sub>) (moiety 2) and the adsorbed N<sub>x</sub>H<sub>y</sub> species (moiety 3), respectively. It has been found that the N<sub>2</sub> molecule gains 0.25|e| end-on and 0.66|e| side-on from the Mo<sub>1</sub>/PMA cluster by Bader charge analysis. For the consequent hydrogenation and reduction steps, Mo<sub>1</sub>/PMA serves as an electron reservoir of electron donation, which buffers the charge variation during N<sub>2</sub> to NH<sub>3</sub> conversion. Fig. 11 (b–d) show that a very small charge fluctuation occurs along the distal, alternating and enzymatic pathways, respectively. In all three pathways, moiety 1 has a similar charge. It can be seen that moiety 3 gains one electron from moiety 2 when a proton coupled with an electron interacts with the adsorbed N<sub>2</sub> molecule. Thus, the Mo<sub>1</sub>/PMA cluster serves as

an electron donor and the adsorbed N<sub>x</sub>H<sub>y</sub> species acts as the electron acceptor in the eNRR. In addition, we also found that the N–N bond lengths (see Fig. 12 and Table S5<sup>†</sup>) are elongated along distal, alternating, and enzymatic pathways till they are ruptured at the 4<sup>th</sup> step in the distal pathway [Fig. 7a and b] and the 6<sup>th</sup> step in the alternating and enzymatic pathways [Fig. 8a and b and 9a and b], suggesting the possibility of N<sub>2</sub> activation on the Mo<sub>1</sub>/PMA cluster. Fig. 12 shows that the N–N bond length of adsorbed N<sub>2</sub> on the Mo<sub>1</sub>/PMA cluster *via* distal, alternating, and enzymatic pathways increases linearly.

The excellent catalytic performance of the Mo<sub>1</sub>/PMA catalyst for the eNRR through the enzymatic mechanism is further confirmed by kinetic analysis. For a precise enzymatic mechanism, the potential energy diagram and the corresponding geometries of the reaction intermediates involved in the nitrogen reduction reaction are presented in Fig. 13 and Fig. S11.<sup>†</sup> The catalytic cycle shows that the N<sub>2</sub> molecule is chemically adsorbed on the 4H site of the Mo<sub>1</sub>/PMA cluster through the side-on configuration, and the calculated adsorption energy is  $-0.58$  eV. Fig. 13 illustrates that the activated N<sub>2</sub> molecule is first protonated to produce the NNH\* radical *via* the transition state (TS1), which has a barrier of 1.15 eV (imaginary frequency 572<sub>i</sub> cm<sup>-1</sup>). The N–N bond stretched from 1.21 to 1.29 Å with the N–H bond formation (1.03 Å) between the N<sub>2</sub> molecule and H atom. Subsequently, the second proton interacts with the NNH\* radical and forms an NHHN\* species through the transition state (TS2). The calculated kinetic barrier (TS2) for NNH\* → HNNH\* conversion protonation is 1.02 eV (imaginary frequency 1310<sub>i</sub> cm<sup>-1</sup>). As a result, the N–N bond length is lengthened from 1.29 Å in the NNH\* radical to 1.39 Å. During the third protonation step, the third proton interacts with the adsorbed HNNH\* species and forms an \*HNNH<sub>2</sub> species *via* the transition state (TS3). Here TS3 has a kinetic barrier of 0.64 eV for the protonation of HNNH\* → \*HNNH<sub>2</sub>

Fig. 11 (a) Geometrical structure of the adsorbed N<sub>x</sub>H<sub>y</sub> species on the Mo<sub>1</sub>/PMA cluster, (b) charge variation of the three moieties along the distal, (c) alternating, and (d) enzymatic pathways, respectively. The moieties 1, 2 and 3 represent four oxygen atoms around the Mo<sub>1</sub> atom, the single Mo<sub>1</sub> atom, and the adsorbed N<sub>x</sub>H<sub>y</sub> species on the Mo<sub>1</sub>/PMA cluster.

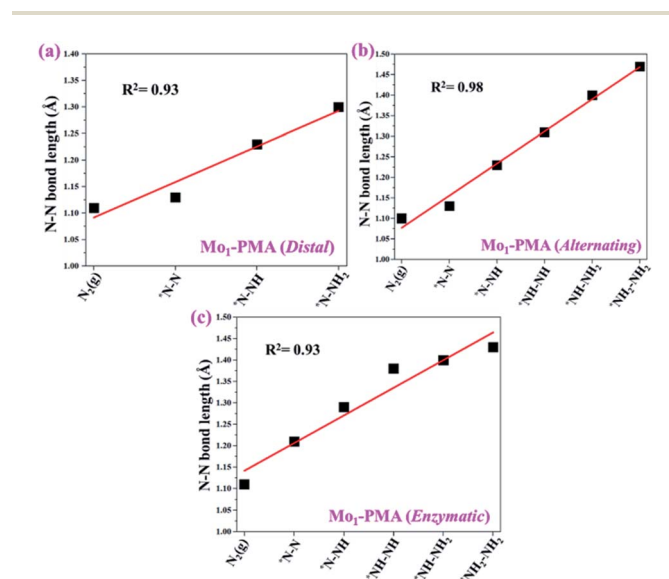

Fig. 12 N–N bond length along (a) distal, (b) alternating, and (c) enzymatic pathways over the Mo<sub>1</sub>/PMA cluster, respectively. The corresponding bond length values are presented in Table S5.<sup>†</sup>

Fig. 13 Reaction profiles for the eNRR over the  $\text{Mo}_1/\text{PMA}$  cluster *via* an enzymatic mechanism. All of the given energies are in electronvolt (eV).

species with one imaginary frequency ( $1016i \text{ cm}^{-1}$ ). The bond length of N–N ( $^*\text{HNNH}_2$ ) is  $1.41 \text{ \AA}$ , which is further extended compared with that of the  $\text{HNNH}^*$  species adsorbed on the  $\text{Mo}_1/\text{PMA}$  cluster. The  $^*\text{HNNH}_2$  species can be further hydrogenated to form the hydrazine species ( $\text{H}_2\text{NNH}_2^*$ ) through TS4 with kinetic barriers of  $1.78 \text{ eV}$  (imaginary frequency,  $479i \text{ cm}^{-1}$ ). The calculated N–N bond length is  $1.43 \text{ \AA}$ , which suggests a single bond character among N atoms. Thus, the formation of the  $\text{N}_2\text{H}_4^*$  species is the rate-limiting step among all six eNRR steps due to the high activation barrier, and these findings are in good agreement with the above thermodynamic and previous theoretical results.<sup>91</sup> Next, the fifth hydrogenation occurs after the N–N bond cleavage, resulting in the formation of the first  $\text{NH}_3$  molecule, and the  $\text{NH}_2^*$  species remains on the  $\text{Mo}_1/\text{PMA}$  cluster. The calculated kinetic barrier for the protonation of  $\text{H}_2\text{NNH}_2^* \rightarrow \text{NH}_3 + \text{NH}_2^*$  species is  $1.20 \text{ eV}$  (TS5, imaginary frequency  $1071i \text{ cm}^{-1}$ ). Finally, the remaining  $\text{NH}_2^*$  species is further hydrogenated, leading to the formation of the second  $\text{NH}_3$  molecule by dissociating the Mo–N bond. The reaction energy and activation energy barrier for the protonation of  $\text{NH}_2^* \rightarrow \text{NH}_3$  conversion are  $-3.76 \text{ eV}$  (exothermic) and  $0.96 \text{ eV}$  (TS6, imaginary frequency  $1431i \text{ cm}^{-1}$ ). Overall, we find that the protonation of  $^*\text{HNNH}_2 \rightarrow \text{H}_2\text{NNH}_2^*$  species is the utmost challenging step among the six eNRR steps, both thermodynamically and kinetically. Subsequently, the second  $\text{NH}_3$  molecule is eliminated, and the dynamic site of  $\text{Mo}_1/\text{PMA}$  could be recuperated to start another eNRR cycle.

Further, spin density analysis, spin magnetic moments, and  $\text{Mo}_1$  oxidation states can provide valuable information on all the elementary steps (distal, alternating, and enzymatic pathways) involved in the eNRR. From the calculated spin magnetic moments, the  $\text{Mo}_1/\text{PMA}$  catalyst has a spin magnetic moment of  $1.54 \mu_{\text{B}}$  at the  $\text{Mo}_1^{2+}$  active center. The adsorbed  $\text{N}_2$ , protonated H and desorbed species  $\text{NH}_3$  are the most important ones in the eNRR. However, the spin magnetic moment is quenched to  $0.61$  side-on and  $0.58 \mu_{\text{B}}$  end-on when  $\text{N}_2$  adsorbs on the  $\text{Mo}_1/\text{PMA}$  cluster, indicating that  $\text{Mo}_1^{2+}$  is oxidized to  $\text{Mo}_1^{3+}$ . The calculated spin density localization, spin magnetic

moments and  $\text{Mo}_1$  oxidation states of all the elementary steps involved in the eNRR *via* distal, alternating, and enzymatic pathways are displayed in Table S6 and Fig. S12–S15,<sup>†</sup> which demonstrate that the spin density, magnetic moment and oxidation state change in all the elementary steps up to the release of the  $\text{NH}_3$  molecule. With the desorption of the  $\text{NH}_3$  molecule, the magnetic moment of the  $\text{Mo}_1$  atom in the final step increased to  $1.37 \mu_{\text{B}}$  and  $\text{Mo}_1^{3+}$  is again reduced to  $\text{Mo}_1^{2+}$ . It is safe to assume that metals in the +II oxidation state are good candidates for the  $\text{M}_1/\text{PMA}$  SAC in the eNRR.

## 4. Conclusions

In summary, by performing DFT calculations combined with the computational hydrogen electrode method, we have proposed a new SAC  $\text{Mo}_1/\text{PMA}$  for activating  $\text{N}_2$  and converting it into  $\text{NH}_3$  under mild reaction conditions. Our results revealed that the single  $\text{Mo}_1$  atom could be stably embedded into the phosphomolybdic acid cluster that possessed outstanding catalytic activity towards the eNRR. The large spin polarization and charge transfer from the  $\text{Mo}_1$ -4d orbital to the  $\text{N}_2$   $2\pi^*$  orbital are liable for the activation of  $\text{N}_2$ . The eNRR process facilitated by the  $\text{Mo}_1/\text{PMA}$  complex proceeds through an enzymatic mechanism with a low overpotential ( $\eta$ ) of  $0.19 \text{ V}$ . In addition, we found that the  $\text{Mo}_1/\text{PMA}$  cluster can impede the HER process and thus promote the eNRR selectivity. Therefore, our theoretical results suggest that  $\text{Mo}_1/\text{PMA}$  is a promising SAC with excellent stability and high efficiency for  $\text{N}_2$  fixation.

Moreover, to explore the effective performance of the  $\text{Mo}_1/\text{PMA}$  catalyst for converting  $\text{N}_2$  to  $\text{NH}_3$  through the enzymatic mechanism, the kinetic activation energy barriers were examined for comparison. From the potential energy profile of the enzymatic mechanism on  $\text{Mo}_1/\text{PMA}$ , we found that the protonation of  $\text{N}_2$  to form the  $\text{N}_2\text{H}_4^*$  species is a kinetic rate-determining step, with an activation barrier of  $1.78 \text{ eV}$ . The calculated kinetic results are in good agreement with thermodynamic results. Moreover, the spin magnetic moments and spin density analysis provide valuable information for all the

elementary steps involved in the eNRR. This work provides valuable guidance for theory and experiment further to explore the potential of PMA-based SACs as eNRR electrocatalysts.
