## Ring expansion of a ring expanded carbene†

Lucía García,<sup>a</sup> Khalidah H. M. Al Furajji,<sup>b</sup> David J. D. Wilson,<sup>b</sup> Jason L. Dutton,<sup>b</sup> Michael S. Hill<sup>\*a</sup> and Mary F. Mahon<sup>a</sup>

**Reaction of phenylsilane with the ring expanded carbene 6-Mes results in facile Si–H oxidative addition to the carbenic carbon at room temperature. Heating the resultant diorganosilane product induces ring expansion through silicon to carbon migration of either the Si–H or Si–Ph bonds.**

The last quarter century has witnessed the emergence of imidazolylidene and related five-membered N-heterocyclic carbenes (NHCs, e.g. IPr, **1**) as one of the most widely applied classes of ligand in contemporary coordination chemistry and catalysis.<sup>1</sup> While the chemical behaviour of NHCs is now well understood, their ring expanded analogues (RENHCs), derived primarily from six- to eight-membered heterocyclic structures (e.g. 1,3-bis(2,4,6-trimethylphenyl)-3,4,5,6-tetrahydropyrimidin-2-ylidene, 6-Mes, **2**), remain relatively underexplored.<sup>2</sup> In general, the incorporation of additional ring atoms delivers enhanced basicity as a result of larger N–C<sub>NHC</sub>–N bond angles and consequent higher HOMO energies. Although this feature provides a further means to modulate the influence of RENHCs when bound to typical metal centres, it may also be anticipated to induce a greater tendency to deleterious side reactions.<sup>3</sup>

In the context of NHC reactivity, we, and others, have recently highlighted that these five-membered rings may be expanded to six-membered heterocyclic structures (e.g. **3–4**), primarily through reactions with the hydridic E–H bonds of a range of silane,<sup>4</sup> borane,<sup>5–10</sup> beryllium<sup>11</sup> and aluminium<sup>12</sup> hydride reagents. A number of density functional theory (DFT) computational studies of this reactivity have highlighted that the ring expansion process ensues in each case through a superficially similar reaction sequence.<sup>12a,13</sup> Initial E–H oxidative addition to the carbenic carbon centre provides species such the isolable derivative **5**,<sup>4</sup> while ring expansion takes place through subsequent insertion of the electropositive main group atom into an endocyclic C–N bond. In every case the initial carbene oxidation was identified as the rate determining step in the reaction, with the relative barrier heights reflected in the facility for the individual processes. In this contribution we describe a combination of synthetic and DFT studies, which demonstrate that the increasingly prominent RENHC class of two electron donor ligand is similarly prone to silane-induced ring expansion. Furthermore, we have isolated the initial product of Si–H oxidative addition and confirm its intermediacy during the ring opening process.

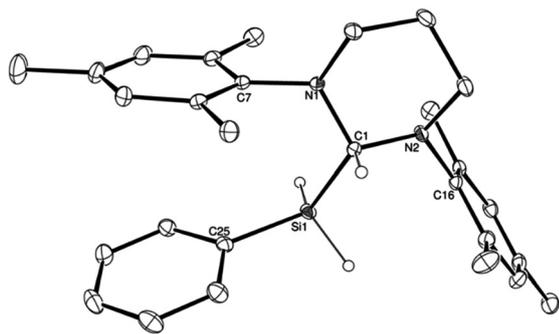

An initial reaction performed in *d*<sub>8</sub>-toluene between 6-Mes (**2**) and PhSiH<sub>3</sub> was observed to take place with the stoichiometric formation of a single new compound (**6**) within 30 minutes at room temperature. The production of compound **6** was characterised through the loss of the plane of symmetry comprising the heterocyclic ring of compound **2**. Most notably, the methyl groups of the *N*-mesityl substituents were observed as three unique singlet resonances in the resultant <sup>1</sup>H NMR spectrum at  $\delta$  2.57, 2.18 and 2.12 ppm, each of which as 6H signals by relative integration. In addition, a further triplet resonance, which integrated as a single proton,

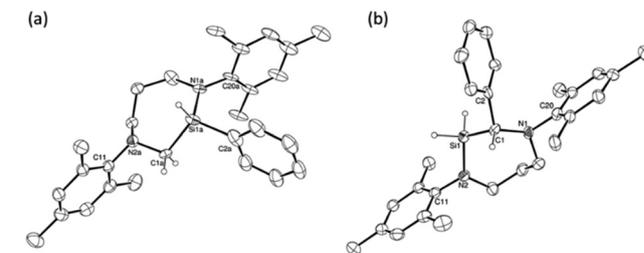

**Fig. 1** ORTEP representation of compound **6** with 25% probability ellipsoids. Hydrogen atoms, except those attached to C1 and Si1 are removed for clarity. Selected bond lengths (Å) and angles (°): Si1–C1 1.9122(17), Si1–C25 1.8666(18), N1–C1 1.465(2), N1–C7 1.439(2), N2–C1 1.469(2), N2–C16 1.435(2), C25–Si1–C1 115.64(7), N1–C1–Si1 113.23(11), N1–C1–N2 106.71(13), N2–C1–Si1 110.45(11).

at  $\delta$  5.30 ppm and a correlated (2H) doublet signal at  $\delta$  4.01 ppm were strongly reminiscent of the respective C–H and SiH<sub>2</sub>Ph signals reported by Bertrand and co-workers for compound **5**,<sup>14</sup> which resulted from analogous room temperature oxidative addition of PhSiH<sub>3</sub> to the saturated imidazolidin-2-ylidene analogue of compound **1**. Similar solution NMR observations have also been described as a result of the migratory insertion reactions of diamidocarbene (DAC) ligands with a variety of B–H,<sup>15</sup> B–B and Cu–H functionalities,<sup>16</sup> while cyclic (alkyl)(amino)carbenes have recently been reported to react at room temperature with the Si–H bonds of both organosilanes and hydrogen-terminated silicon surfaces.<sup>17</sup> On this basis we were able to ascribe compound **6** as a similar product of Si–H oxidative addition, (6-Mes-H) SiH<sub>2</sub>Ph (eqn (1)), a deduction that was confirmed by a subsequent X-ray diffraction analysis performed on a single crystal obtained by slow evaporation of a pentane solution. The results of this analysis are shown in Fig. 1, while selected bond length and angle data are provided in the figure caption.

Radius has previously reported that compound **5** undergoes ring expansion to provide the fully saturated analogue of compound **3** when heated to 100 °C for 5 hours.<sup>4</sup> Accordingly, a *d*<sub>8</sub>-toluene solution of compound **6** was observed by <sup>1</sup>H NMR spectroscopy to undergo complete conversion to a mixture of two new isomeric compounds, **7** and **8**, which were observed to form in a respective 2 : 1 ratio after heating at 120 °C for four days. The major species (**7**) displayed a single Si–H environment (<sup>1</sup>J<sub>SiH</sub> = 204.4 Hz) as a doublet resonance at  $\delta$  5.39 ppm, whereas the Si–H environments of the minor component (**8**) appeared as two mutually coupled doublet of doublets and doublet signals (<sup>2</sup>J<sub>HH</sub> = 10.8 Hz) centred at  $\delta$  5.06 and 4.13 ppm, respectively.

**Fig. 2** (a) ORTEP representation of compound **7** with 25% probability ellipsoids. Hydrogen atoms, except those attached to C1a and Si1a are removed for clarity. (b) ORTEP representation of compound **8** with 25% probability ellipsoids. Hydrogen atoms, except those attached to C1 and Si1 are removed for clarity.

lets and doublet signals (<sup>2</sup>J<sub>HH</sub> = 10.8 Hz) centred at  $\delta$  5.06 and 4.13 ppm, respectively.

The origin of these observations was resolved by the isolation of compounds **7** and **8**, which crystallised as single co-crystals from pentane solution. The resultant X-ray diffraction analysis revealed the two compounds to be isomers resulting from formal transfer of either two silane hydrogen atoms (**7**, eqn (2) and Fig. 2a) or one silane hydrogen and one phenyl substituent (**8**, eqn (2) and Fig. 2b) to the N<sub>2</sub>C heterocyclic carbon centre of **2**. Resolution of the electron density in the co-crystal required modelling of the disorder over two proximate positions that pertained to atoms Si1, N1, N2, C1–C7 and the carbon atoms of the C20-containing *N*-methyl group. Although the constitution of the two isomers was confirmed by the location and refinement of the hydrogen atoms attached to the silicon centres, the disorder ratio, 34(**7**):66(**8**), in the solid state was not representative of the isomer ratio evident in the <sup>1</sup>H NMR spectrum of the reaction mixture.

The greater facility for hydrogen-to-carbon over phenyl-to-carbon transfer implied by the *in situ* NMR analysis is consistent with Radius and co-workers' earlier observation that higher reaction temperatures are necessary to effect NHC ring opening with Ph<sub>2</sub>SiH<sub>2</sub> and PhSiH<sub>3</sub>.<sup>4</sup> To further inform our understanding of the RENHC ring expansion process, SCS-MP2/def2-TZVP(acetoneitrile-PCM)//M06-2X/def2-TZVP calculations on a model system with *N*-Ph NHC substituents were performed to examine the thermochemical properties of the two competing pathways. The results were similar to those previously elucidated by our group and others on the mechanism for the analogous expansion reaction with the five-membered carbene rings,<sup>12,13</sup> and are consistent with the current experimental observations. The two pathways follow a common first step with the transfer of a hydride from silicon to the carbene carbon and formation of a Si–C bond *via* T1 forming **B** (Fig. 3). The second step involves ring-opening of the endocyclic carbene C–N bond giving **C** *via* T2. The relative barrier for these two steps show strong basis set and method dependence (see ESI† for method and basis set results). At the SCS-MP2/def2-TZVP

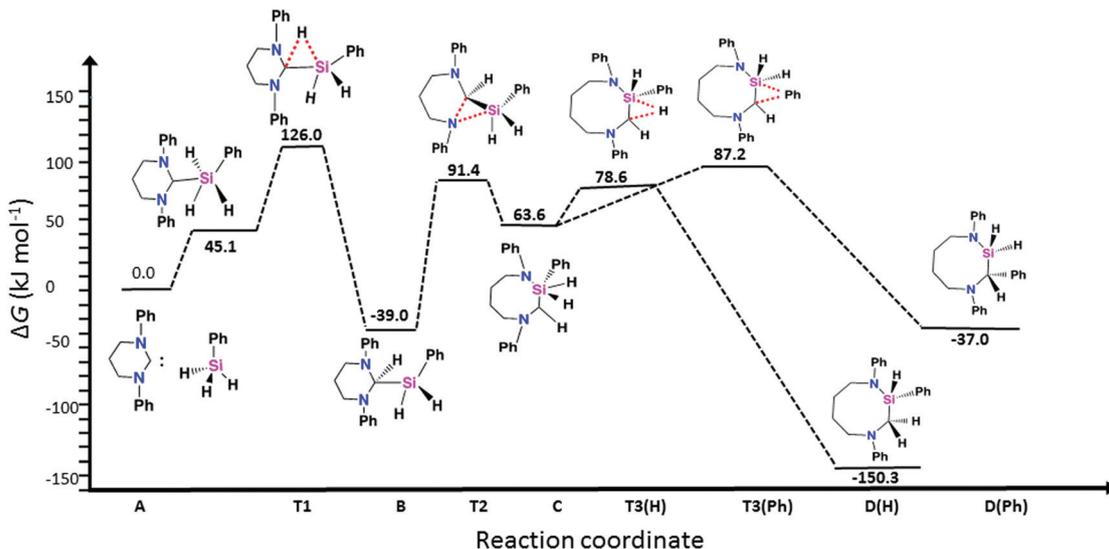

Fig. 3 Calculated reaction profile (SCS-MP2/def2-TZVP, including implicit MeCN solvent model).

level the barriers are very similar at 126 (T1) and 130 (T2)  $\text{kJ mol}^{-1}$ . Most methods considered tend to favour T2 as rate determining, consistent with the experimental observations.

The third step onwards from C discriminates the two observed products, for which the major product arising from a second hydride migration is both thermodynamically and kinetically favoured over the minor phenyl migration product. The barrier for the second hydride migration (T3H) is 15  $\text{kJ mol}^{-1}$ , while for phenyl migration (T3Ph) it is 24  $\text{kJ mol}^{-1}$ . The overall hydride migration product is 111  $\text{kJ mol}^{-1}$  lower in free energy than B, while the phenyl migration product is nearly equal in energy to B. Overall, from the starting carbene and phenylsilane, the  $\Delta G$  for the two reactions are  $-150 \text{ kJ mol}^{-1}$  and  $-37 \text{ kJ mol}^{-1}$  for secondary hydride and phenyl migration, respectively.

In conclusion, we have described the first example of a main group-centred ring expansion reaction of a ring expanded carbene. These results demonstrate that the previously observed potential for E–H oxidative addition and ring expansion of NHCs must be a similar consideration in the development of future applications of RENHCs. We are continuing to study this and related reactivity.
