## Synthesis and excited state processes of arrays containing amine-rich carbon dots and unsymmetrical rylene diimides†

Luka Đorđević, <sup>a</sup> Philipp Haines, <sup>b</sup> Michele Cacioppo, <sup>a</sup> Francesca Arcudi, <sup>a</sup> Tobias Scharl, <sup>b</sup> Alejandro Cadanel, <sup>bcd</sup> Dirk M. Guldi <sup>\*b</sup> and Maurizio Prato <sup>aeef</sup>

Combining carbon dots (CDs) with  $\pi$ -extended chromophores is an attractive way to study the electronic and energy processes of the former as a key step to many applications, including photosensing, photocatalysis, or photosensitization. CDs, in conjugation with chromophores, can have value in preparing donor–acceptor hybrids, and can also be used as scaffolds to support electronic communication between dyes. In this work, we conjugate two different rylene diimides, naphthalene and perylene diimides (NDI and PDI, respectively), with amorphous nitrogen-doped carbon dots. We take advantage of the imidization reaction between the amine-rich surface of the carbon dots and the monimide monoanhydride precursors of NDIs and PDIs, under microwave assisted conditions. The resulting (nano)hybrids were characterized also by spectroscopic methods. In particular, time-resolved spectroscopy for the multichromophoric array, consisting of CDs and both rylene diimides, allowed us to elucidate the complex inter-chromophoric interactions taking place in the excited state.

## Introduction

The organization of chromophores is of crucial importance for a wide variety of technological applications. Particularly in the field of materials science, numerous approaches have

been developed to arrange chromophores into functional architectures.<sup>1</sup> Inspired by natural light-harvesting complexes, in which the precise positioning of chromophores is accomplished thanks to a protein scaffold,<sup>2</sup> various methods and artificial scaffolds have been explored to mimic the biomolecular units. Several supramolecular and covalent systems that have been developed are based on rigid helical polymers,<sup>3</sup> nucleic acids,<sup>4</sup> micelles,<sup>5</sup> and carbon nanomaterials,<sup>6</sup> to name a few.

Among the various carbon nanomaterials, small (<10 nm) carbon nanoparticles called carbon dots (CDs) have emerged due to their peculiar properties, mainly the photophysical ones.<sup>7</sup> Coupled with ready availability, water solubility and low toxicity of CDs, all of the above reasons suggest why this class of nanomaterial has recently attracted attention. Combination of CDs with  $\pi$ -extended chromophores and other nanomaterials has been an interesting way to study the electronic and energy processes of the former, as a key step to many applications, including photocatalysis, photosensing, or photosensitization.<sup>8</sup> Our groups and others have coupled, through supramolecular and covalent chemistry, CDs with chromophoric systems that include porphyrins,<sup>9</sup> perylene diimides,<sup>10</sup>  $\pi$ -extended tetraphiafulvalenes,<sup>11</sup> pyrenes<sup>12</sup> and other nanomaterials.<sup>13</sup>

We have placed particular attention on amorphous nitrogen-doped CDs ( $\alpha$ -N-CDs or carbon nanodots, NCNDs).<sup>7b</sup> These small and monodisperse ( $2.5 \pm 0.8$  nm) CDs can be prepared by fast hydrothermal microwave-assisted heating, using a

two-component approach,<sup>7b</sup> resulting in nanoparticles with an amine-rich surface. These amino groups have been exploited for carbodiimide-mediated amide couplings with chromophores bearing carboxylic groups, including Ru(bpy)<sub>3</sub><sup>2+</sup>,<sup>14</sup> porphyrins<sup>15</sup> and phthalocyanines.<sup>16</sup> In the first example, the conjugation resulted in a high electroluminescent emission, with the carbon nanodots acting as co-reactant to the ruthenium dye emitter.<sup>14</sup> In the case of the free-base *meso*-tetrakisarylporphyrin and NCNDs hybrid, it was observed that visible light excitation is followed by a charge separation (one-electron reduced NCNDs and one-electron oxidized porphyrin) and recombination.<sup>15</sup> Finally, even in cases where carbon nanodots and chromophores do not seem to interact, the former can support the electronic communication between a pair of chromophores. This was observed very recently when, upon light irradiation, a pair of zinc phthalocyanines present on the NCND surface underwent symmetry-breaking charge transfer/separation and recombination dynamics.

Now, we report the preparation of covalent conjugates between carbon dots and naphthalene diimides (NDIs) and perylene diimides (PDIs), as depicted in Fig. 1. We show that a direct (microwave-assisted) imidization reaction between the amino groups on the surface of CDs and the tylene monoanhydride monoimide precursors is a convenient and efficient strategy for conjugation. The tylene dyes were chosen because their widespread use as colorants, their great chemical, thermal, and photo stabilities, in addition to high extinction coefficients.<sup>17</sup> Furthermore, tylene diimides have been widely used not only as n-type organic semiconductors,<sup>18</sup> but were also employed as multi-chromophoric nanoemitters or as light harvesters, used to study

electron transfer and energy cascades processes in multichromophore arrangements,<sup>19</sup> as well as in photoredox catalysis.<sup>20</sup> We anticipated observing electronic communication between CDs and tylene chromophores, as PDIs are also known to undergo one-electron reduction,<sup>20a</sup> in presence of amine donors and irradiation, while the amino groups on the NCNDs surface have been reported to oxidize relatively easily.<sup>14</sup>

## Results and discussion

### Syntheses of reference compounds and tylene monoimide monoanhydrides

The preparation of symmetric naphthalene and perylene diimides reference compounds was accomplished in a straightforward manner, by taking advantage of literature procedures (Scheme 1).<sup>21</sup> Specifically, heating a mixture of naphthalene dianhydride and an excess of butylamine, in acetic acid, yielded *N,N'*-bis(*n*-butyl)naphthalene-1,4,5,8-tetracarboxylic diimide (NDI-Ref), after work-up and purification.<sup>21b</sup> On the other hand, the reference perylene diimide was prepared by reacting commercial perylene dianhydride with 2,6-diisopropylaniline, in molten imidazole, in order to obtain *N,N'*-bis(2,6-diisopropylphenyl)perylene-3,4,9,10-tetracarboxylic diimide (PDI-Ref).<sup>21a</sup> For the preparation of the unsymmetrical naphthalene and perylene diimides precursors for the imidization reactions with carbon dots, different procedures had to be employed. In the case of naphthalene monoimide monoanhydride (**1**), the product was obtained, in one step, by refluxing an equimolar solution of *n*-butylamine and naphthalene dianhydride in a phosphate buffered solution.<sup>22</sup> Although it is possible to prepare unsymmetrical PDIs in one step,<sup>23</sup> the path to pure and sterically hindered perylene monoimide monoanhydrides requires additional steps. First, the perylene dianhydride (PTCDA) was converted into the tetrabutyl tetraester (**3**),<sup>24</sup> which can be relatively easily transformed into

Fig. 1 Schematic representation of the materials used in this work. (i) *n*-Butylamine,  $\text{CH}_3\text{COOH}$ , 100 °C, overnight; (ii) *n*-butylamine,  $\text{H}_2\text{O}$  pH = 6.4, 100 °C, overnight; (iii)  $\text{H}_2\text{O}$ , 240 °C,  $\mu\text{W}$ , 180 s; (iv) 2,6-diisopropylaniline, imidazole, 190 °C,  $\text{N}_2$ , 24 h; (v) *n*-butanol, 1-bromobutane, 1,8-diazabicyclo[5.4.0]undec-7-ene, DMF, 60 °C, overnight; (vi) *p*-toluenesulfonic acid, toluene/hexane (v/v), 100 °C, 5 h; (vii) 2,6-diisopropylaniline, imidazole, 130 °C,  $\text{N}_2$ , 5 h; (viii)  $\text{H}_2\text{SO}_4$ ,  $\text{CH}_3\text{COOH}$ , 118 °C, 2 h.

the monoanhydride diester (**4**)<sup>25</sup> by carefully adjusting the reaction conditions (namely heating a toluene/hexane solvent mixture in a 5:1 v/v ratio). The monoanhydride diester was then reacted with 2,6-diisopropylaniline to obtain the monoimide diester (**5**).<sup>26</sup> Finally, the monoimide diester was transformed into monoimide monoanhydride (**2**) by refluxing an acetic acid (with sulfuric acid) solution,<sup>27</sup> yielding the precursor for the covalent attachment to NCNDs. Meanwhile, amorphous nitrogen-doped carbon dots (NCNDs) were prepared and purified according to our previously reported procedure,<sup>28</sup> which gives carbon-based nanoparticles with a homogeneous size distribution around 2.5 nm, blue fluorescence (17% quantum yield) and with an estimated amount of 1350  $\mu\text{mol g}^{-1}$  amino groups on the surface.

### Model reaction with 1,8-naphthalic anhydride

Before proceeding with the preparation of the covalent (nano)hybrids, we investigated the reaction conditions for the imidization of monoimide monoanhydride precursors, which usually require not only high temperatures, but also long reaction times.<sup>29</sup> We therefore opted for a microwave-assisted coupling reaction to shorten the reaction times.<sup>29a</sup> First, we have tested the stability of NCNDs in the reaction conditions required for the imidization reactions. DMF solutions of only NCNDs and triethylamine were heated under microwave irradiation at 140 °C for 5, 15 and 30 minutes, followed by dilution and acquisition of the UV-Vis spectra. Compared to a solution of untreated NCNDs, the absorption profile did not show significant changes (Fig. 2b), which suggests that the NCNDs are thermally stable, even in solutions. Subsequently, we proceeded with performing control experiments using different molar amounts of 1,8-naphthalic anhydride as a model substrate (Fig. 2c).<sup>23</sup> The UV-Vis absorbance spectra showed an apparently linear dependency on the equivalent of the naphthalene monoanhydride (NMA) precursor used, with the reaction not proceeding after more than 1 equivalent of NMA was added.

Fig. 2 Probing the imidization reaction. (a) Scheme for the model reaction with 1,8-naphthalic anhydride. (b) UV-vis spectra of CDs under different times of  $\mu\text{W}$  irradiation. (c) UV-vis spectra of CDs reacted with different amounts of 1,8-naphthalic anhydride for 30 min.

We have therefore found suitable reaction conditions (DMF, 140 °C for 30 minutes) for reacting NCNDs with tylene monoimide monoanhydride precursors.

### Preparation and characterization of hybrid materials

The above reaction conditions were employed for coupling NCNDs with naphthalene or perylene monoimide monoanhydrides **1** and **2**.<sup>30</sup> Besides preparing the NCND-NDIs and NCND-PDIs conjugates, we made an effort to prepare a material that contains both NDIs and PDIs, by using 0.25 equivalents of both monomide monoanhydrides precursors, under the same microwave irradiation conditions.<sup>31</sup> In all three cases, after successful microwave irradiation of the test reactions, the imidization reactions were confirmed by recording the UV-Vis spectra (*vide infra*, Fig. 4), followed by scale-up the reactions. The (nano)hybrids mixtures, after each reaction, were loaded onto a column and purified by size-exclusion chromatography (SEC, DMF as eluent),<sup>28b</sup> with the various fractions collected and checked by UV-Vis spectroscopy. Finally, the product fractions were combined, dried under reduced pressure, and collected as powders after lyophilization.

In order to confirm the successful imidization reaction and formation of the hybrid materials, we performed Fourier-transform infrared spectrophotometry (Fig. 3 and ESI,† Fig. S2–S4). The FT-IR spectrum of NCNDs typically shows broad peaks that relate to O–H/N–H bonding at 3357  $\text{cm}^{-1}$ , C–H stretching vibrations at 2945 and 2873  $\text{cm}^{-1}$ , C=O vibrations at 1766, 1705 and 1654  $\text{cm}^{-1}$ , C=N at 1575  $\text{cm}^{-1}$ , C–N at 1490 and 1451  $\text{cm}^{-1}$ , C–O vibrations at 1383 and 1351  $\text{cm}^{-1}$ , and C–O–C vibrations at 1210 and 1111  $\text{cm}^{-1}$ . In contrast, for the perylene monoimide monoanhydride **2** we observed distinctive C=O stretching vibrations for the anhydride at 1771 and 1734  $\text{cm}^{-1}$  and imide at 1702 and 1662  $\text{cm}^{-1}$ , in addition to the aromatic C–H stretching at 3035  $\text{cm}^{-1}$ , aliphatic C–H stretching at 2967 and 2866  $\text{cm}^{-1}$ , conjugated C=C stretching at 1595  $\text{cm}^{-1}$ , C–N stretching at 1365  $\text{cm}^{-1}$ , C–O stretching at 1247  $\text{cm}^{-1}$ , and C–H bending at 811 and 739  $\text{cm}^{-1}$ . Importantly, the disappearance of the anhydride C=O stretching in the conjugates confirmed the successful imidization reaction. Also, additional features confirmed the presence of both NCNDs and perylene diimide. For example, in the C–H stretching characteristic region bands at 2955, 2932 and 2873  $\text{cm}^{-1}$  are discernible, C=O stretching modes at 1706 and 1665  $\text{cm}^{-1}$  are more pronounced next to the C–N stretching at 1355  $\text{cm}^{-1}$  and the C–O stretching at 1251  $\text{cm}^{-1}$ , which originates from PDIs.

We further characterized the materials by absorption and fluorescence spectroscopies (Fig. 4 and ESI,† Fig. S5–S8). In DMF, both NDI-Ref and the monoanhydride precursor **1** showed two well-resolved absorption peaks due to  $S_0 \rightarrow S_1$  transitions, which are characteristic for monomeric NDIs: 360 and 381 nm for NDI-Ref as well as 356 and 374 nm for **1**.<sup>32</sup> In the NCND-NDIs conjugate, next to the broad absorption originating from NCNDs, two well-resolved absorption peaks confirmed the successful imidization reaction. In fact, the corresponding maxima are identical to those seen for NDI-Ref. In the case of PDI and its monoimide monoanhydride precursor **2**, well-resolved

Fig. 3 FT-IR spectra of rylene diimide precursors (**1** and **2**), references (NCNDs, NDI-Ref, PDI-Ref), and hybrid materials (NCND-NDIs, NCND-PDIs, NCND-NDI/PDIs) as KBr pellets.

absorptions were observable. Once again, they originate from the  $S_0 \rightarrow S_1$  transitions, but they are red-shifted relative to NDI: 492 and 528 nm for PDI-Ref, as well as 487 and 523 nm for compound **2**. Also in this case, after the imidization reaction, the absorption spectra showed a broad NCND-centered absorption next to well-resolved PDI absorption maxima at 491 and 527 nm. As Fig. 4 shows, the absorption spectra of the NCND-NDI/PDIs conjugate revealed features of all three constituents: broad NCND-centered absorption in the UV region, NDI-centered maxima at 360 and 381 nm, and PDI-centered maxima at 491 and 527 nm.

As a complement we recorded the fluorescence of all references and conjugates (ESI,† Fig. S8–S12) and obtained evidences of the formation of the conjugates, similar to those concluded from the UV-Vis investigations. Mirror images of the absorptions are the emissions of NCNDs, NDI-Ref, and PDI-Ref in the ranges from 300 to 500, 375 to 500, and 525 to 650 nm, respectively. In terms of fluorescence quantum yields, PDI-Ref is by far the strongest fluorescence with a quantum yield of 93% ( $\lambda_{ex} = 480$  nm), followed by NCNDs (QY 9.2%), while NDI-Ref fluorescence is rather weak (QY < 0.1%). When turning to the NCND-PDIs conjugate, we noted in the 3D heat maps or in the excitation dependent PL spectra (ESI,† Fig. S8 and S11) PDI-centered fluorescence across the entire excitation wavelength range, that is, from 300 nm to nearly 550 nm, with very weak residual NCND fluorescent features. The aforementioned leads us to postulate a likely energy transfer scenario. From a closer look at the PDI fluorescence quantum yield of 40% ( $\lambda_{ex} = 480$  nm), as a qualitative measure for excited state interactions between PDIs and NCNDs, we infer an additional

Fig. 4 UV-Vis absorption spectra of rylene diimide precursors (**1** and **2**), references (NCNDs, NDI-Ref, PDI-Ref) and hybrid materials (NCND-NDIs, NCND-PDIs, NCND-NDI/PDIs) in DMF, at room temperature. Vertical lines in grey are guides to help the comparison between the naphthalene and perylene diimide-based materials.

deactivation channel once the PDI singlet excited state is formed. The picture is different for the NCND-NDIs conjugate, with the NCND- as well as NDI-centered fluorescence overlapping in the 300 to 500 nm range and beyond (QY 2.1%). Besides, a weak excitation-dependent emission is observed between 500–600 nm. It is likely to involve from surface trap states originated upon covalent rylene attachment. Interestingly, intense PDI-centered fluorescence obscures the observation of NCND surface trap states in materials containing PDI. We conclude the lack of any NCND-to-NDI energy transfer in NCND-NDIs is due to their nearly isoenergetic excited states. In the NCND-NDI/PDIs conjugate, the PDI-centered fluorescence dominates. As a matter of fact, its quantum yield is 25% ( $\lambda_{ex} = 480$  nm). From these measurements, we infer that NCND-NDI/PDIs act similar to what we have seen for NCND-PDIs.

As a complement to the steady-state fluorescence measurements we turned to transient absorption measurements (TAS) on the femto-, pico- and nanosecond timescales. We started with the references. In the case of fs-TAS with NCNDs, 387 nm photoexcitation leads to differential changes that include maxima at 435 and 600 nm (Fig. S14, ESI†). A kinetic model, which is based on three species, was used: the initial excited state transformed in 2.4 ps into an intermediate state and subsequently in 370 ps into a very long-lived state (Fig. 5). The third excited state lives longer than the resolution of our experiment. The intermediate state is centered around trap states, which are strongly emissive in NCNDs (*vide supra*). No signal was, however, observed when exciting NCNDs at 500 nm.

Fig. 5 Kinetic models used to fit the fs-TAS data of reference (NCNDs, PDI-Ref, NDI-Ref) and hybrid materials (NCND-NDIs, NCND-PDIs, NCND-NDI/PDIs).

Turning to PDIs under 500 nm photoexcitation (Fig. S15, ESI<sup>†</sup>), a three species kinetic model was used to fit the experimental data (Fig. 5). The first species with maxima at 695 and 940 nm as well as minima at 460, 490, 535 and 580 nm is a vibrationally hot singlet excited state. Notable is the fact that the minima of the first species carry contributions from ground state bleaching at 460, 490 and 535 nm and stimulated fluorescence at 580 nm. It undergoes vibrational relaxation with a lifetime of 5.4 ps to form, in parallel, the second and the third species. The second species lasts for 261 ps and is ascribed to a vibrationally relaxed singlet excited state of a small PDI-Ref fraction that is aggregated. The third species is the long-lived and bright-fluorescent singlet excited state, with a lifetime of 4.1 ns, by which it decays quantitatively to the ground state. Important is the fact that after vibrational relaxation any appreciable changes are discernable in the differential absorption spectra.

The excited state dynamics of NDI-Ref are quite complex (Fig. S16, ESI<sup>†</sup>), in line with literature observations. It has been demonstrated that photoexcitation of NDIs is followed by a very efficient intersystem crossing to the corresponding triplet manifold.<sup>33</sup> Also, photochemical products and charge separated states evolve from the singlet and triplet excited states, respectively.<sup>33</sup> In our 387 nm experiments with NDI-Ref, the singlet excited state with its maxima at 460 and 590 nm is populated instantaneously, and it intersystem crosses to the triplet excited state within 300 fs. The latter is characterized by 479, 590 and 690 nm maxima and a 1.2 ps lifetime. From this state, the third species evolves, including 480, 608 and 680 nm characteristics. These signals match the fingerprint absorptions at 474, 608, 680 and 755 nm obtained upon spectroelectrochemical reduction of NDI-Ref (ESI<sup>†</sup> Fig. S13). From this

analogy we assign this species to a charge-separated (CS) state.<sup>34</sup> Finally, CS decays to the ground state *via* a 4.0 ps lasting charge recombination. Some minor components, all of them with weaker intensity (around 20 times lower), which correspond to photochemical products that originate from the singlet excited state are observed with lifetimes of, for example, 50 ps and >10 ns.

After gathering information on the references, we focused our attention on NCND-NDIs. When photoexcited at 387 nm, neither the singlet excited state of NDI, nor any NCND-centered excited state were observed (ESI<sup>†</sup> Fig. S17). Instead, the first species which was discernable was the triplet excited state of NDI with 470, 590 and 680 nm maxima as well as a 600 fs lifetime. The latter populates the same CS with maxima at 475, 605 and 680 nm that was found in the experiments with NDI-Ref. It decays *via* charge recombination in 4.2 ps to the ground state. Minor components with 77 ps and >10 ns lifetimes were also noticed. Overall, the NCND-NDIs dynamics are identical to the NDI-Ref dynamics, and are consistent with the notion of weak excited state interactions between NCNDs and NDIs in NCND-NDIs.

In the case of NCND-PDIs, the differential absorption spectrum, early on, is similar to that of PDI-Ref with maxima at 695 and 930 nm and minima at 460, 490 and 535 nm. The excited state dynamics of NCND-PDIs upon selective PDI excitation at 500 nm differ, however, from those described for PDI-Ref. A trend that is evident when comparing the 610 nm kinetics for PDI-Ref (ESI<sup>†</sup> Fig. S15) with those of NCND-PDIs (ESI<sup>†</sup> Fig. S18). Global analyses of the data reveal that a four species, rather than a three species, kinetic model is needed to fit the data (ESI<sup>†</sup> Fig. S21). Our model includes the decay of the PDI-centered excited states in NCND-PDIs with lifetimes of 2.3 ps for the vibrationally hot singlet excited state, 211 ps for

**Fig. 6** Top left: Differential absorption 3D map obtained upon fs-TAS of NCND-NDI/PDIs in DMF at room temperature, with 387 nm excitation. Top right: Time absorption profiles and corresponding fittings at 490, 610, and 990 nm. Bottom left: Species associated differential spectra of the  $\text{NDI}^{\bullet+}\text{NDI}^{\bullet-}$  CS state (black),  $\text{NCND}^{\bullet+}\text{PDI}^{\bullet-}$  CS state (red), PDI-centered  $\text{S}_1$  (agg) (blue) and PDI-centered  $\text{S}_1$  (green). Bottom right: Concentration evolution over time.

the vibrationally relaxed singlet excited state in aggregates, and 3.0 ns for the singlet excited state. The model is also based on an additional excited state, which is populated on the PDI side exclusively from the vibrationally hot singlet excited state and features the fingerprint absorptions of the one electron reduced form of PDI at 690 and 980 nm. These are consistent with those observed for the electrochemically reduced PDI-Ref at 700, 765, 795 and 954 nm (ESI,† Fig. S13). In essence, this additional excited state is unambiguously assigned to a charge-separated state. CS undergoes charge recombination within 19 ps, by which the ground state is reinstated. We were, however, unable to deconvolute the energy transfer from NCND to PDIs in fs-TAS experiments with NCND-PDIs under 387 nm excitation (Fig. S19, ESI†), which assists in selectively photoexciting NCNDs. As a matter of fact, we fit the data using the kinetic model depicted in Fig. 5. It takes an ultrafast energy transfer into account with an upper limit of 300 fs. Lifetimes of 226 ps, 2.8 ns, and 13 ps match the values determined upon 500 nm excitation. In short, our measurements demonstrate that a CS evolves in NCND-PDIs, either directly after PDI excitation or indirectly after NCND excitation. In the latter case, an energy transfer from NCND to PDI comes first.

Finally, we studied the NCND-NDI/PDIs conjugate, where excitation at 500 nm initiates the same excited state cascade that was observed for NCND-PDIs upon 500 nm photoexcitation (please compare the 610 nm kinetics in Fig S18 and S20, ESI†). Thus, we applied the same kinetic model, which is based on four species. In NCND-NDI/PDIs, the vibrationally hot singlet excited state decays in 700 fs and feeds the vibrationally relaxed singlet excited state in aggregates, the singlet excited state, and the CS state, whose lifetimes are 218 ps, 3.1 ns and 16 ps, respectively (ESI,† Fig. S17).

Selective NDI photoexcitation at 387 nm triggers a complex decay in NCND-NDI/PDIs. Already at very short time delays, the

one-electron reduced form of NDI with its 475 nm characteristic are observed, together with a PDI-centered singlet bleaching at 535 nm (Fig. 6). Global analyses were performed with a four species kinetic model that is depicted in Fig. 5. We postulate that, right after light absorption, the NDI-centered singlet excited state populates, *via* intersystem crossing, the  $\text{NDI}^{\bullet+}\text{NDI}^{\bullet-}$  CS state, and *via* energy transfer, the PDI-centered singlet excited states. Notably, the  $\text{NDI}^{\bullet+}\text{NDI}^{\bullet-}$  CS state, with absorptions at 475, 610 and 680 nm transforms in 2.8 ps to a  $\text{NCND}^{\bullet+}\text{PDI}^{\bullet-}$  CS state, with its fingerprint absorptions at 700 nm and a shoulder at 990 nm. *Per se*, this process is remarkable, since the electron and the hole undergo charge shift processes.<sup>35</sup> Notably, CS in NCND-NDI/PDIs, that is,  $\text{NCND}^{\bullet+}\text{PDI}^{\bullet-}$ , possess the same differential absorption spectrum seen for NCND-PDIs (ESI,† Fig. S14). It decays to the ground state *via* charge recombination in 10 ps. In parallel decay pathways, PDI-centered vibrationally relaxed singlet excited state in aggregates and singlet excited states, with bleaching at 490 and 530 nm, decay with 172 ps and 2.5 ns, respectively.

From our observations, we conclude that in the NCND-NDIs/PDIs, inter-chromophore interactions take place in the excited state, in the form of energy transfer, charge transfer, and charge shift processes.

## Conclusion

In the present work we have synthesized two rylene monoimide monoanhydrides (naphthalene **1** and perylene **2**) and have performed imidization reactions with the amines present on the surface of amorphous N-doped carbon nanodots. The imidization reaction was first optimized using 1,8-naphthalic anhydride as model compound, in DMF and under microwave irradiation. Imidization reactions with the rylene diimides were confirmed by infrared spectrophotometry and photophysical characterizations. Given the interest that the carbon dots have recently attracted in electron donor–acceptor systems and as scaffolds that support electronic communication between dyes, this work expands the chemical toolbox, in terms of reactions and chromophores employed. In this contribution, we employed chromophores displaying absorption in different regions of the visible spectra, and demonstrated that their excited states are electronically communicating. We envisage the use of CDs other than the ones presently used and different rylene diimides for the preparation of multichromophoric arrays or hybrid polymers with panchromatic absorption.

## Acknowledgements

This work was supported by the University of Trieste, INSTM, AXA Research Fund, the Italian Ministry of Education MIUR (cofin Prot. 2017PBXPN4), the Spanish Ministry of Economy

and Competitiveness MINECO (project PID2019-108523RB-I00), and the Maria de Maeztu Units of Excellence Program from the Spanish State Research Agency (MDM-2017-0720). Additional support is acknowledged from the Deutsche Forschungsgemeinschaft (DFG) via SFB 953 “Synthetic Carbon Allotropes” and the Excellence Cluster “Engineering of Advanced Materials”. AC is an ALN member.

30 We settled on using 0.25 eq. of compounds **1** or **2** in order to have some residual free amino groups on the carbon nanodots and keep solubility in polar organic solvents.

31 Being a statistical approach, the control of number and distribution of different chromophores on on CDs is beyond the scope of this work.

34 Charge-separated state may be produced by the reaction of a NDI-Ref triplet excited state with a NDI-Ref in its ground state, as in the reference above.

35 Our attempts to fit the data using models, where both CS states are not connected failed.
