Directional crystallization of C8-BTBT-C8 thin films in a temperature gradient†

Guillaume Schweicher,^{id a} Guangfeng Liu,^{id *a} Pierre Fastré,^a Roland Resel,^{id b} Mamatimin Abbas,^{id c} Guillaume Wantz^{id c} and Yves Henri Geerts^{id ad}

A directional crystallization of the compound 2,7-dioctyl[1]benzothieno[3,2-b][1]benzothiophene (C8-BTBT-C8) based on a temperature gradient approach has been used as a post-deposition process to control the crystalline morphology of thin films. C8-BTBT-C8 films of arbitrary thicknesses have been fabricated by spin-coating and subjected to the directional crystallization process. Dewetting is prevented by the liquid crystal phase of C8-BTBT-C8, allowing the formation of flat and rather uniform thin films with large crystalline domains. Spin-coating concentration, gradient magnitude, and cooling rate have been varied to explore a large set of crystallization conditions and to correlate them with the thin film morphology. The latter has been characterized by a combined use of optical profilometry, polarized optical microscopy, X-ray reflectometry, and X-ray diffraction measurements. The characterization results confirm that the roughness and crystalline order of the thin films are improved after the temperature gradient treatments: (1) high cooling rate treatments (≥ 9 °C min⁻¹) significantly reduce the roughness of high thickness films, leading to good continuity and uniformity of the films; (2) dendritic growth dominates not only the films with low thickness but also films with high thickness treated at low cooling rates (< 9 °C min⁻¹); (3) the out-of-plane order and the in-plane alignment of the crystallites are also remarkably enhanced by the temperature gradient treatments.

Introduction

In the last three decades, thin-films of organic semiconductors (OSCs) have attracted considerable attention, because they are key components for constructing next-generation light-weight, stretchable and wearable optoelectronic organic devices.^{1–7} The control of thickness, roughness, and crystalline morphology at different length-scales and over large areas is crucial for the performances of OSCs.^{8–10} Crystalline morphology is defined here as comprising crystal shape, crystal size, crystal orientation, crystal alignment, less ordered regions, defects, polymorphs, and grain boundaries. The fabrication of high-quality, large-scale (> 1 cm²) single crystalline thin-films of OSCs remains challenging.^{11–14} Thin films of OSCs are fabricated either by

vapor deposition, solution processing, or from the melt, each method bearing its own advantages and disadvantages. Vapor deposition, which is only applicable to small molecules, allows the reproducible production of thin films with controlled thickness and roughness. The orientation of the molecules *versus* a substrate, which is governed by the anisotropy of surface tension of the different crystallographic faces, is generally spontaneously achieved. Grain size and grain boundary width are controllable by pressure, deposition rate and temperature conditions. However, the alignment of crystals along a specific in plane direction generally requires preliminary substrate patterning.^{13,15,16} A plethora of solution deposition techniques, such as drop-casting, spin-coating, inkjet printing, dip coating, blade coating, zone casting, and edge casting, have been developed for both small molecules and polymers.^{11,16} They evidently require sufficient solubility in solvents. Drop-casting allows nearly no control of either thickness, roughness, or morphology. Spin-coating is a widely applicable method for obtaining films of tailored thickness and roughness, but with poor control of crystalline morphology. Inkjet printing has the advantage of easy patterning of thin films on the micron scale.¹⁷ Dip coating, blade coating, zone casting, and edge casting are directional methods with good control of thickness, roughness, and crystalline morphology, including some alignment.^{14,15,18} Over the years, shearing has emerged as one of the best techniques for thin film fabrication.^{19–21} Thin rather

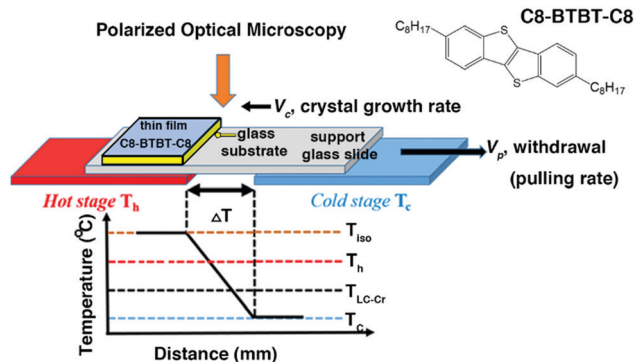

Fig. 1 Schematic drawing of the ΔT set-up. T_{iso} and $T_{\text{LC-Cr}}$ are the isotropization and the liquid-crystal to crystal phase transition temperatures, respectively. T_{h} and T_{c} are the temperatures of the hot and cold stage. ΔT is the temperature difference between the hot and cold stage. V_{p} and V_{c} are the lateral pulling rate and the crystal growth rate of the sample. The sample is constituted of a glass substrate covered by a thin film of C8-BTBT-C8. Inset: The molecular structure of C8-BTBT-C8.

uniform aligned films are achievable and even some new polymorphs have been obtained.^{19,21} Through optimization of solvent evaporation conditions, wafer scale single crystals as thin as one molecular layer have been obtained using the shearing technique.²² A less common approach is the production of crystalline thin films from the melt.^{23–26} In the past few years, our group has investigated the directional crystallization of organic solids starting from their melt by using a temperature gradient (ΔT) (Fig. 1).^{27–30} This technique, also known as directional crystallization or solidification, is essentially an adaptation of the method of Percy Bridgman to thin films of molecular compounds using the set-up invented by Kenneth Jackson.³¹ Although this technique has commonly been used for the study of organic compounds such as *n*-alkanes and *m*-nitroaniline,^{32–36} it has not widely been applied to control the crystalline morphology of OSC thin films. This technique presents several advantages: (i) nucleation and growth processes are decoupled, (ii) growth occurs preferentially through some selected crystallographic faces, (iii) uniaxial alignment takes place, and (iv) the number of molecules entering the crystal phase per unit time and through some crystallographic faces is externally controllable.^{27–30}

Up to now, the temperature gradient method has been applied to rather thick films (μm thick) sandwiched between two glass slides to avoid the unwanted dewetting of the melt state.³⁷ As a consequence, film thickness could hardly be controlled unless for OSCs exhibiting a smectic phase before the isotropization temperature (T_{iso}). Indeed, smectic phases are less prone to dewetting and tend to spread on substrates, allowing direct processing in a thermal gradient from a non-sandwiched thin film as we will describe further now.^{38,39} First, a thin film of arbitrary thickness is conventionally fabricated by spin-coating. Then, the gradient method exploiting the crystal to smectic transition is used as a post-deposition processing method to tailor crystalline morphology. 2,7-Dioctyl[1]benzothieno[3,2-*b*][1]benzothiophene, abbreviated as C8-BTBT-C8, which is a largely studied OSC, forms a smectic A

(SmA) phase from 110 to 126 °C and qualifies as an adequate molecular system for such study.^{26,40–42} The goal of this work is to investigate the crystalline morphology of thin films of C8-BTBT-C8 as a function of the directional crystallization conditions.

Experimental section

1. Materials

C8-BTBT-C8 and 2,7-didodecyl[1]benzothieno[3,2-*b*][1]benzothiophene, abbreviated as C12-BTBT-C12, have been synthesized according to the literature.⁴⁰ Purification of the materials has been performed through a chromatographic column using hexane and purity has been assessed using NMR spectroscopy.⁴³ A HPLC-grade (>99.8%, Sigma-Aldrich) toluene solvent was used without further purification. 15 mm × 10 mm × 0.7 mm sized glass substrates (D 263 Borosilicate thin glass from Präzisions Glas & Optik GmbH, Germany) were used for the experiments. They were sonicated for 10 minutes in deionized water and acetone, then blown dry with nitrogen and exposed for 30 minutes to an ultraviolet-ozone (Procleaner Plus; Bioforce Nanosciences) treatment before the experiments.

2. Differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA)

DSC was performed at 10 °C min⁻¹ under a dry nitrogen gas atmosphere in a PerkinElmer Diamond 6 instrument (temperature range 30–150 °C). TGA measurement was performed in a PerkinElmer Pyris 6 TGA. The powder sample underwent a linear ramp of increasing temperature up to 600 °C at a rate of 10 °C min⁻¹ in an inert atmosphere of nitrogen.

3. Polarized optical microscopy (POM)

The ΔT hot stage was mounted on a polarized optical microscope (Nikon Eclipse 80i), allowing *in situ* observations. The images of the thin films were recorded before and after the thermal gradient treatment by a Carl Zeiss AXiO Imager A1 polarized optical microscope.

4. Temperature gradient apparatus

The set-up shown in Fig. 1 consists of a Linkam GS350 system presenting two individual heating stages separated by a gap. The distance (gap) between the two stages where the thermal gradient will be generated is 2 mm. During the ΔT experiments, the hot stage is set at a temperature T_{h} , situated between the isotropization temperature of the material, C8-BTBT-C8, (T_{iso}) and the LC to crystal transformation temperature ($T_{\text{LC-Cr}}$); while the cold stage is maintained at a temperature T_{c} , below $T_{\text{LC-Cr}}$ of C8-BTBT-C8. T_{iso} and $T_{\text{LC-Cr}}$ temperature values were evaluated by DSC. The system was covered by a hermetic lid so that the system was thermally independent of the laboratory environment.

5. C8-BTBT-C8 thin film fabrication using the ΔT method

C8-BTBT-C8 thin films were initially prepared by spin-coating (Specialty Coating Systems Model P6700 Series spin-coater)

with different solution concentrations (2.3 mg ml⁻¹, 5.4 mg ml⁻¹, 10.5 mg ml⁻¹, 13.5 mg ml⁻¹, and 20 mg ml⁻¹; solvent: toluene) on pre-cleaned 15 mm × 10 mm × 0.7 mm thin glass substrates. The spin-coating parameters are as follows: 150 μl of solution, 150 rpm (5 s, the first step), 1500 rpm (5 s, the second step), and 3000 rpm (30 s, final step). The thickness of the thin films was measured by specular X-ray diffraction (sXRD). Thin films of C8-BTBT-C8 were then processed using the Δ*T*. The Δ*T* treatments for ten spin-coated samples, produced using a 20 mg ml⁻¹ concentration, were carried out using two *T*_h – *T*_c couples: (1) 120 °C – 90 °C and (2) 120 °C – 60 °C, and five different pulling rates (*v*_p: 1 μm s⁻¹, 5 μm s⁻¹, 10 μm s⁻¹, 25 μm s⁻¹ and 50 μm s⁻¹) respectively, see Table 1 for full conditions.

6. XRD

Low angular range specular X-ray diffraction (sXRD) curves of the C8-BTBT-C8 thin films, in the 2θ range between 0.4° and 3.8° with an angular resolution of 0.005° per step and a typical counting time of 5 s, were collected on a Bruker D8 Advance diffractometer using Cu Kα radiation (λ = 1.5418 Å) under a θ/θ (specular) reflection geometry, at room temperature. Low angular range sXRD curves are presented as the scattering intensity versus the scatter vector, *q*_z (nm⁻¹), using eqn (1):

$$q = 4\pi \times \sin \theta / \lambda \quad (1)$$

where λ = 1.5418 Å. The thickness of the thin films can be evaluated by the angular separation between two maxima (constructive interference) or minima (destructive interference) of consecutive fringes using eqn (2):

$$n = 2\pi / (q_1 - q_2) \quad (2)$$

where *n* is the thickness of the thin film and *q*_i is the momentum transfer of an extremum. The low angular range sXRD curves show a total external reflection plateau up to *q*_z = 0.34 nm⁻¹ (on glass substrates), providing information on the critical angle. The value of the total reflection critical angle is similar to the one achieved in our previous X-ray reflectivity (XRR) studies of spin-coated thin films of C8-BTBT-C8 on Si-wafers covered with a

150 nm thermally grown oxide layer (*q*_z = 0.31 nm⁻¹).³⁸ The FWHM (full width at half the maximum of a diffraction peak) of the (002) Bragg peak (*q*_z around 4.34 nm⁻¹) was determined. The coherence length, *L*_C (perpendicular to the substrate surface in this case, that is, the vertical crystallite size), was estimated using the Scherrer equation⁴⁴ eqn (3):

$$L_C = 2\pi / \Delta q \quad (3)$$

Δ*q* is the FWHM.

The sXRD pattern of the C8-BTBT-C8 powder sample was collected on a Bruker D8 Advance diffractometer using Cu Kα radiation (λ = 1.5418 Å) at room temperature, in the 2θ range between 2° and 40° with an increment of 0.02° per step and a counting time of 0.5 s per step at room temperature. The sXRD pattern of the LC phase was collected on a Bruker D8 Advance diffractometer using Cu Kα radiation (λ = 1.5418 Å) and equipped with a MRI (material research instruments) heating stage for high temperature measurements, using similar parameters except a 2θ range between 2° and 30°. sXRD patterns of the thin films, in the 2θ range between 2° and 10° with an increment of 0.02° per step and a counting time of 0.15 s, were collected on a Rigaku Ultima IV diffractometer using Cu Kα radiation (λ = 1.5418 Å) per step, at room temperature.

6.1. In-plane GIXD. In-plane grazing incidence XRD measurements were performed on a Rigaku Ultima IV diffractometer using Cu Kα radiation (λ = 1.5418 Å). An in-plane 2θ_z/φ scan is a technique for measuring lattice planes normal to the surface of a thin film. The direction of the scatter vector is kept constant. A grazing-incident X-ray beam is employed in a 2θ_z/φ scan in-plane XRD measurement so that the incident X-ray beam travels a long distance inside the thin film, and thus high diffraction intensities from the film could be obtained. Meanwhile, the angle of the incident X-ray beam can be controlled independent of the sample rotation angle (φ) and the position of the detector (2θ_z) in the geometry of a 2θ_z/φ scan. 2θ_z/φ scans for the thin films were carried out in the 2θ_z range between 5° and 50° with a sampling of 0.02° per step and a speed of 0.08° min⁻¹ at room temperature. The beam incident angle α_i has been kept at 0.18°.

6.2. XRD pole figures. Pole-figure measurement is an XRD technique where the diffraction angle (2θ) is fixed and the diffracted intensity is collected by varying the tilt angle from the sample surface normal direction (Ψ) and the rotation angle around the sample surface normal (φ). The obtained diffracted intensity data can be plotted as a function of the tilt angle and rotation angle to quantitatively evaluate the orientation texture of the sample. Pole figures for the different C8-BTBT-C8 thin film samples were measured on a PHILIPS X'Pert system equipped with an ATC3 cradle using Cr Kα radiation (λ = 2.291 Å) and a graphite secondary monochromator. A schematic representation of the pole-figure measurement geometry is shown in Fig. S13 (ESI†). Pole figures were plotted using the software STEREOPOLE.⁴⁵

7. Optical profilometry

The surface morphology study of the C8-BTBT-C8 thin films before and after the Δ*T* treatment was carried out using an

optical profilometer (Veeco NT9080) in phase shifting interferometry (PSI) mode. Each image was analysed by the software Vision 4.3 to get the 3D surface morphology and surface roughness statistics (R_a). R_a is the arithmetical mean deviation of the assessed profile:

$$R_a = \frac{1}{A} \iint_A |z(x,y)| dx dy \quad (4)$$

where A is the area of the defined range, and $|z(x,y)|$ is the distance between a point (x,y) in the plane and the center plane. It is worth mentioning that the color of the scale bar represents the height range set in the software for the visualization of the specific image (red for high and blue for low values, respectively) and not the height scale present in the performed scan. These are arbitrary values set to improve the contrast and visualization of the profilometry scan.

8. Crystal growth morphology calculation

The crystal growth morphology of C8-BTBT-C8 was predicted using the software Mercury 3.10.3 based on the Bravais-Friedel-Donnay-Harker (BFDH) method.^{46–48}

9. Calibration of the magnitude of the temperature gradient set-up (G_{exp})

Previous work has shown that the effective magnitude of the temperature gradient (G_{exp}) that forms between the hot and cold zones is less than the magnitude simply calculated by the equation $G = (T_h - T_c)/x$, where $x = 2.0$ mm is the gap between the hot and cold stages.^{27–30} The calibration of the ΔT setup has been carried out as previously reported³⁰ and is detailed in the ESI† (Table S1 and Fig. S1). $G_{1\text{exp}} \approx 6$ and $G_{2\text{exp}} \approx 11$ °C mm⁻¹ for $T_h - T_c$ couples 120 °C – 90 °C and 120 °C – 60 °C, respectively.

Results and discussion

1. Crystal structure and thermotropic behaviour of C8-BTBT-C8

The crystal structure of C8-BTBT-C8, first reported by Takimiya *et al.* from single crystal X-ray diffraction measurements performed at 293 K, belongs to a monoclinic system, with the space group $P2_1/a$ and unit cell parameters $a = 5.907$ Å, $b = 7.890$ Å, $c = 29.086$ Å, and $\beta = 91.94^\circ$.⁴⁰ The crystal growth morphology of C8-BTBT-C8, shown in Fig. 2a, presents a lamellar hexagonal shape with edge-on upstanding molecules on the main face (001). The thermal stability of C8-BTBT-C8 is higher than 300 °C (onset temperature: 334 °C, shown in the TGA curve in Fig. S2, ESI†). The Cr-to-LC and LC-to-Cr phase transitions are reproducibly observed in the DSC curves (Fig. 2b), showing a liquid crystal phase from 108.9 °C to 125 °C upon heating. The fan shaped features visible in the POM image at 124 °C (Fig. 2c) combining to form the only two diffraction peaks visible in the sXRD pattern recorded at 120 °C (Fig. 2d) confirm the high temperature SmA phase of C8-BTBT-C8, in excellent agreement with the previous data.^{38,40}

Fig. 2 (a) Predicted crystal growth morphology of C8-BTBT-C8 based on the BFDH method. (b) DSC trace of C8-BTBT-C8. (c) POM image of the fan shaped texture of the SmA liquid crystal phase of C8-BTBT-C8 recorded at 124 °C. (d) sXRD pattern of the SmA phase recorded at 120 °C.

2. Crystallization of C8-BTBT-C8 thin films in ΔT using the LC to Cr transition

2.1. Crystallization conditions. First, thin films of C8-BTBT-C8 were prepared on borosilicate glass substrates by spin-coating from toluene solutions, using five different concentrations: 2.3 mg ml⁻¹, 5.4 mg ml⁻¹, 10.5 mg ml⁻¹, 13.5 mg ml⁻¹ and 20 mg ml⁻¹. These films, numbered as samples 1–5, serve as a comparison point with samples 6–19 processed in the thermal gradient, see Table 1. Note that borosilicate glass exhibits a higher thermal conductivity, $\lambda = 0.926$ W m⁻¹ K⁻¹, than the one of C8-BTBT-C8 along the a and b directions, $\lambda \approx 0.18$ W m⁻¹ K⁻¹.⁴⁹ Moreover, the C8-BTBT-C8 films are much thinner than glass slides. These two conditions ensure a rapid local thermalization of C8-BTBT-C8 films with their environment. Crystallization of C8-BTBT-C8 occurred in films 1–5 upon solvent evaporation during spin-coating with not much control (*vide infra*). Second, films of increasing thickness were subjected to crystallization under the same ΔT conditions (films 6 to 10). Third, the thickest films, spin-coated at 20 mg ml⁻¹, crystallized under various ΔT conditions, *i.e.* with $1 \leq V_p \leq 50$ μm s⁻¹ and using $G_{\text{exp}} \approx 6$ and 11 °C mm⁻¹, to explore a large set of experimental conditions (films 10 to 19). The cooling rate at the growth front was varied by nearly two orders of magnitude, *i.e.* ranging from 0.36 to 33 °C min⁻¹ (Table 1).

2.2. Films of different thicknesses and subjected to the same thermal gradient process. Optical profilometry, POM, and sXRD have been combined to assess thickness, roughness and crystalline morphology of the thin films prepared using different concentrations. The spin-coated thin film 1 at a very low concentration was pretty homogeneous; but the thin films became more and more inhomogeneous with aggregation of small crystals for samples 2–5, as shown in Fig. 3a, c and Fig. S3 (ESI†) (3D views). Likely, increasing inhomogeneities

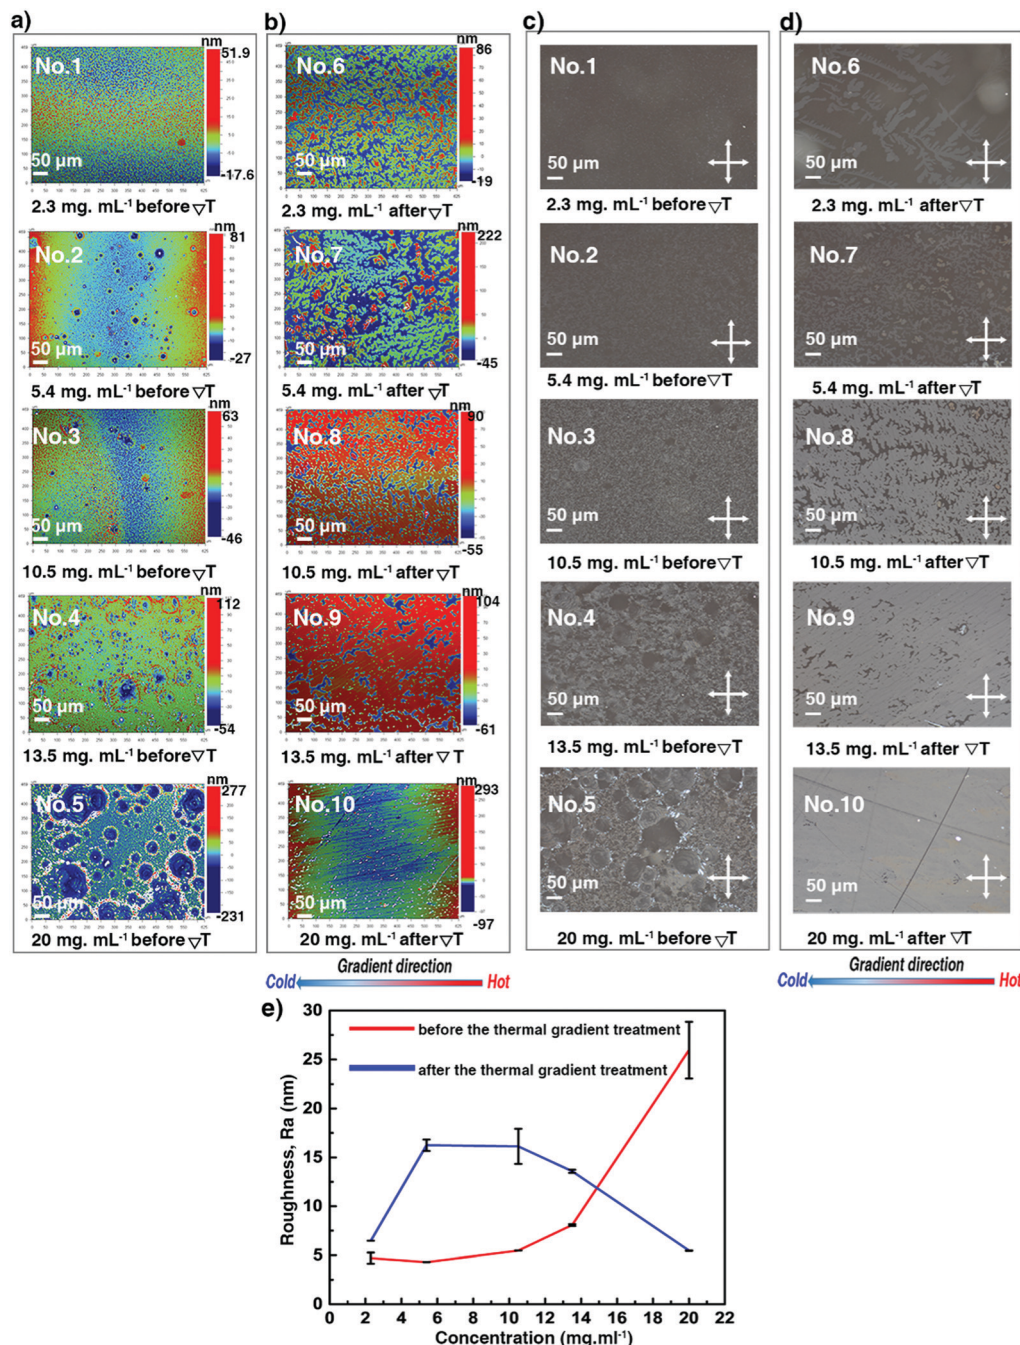

Fig. 3 Surface morphology of the C8-BTBT-C8 spin-coated thin films produced using different solution concentrations before: (a) optical profilometry images and (c) POM images; and after the ΔT treatment: (b) optical profilometry images and (d) POM images, recorded at room temperature. The gradient direction is highlighted (bottom). (e) Evolution of the film surface roughness (R_a) as a function of the solution concentration. See also Table S2 (ESI†).

result from heterogeneous type dewetting, which may occur during spin-coating.^{37,50} It is known that dust particles can serve as nucleation points in heterogeneous dewetting by weakening mechanically thin films, locally. The DSC curves shown in Fig. 2b suggest that some dust particles are present in the C8-BTBT-C8 powder sample, resulting in a ratio of $T_{LC-Cr}/T_{Cr-LC} = 0.96$ (367.15 K/382.05 K). A decrease of this ratio close to or below 0.8 usually indicates that contamination is significantly reduced.⁵¹

Moreover, the number of dust particles scales with volume.⁵¹ Consequently, for a given sample area, there should be fewer dust particles in thinner films than in thicker ones, making thicker films more prone to heterogeneous dewetting. Fig. 3e shows that the surface roughness (R_a in nm) of films 1–5 increases non-linearly with concentration. Only films 1 and 2 showed Kiessig fringes in their sXRD curves (Fig. 4a), allowing us to determine a thickness of 13.3 and 26.3 nm, respectively.

We now turn our attention to thin films 6–10, subjected to ΔT treatments, which differ by their thickness, as shown in Table 1. They were analysed *via* POM, optical profilometry, and sXRD. Fig. 3b, d and Fig. S3 (ESI[†]) show that films 6–8 exhibit a dendritic growth pattern and a partial coverage of the glass substrates. But for film 9, the dendritic growth is avoided to some degree. However, the continuity of this thin film is still poor. A rather uniform surface morphology has been obtained for film 10. The dendritic growth was avoided, and the thin film covered the whole area of the substrate, although there were still some small pin-hole-like defects in the sample. As shown in Fig. 3e and Table S2 (ESI[†]), the ΔT treatment leads to a little increase of R_a values, in the 6.5 to 16.2 nm range, for films 6–9. But, for film 10, the surface roughness decreases, *i.e.* R_a of 26.0 nm (before ΔT) *versus* R_a of 5.5 nm (after ΔT). Films 6–9 give rise to distinctive curves with Kiessig fringes, as displayed in Fig. 4b, allowing the determination of their thickness. The thickness scales linearly with concentration, as can be seen in Fig. 4c and Table S2 (ESI[†]). However, no prominent Kiessig fringes can be observed for film 10 because of its too large thickness (period of oscillation is too small for the resolution of our X-ray optics). A noticeable observation in Fig. 4c is that the thickness of film 1 vs. 6 and of film 2 vs. 7 apparently increases. This peculiarity is likely to result from the discontinuity of thin films 6–7 after ΔT processing. The current results corroborate our previous reports on the annealing of spin-coated C8-BTBT-C8 thin films, without ΔT processing, but for which a disordered-layers-to-ordered-islands transition was observed.^{38,52} An intense diffraction peak is present at q_z around 2.2 nm^{-1} in all films (Fig. 4a and b). The peak is identified as the 001 Bragg peak of the crystal structure of C8-BTBT-C8 (Fig. S6, ESI[†]). This, combined with the sole observation of the 00 l family within the whole specular scans of the samples (see Fig. S7, ESI[†]), suggests a preferential orientation of the (00 l) planes parallel to the glass

substrate for all films, in agreement with previous reports.⁵³ The sXRD data in the 2θ range between 2° and 10° also highlight a decrease of the FWHM (Fig. 4d and Fig. S8 and Table S2, ESI[†]) of the 002 Bragg peak, which is attributed to the increase of the vertical crystallite size (Fig. 4e and Table S2, ESI[†]) after the ΔT treatment, for all concentrations. The FWHM of the (002) reflection has been used for the analysis due to the less pronounced impact of the Fresnel reflectivity for (002) (compared to (001)). Altogether, these results suggest a better out-of-plane crystalline order of the thin films after the ΔT treatment. The results of the in-plane GIXD of films 5 and 10 are displayed in Fig. S9 (ESI[†]). Random in-plane alignment of crystallites was revealed for film 5, as shown by the presence of all observable $hk0$ reflections in the $5\text{--}50^\circ 2\theta_z$ range. The in-plane $2\theta_z/\phi$ scan of film 10 presents intense $\{020\}$ reflections until the second order, highlighting an in-plane alignment. However, a 200 reflection is still observed, although with very small intensity. This can be attributed to the multiple in-plane alignments of the sample. The observation demonstrates that the in-plane crystalline alignment of the thin film is dramatically improved by the ΔT approach. All results presented above indicate that the optimal concentration of the C8-BTBT-C8 solution is 20 mg ml^{-1} to produce continuous, uniform and low roughness thin films on glass substrates using the ΔT approach.

2.3. Thin films of C8-BTBT-C8 with comparable thickness but treated under different ΔT conditions. Thin films 10–19, obtained at 20 mg ml^{-1} , have been selected to investigate the influence of the ΔT conditions on thickness, roughness, and crystalline morphology of the thin films. The investigated ΔT conditions are listed in Table 1. After the ΔT treatments, roughness and surface morphology were analysed *via* POM and optical profilometry. The dendritic growth patterns and the partial covering of the substrate, previously observed for thin films produced using lower solution concentrations, appear for

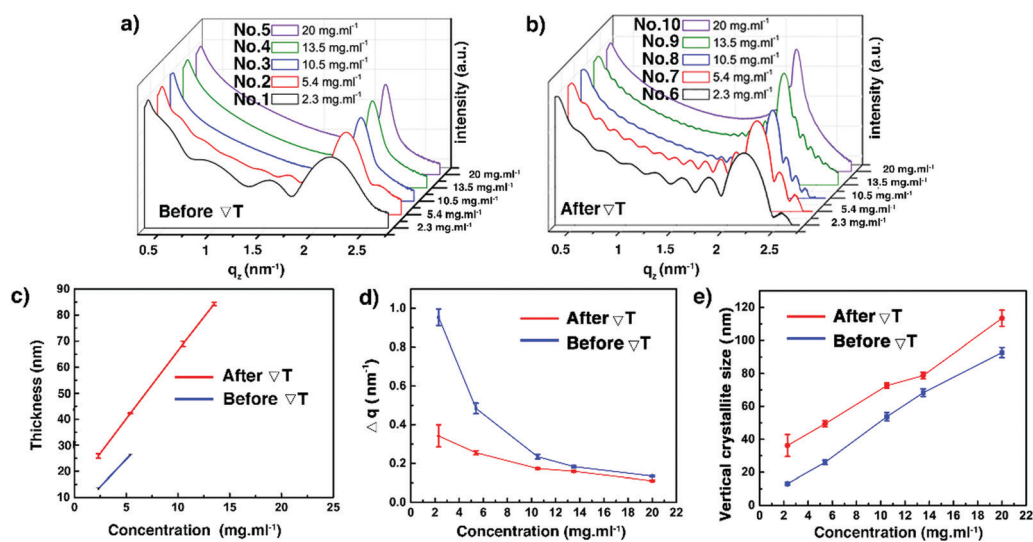

Fig. 4 Low angular range sXRD patterns of the C8-BTBT-C8 thin films (1–10) before (a) and after (b) the ΔT treatment, recorded at room temperature. Evolution of the film thickness (c), the FWHM of the (002) Bragg peaks (d), and the vertical crystallite size (e) as a function of the solution concentration before and after the ΔT treatments. See also Table S2 (ESI[†]).

the films 11–16, treated by lower pulling rates/cooling rates ($V_p \leq 10 \mu\text{m s}^{-1}$, $C_{\text{exp}} \leq 6.6 \text{ }^\circ\text{C min}^{-1}$). However, films 10, 17, 18, and 19 cover almost completely the substrates and present large apparently uniform domains. The surface morphology of films 14 and 19 is depicted in Fig. 5a and b, highlighting the features of partial or complete covering of the glass substrate. The complete set of POM and optical profilometry images of films 10–19 is presented in the ESI† see Fig. S4 and S5. As shown in Fig. 5c and Table S3 (ESI†), R_a values of films 10–19 decrease by a factor of five to reach a minimum value of about 5 nm. Many small cracks are found in films 10–19, which were generated upon cooling from T_c to room temperature. They are believed to originate from the difference in the thermal expansion coefficients of C8-BTBT-C8 and the rigid substrate. Fig. S11a (ESI†) displays the low angular range sXRD patterns of films 10–19. Although the ΔT treatments flatten the film surface and improve the covering of the substrate, the thicknesses of the films prepared at 20 mg ml^{-1} are too large, causing the oscillation period to approach the limit of our X-ray instrument resolution. Only films 11–14 and 16 show observable Kiessig fringes before $q_z = 1.7 \text{ nm}^{-1}$, indicating that the thicknesses are roughly $> 130 \text{ nm}$ (Fig. S11b, see also Table S3, ESI†).

Similar to the samples prepared from different concentrations, the observation of a strong diffraction peak at q_z around 2.2 nm^{-1} combined with the sole observation of the $00l$ family

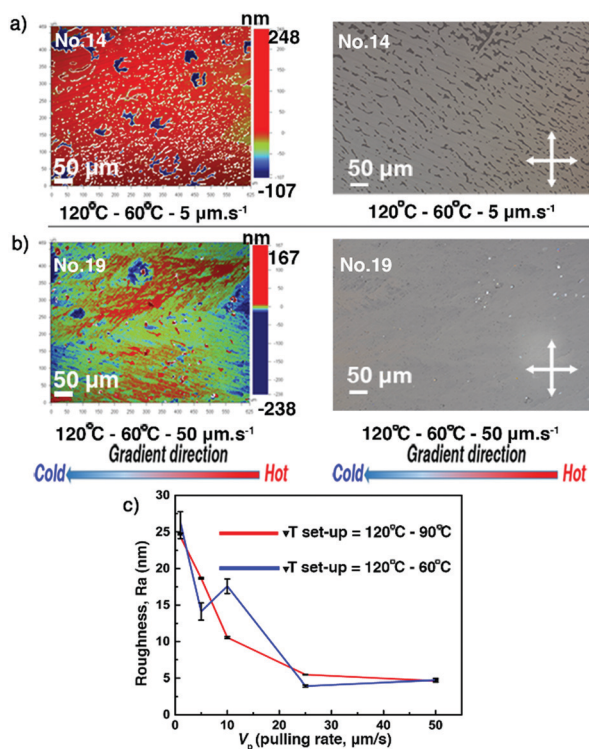

Fig. 5 The surface morphology (optical profilometry and POM images) of the C8-BTBT-C8 thin films 14 (a) and 19 (b) presents the features of partial or complete covering of the glass substrate. Images were recorded at room temperature. The gradient direction is highlighted (bottom). (c) Evolution of the film surface roughness (R_a) as a function of the pulling rate (V_p) for different $T_h - T_c$ couples. See also Table S3 (ESI†).

through the whole specular diffraction pattern for films 10–19 (see Fig. S10, ESI†) highlights a preferential orientation of the $(00l)$ planes parallel to the glass substrate. Besides, compared with the just coated film 5, the FWHM of the (002) reflection of films 11–19 is reduced (Fig. 6a and Fig. S12, ESI†), resulting from the increase of the vertical crystallite size after the ΔT treatments (Fig. 6b). The results highlight again the fact that the ΔT approach can improve the out-of-plane crystalline order of the thin films. However, there is no remarkable difference of the FWHM among films 11–19 (Table S3, ESI†), a result of the limit of the resolution of the X-ray optics. To assess the in-plane alignment of crystallites in the samples, pole figure measurements were carried out for films 10–19 and for film 5, which has undergone no ΔT processing (Fig. 7 and Fig. S14, ESI†). The particular $\{113\}$ reflection was chosen because of its high peak intensity (Fig. S6, ESI†). As expected, a totally random in-plane alignment of crystallites was observed for the coated film 5, as evidenced by a wide intensity distribution of the $\{113\}$ reflection along with azimuthal and meridional rotations of the sample (Fig. 7a). This result is consistent with the presence of 110, 020, 120, 200, 130, and 040 peaks in the in-plane $2\theta_z/\phi$

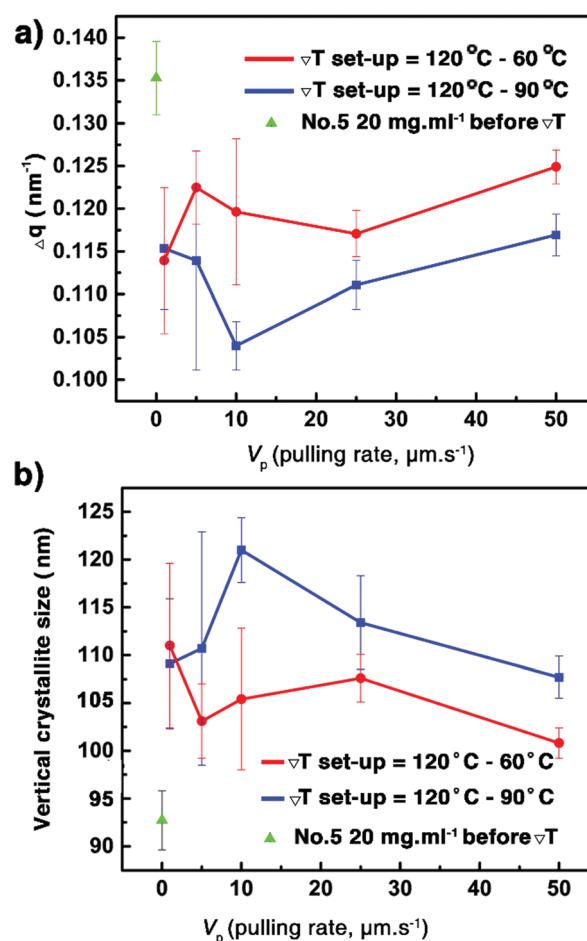

Fig. 6 Evolution of the FWHM of the (002) Bragg peaks of the samples (a) and the vertical crystallite size of films 10–19 as a function of the pulling rate (V_p) (b). The data of just coated film 5 are shown for comparison. See also Table S3 (ESI†).

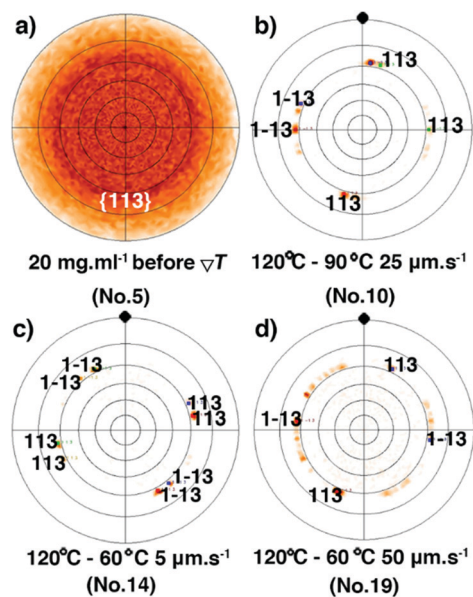

Fig. 7 (a) Pole figure of {113} reflections for the spin-coated film 5 before the ΔT treatment. Pole-figure measurements of {113} reflection for films 10 (b), 14 (c) and 19 (d), after the ΔT treatments. The black solid dot highlights the temperature gradient direction.

scan of film 5, displayed in Fig. S9 (ESI[†]). Importantly, the ΔT processing on films 10–19 causes a much better in-plane alignment of crystallites, as shown in Fig. 7b–d and Fig. S14 (ESI[†]). Among films 10, 17, 18, and 19 with good continuity and low surface roughness, number 10 exhibits the best in-plane alignment of crystallites with the narrowest discrete spots, suggesting that highly aligned crystalline domains were produced using $V_p = 25 \mu\text{m s}^{-1}$, $G_{\text{exp}} = 6 \text{ }^\circ\text{C mm}^{-1}$, and $C_{\text{exp}} = 9 \text{ }^\circ\text{C min}^{-1}$. However, the uniaxial alignment that takes place exhibits various angles along the ΔT direction. Films 10–19 are definitively polycrystalline even if large domains are observed. This observation agrees with the POM images in Fig. 5 and Fig. S4 (ESI[†]). The lack of univocal uniaxial alignment contrasts with the one observed for terthiophene and resorcinol processed under comparable ΔT conditions.^{27,30} The reason is likely related to the a and b parameters that differ only slightly and to the plate-like crystal growth morphology, shown in Fig. 2a, which results from rather comparable crystal growth rate of planes $hk0$. It is also noteworthy that the thermal conductivity coefficients along a and b are the same.⁴⁹

Conclusions

In this contribution, we have explored the post-deposition processing of thin films of the C8-BTBT-C8 compound by directional crystallization using a temperature gradient. The smectic phase of C8-BTBT-C8 prevents dewetting and allows film formation by spin-coating to be decoupled from the control of crystalline morphology. Results obtained *via* POM, optical profilometry, sXRD, GIXD and pole figures show a dramatic effect of the temperature gradient processing. Roughness drops and

films flatten significantly. They cover the substrate much better. Considerably larger and more ordered crystal domains are obtained. However, no univocal uniaxial alignment is observed. This study demonstrates also that directional crystallization is achievable using a liquid crystal to crystal phase transition.
